Cardiological Society
CARDIOLGY
Update 2018

PREFACE

Editor-in-Chief

Kewal C Goswami MD DM
Professor
Department of Cardiology
All India Institute of Medical Sciences
New Delhi, India

I am pleased to offer *Cardiology Update – 2018* for release at the 70th Annual Conference of the Cardiological Society of India. As President – Elect of this august body I must remind our entire community that cardiovascular diseases remain the scourge of modern day life where the demands and pressures of a fast moving lifestyle are in direct conflict with human biological needs. Developing countries like ours are facing the brunt of this epidemic grappling with cardiovascular disease in ever younger populations at the peak of their productive lives, often nipping careers that are yet to find flight. Though considerable progress has been achieved in the understanding and treatment of cardiovascular diseases with an era of personalized medicine not too far distant in the future in the developed world, the cardiologist in countries like ours still faces challenges in knitting together a strategy that is realistic and affordable for his patient. Yet this strategy has to be scientifically robust and find peer acceptance across the entire community of cardiologists. Equally he is required to extend state of the art care for his other group of elite patients who can easily move across continents to seek contemporary care. This dual challenge is an enigmatic problem for which solutions will not be easy to define and implement. I hope readers of the book are motivated and spurred to greater ideas and loftier goals in helping our country tackle this menace of cardiovascular diseases.

With the burgeoning amount of information already available on the web and in print, colleagues often question me on the need for another textbook on cardiology. Indeed even I was flummoxed about whether I should indeed embark upon such a venture or whether this was an exercise in futility. Exhaustive texts are so easily available at the press of a button of your phone, tablet and laptop. However paradoxically, there are many textbooks of cardiology and even more journals, focused updates of relevant contemporary topics in everyday cardiology often do not find space in both textbooks as well as journals. Lengthy discourses in modern day cardiology textbooks (and subspecialty reviews in journals) often obfuscate bed side dilemmas of modern medicine and a litany of clinical trials published every other week sometimes create more questions than offering answers. This edition of *Cardiology Update – 2018* attempts to bring into sharp focus these very controversial yet relevant topics, with views from Indian experts that define approaches and color practices in our sphere of life. This reflects the theme of this years' 70th Annual Conference of Cardiological Society of India – Translating Recent Advances into Regional Needs. We hope this book is useful not only for residents in training, but also for general physicians and general cardiologists as well as for interventional cardiologists and electrophysiologists. A lot of effort was put in compiling topics that are relevant for everyday cardiology and find scant mention in available texts. Medicine is as much an art as it is a science. As many of these chapters are authored by leading subject experts in the country, we hope the reader is not only enriched with knowledge that is captured from an Indian standpoint, but also able to translate this into improving his/her practice, an important objective of this book (as well as the conference).

I am profusely thankful to the galaxy of reputed national and international faculty who have taken considerable time and effort to compile this edition of *Cardiology Update*. I recognize they have taken precious time out of their busy schedules to give their considered views on important issues on contemporary cardiology and appreciate their sincere efforts in making this book possible. I would also like to place on record my sincere gratitude for Jaypee Publishers in working tirelessly with the authors and compiling this book. Mankind Pharmaceuticals has been very kind to extend an unrestricted educational grant for the publication of this book and I am deeply grateful to them. I also extend my sincere thanks to the members of the entire Cardiological Society of India including its office bearers in offering constructive advice and guidance and being supportive in making this manuscript possible. I am also greatly indebted to my editorial team in painstakingly going through the numerous manuscripts.

I would be failing in my duty if I do not acknowledge my family including my wife and mother for putting up with my prolonged absences from home.

With warm personal regards

CONTENTS

SECTION 1: CORONARY ARTERY DISEASE RISK FACTORS

1. Smokeless Tobacco and Cardiovascular Disease	3
<i>Surender Deora, Kewal C Goswami</i>	
Pharmacokinetics of smokeless tobacco	5
Smokeless tobacco and cardiovascular risk factors	5
Smokeless tobacco and cardiovascular disease	6
Health policy implications	6
2. Alcohol and Coronary Artery Disease: Fact versus Fiction	8
<i>JPS Sawhney, Kushal Madan</i>	
Understanding “standard drink”	8
Alcohol and cardiovascular mortality	8
Alcohol and coronary artery disease	8
Alcohol and cardiovascular medications	9
Possible mechanisms for coronary artery disease protection by alcohol	9
Drinking patterns and coronary heart disease	9
Influence of age and sex on cardiovascular effects of alcohol	9
The genetics of alcohol and cardiovascular disease	10
Points to consider from the past studies	10
Alcohol and Indian population	11
Detrimental effects of alcohol intake	11
A word of caution	11
3. Vitamin D and Cardiovascular Disease: Indian Perspective	13
<i>Ramu Adela, Rajesh Khadgawat</i>	
Assessment of vitamin D nutritional status	13
Vitamin D nutritional status in the world and in India	13
Vitamin D and nonskeletal effects	14
Vitamin D and cardiovascular diseases	14
Mechanism of vitamin D and proposed cardioprotection	15
Vitamin D and cardiovascular disease: evidences from observational studies	15
Vitamin D and cardiovascular disease: evidences from interventional studies	17
Indian studies	17
4. Hormone Replacement Therapy and Cardiovascular Diseases	20
<i>Geetha Subramanian, Aviraj Choudhary, Kamaldeep Bansal</i>	
Menopause-induced changes in cardiovascular functions	20
Effects of hormone replacement therapy on coronary heart disease risk	21
Clinical studies of hormone replacement therapy and coronary heart disease	21

SECTION 2: LIPIDS AND DIET

5. Cholesterol and Coronary Artery Disease Controversy	27
<i>Rajiv Bajaj</i>	
Cholesterol and coronary artery disease controversy	27
Functions of cholesterol	28
Early research on cholesterol	29
Diet and health	30
Present and future	31
6. Indian Dyslipidemia: Challenges in Management	32
<i>Saumitra Ray, Sumanta Chatterjee</i>	
Indian epidemiological studies on dyslipidemia	32
Association between lipid levels and risk of heart disease in India	33
Laboratory parameters assessment	34
Inadequate management of dyslipidemia in India	34
Indian guideline recommendation on dyslipidemia management	34
Cardiovascular risk stratification of Indian patient	35
Treatment goal according to ASCVD risk stratification	35
Cardiovascular disease prevention: lipid targets	35
Lowering of low-density lipoprotein reduces risk of cardiovascular events	36
Drugs for management of dyslipidemia	36
Drugs for management of hypertriglyceridemia	36
Familial hypercholesterolemia in India	37
Dyslipidemia in type 2 diabetes and metabolic syndrome	37
Dyslipidemia in acute coronary syndrome	37
Dyslipidemia in moderate-to-severe chronic kidney disease	37
Dyslipidemia and stroke prevention	37
Safety assessment during pharmacotherapy in dyslipidemia	37
7. Indian Diet and Coronary Artery Disease	39
<i>Abhishek Gupta, MP Girish, Mohit D Gupta</i>	
Prevalence of disease—is there underestimation of actual problem?	39
Diet and coronary artery disease: evidence	39
Indian diet	39
Contaminated vegetarianism	40
Oil consumption	40
Fruit and vegetables in Indian diet—more productions but less consumption	41
Antioxidants—do they have any role in our diet?	42
Protein source—Indian food/cuisine is high in carbs, starch, and fat	42
Susceptibility of Indians	43
Preventive measures to reduce this epidemic	43
8. Edible Oils: What is Right and What is Wrong?	46
<i>Sonia Arora, Vitull K Gupta, Meghna Gupta</i>	
Composition of fats	46
Trans fatty acids or partially hydrogenated fatty acids	47

Cholesterol 48	
What are edible oils? 48	
What is right and what is wrong oil? 48	
Characteristics of different oils 49	
Choosing the right oil 50	
Why rotation or blending is needed? 50	
9. Statins and Diabetes	53
<i>Rajeev Bagarhatta, Sohan K Sharma, Dinesh Gautam</i>	
Pathophysiology of dyslipidemia in diabetes 53	
Management of dyslipidemia in diabetes 53	
New onset diabetes with statin 55	
10. Statin Intolerance: Guide to Management	57
<i>Mrinal K Das</i>	
Definitions of statin intolerance 57	
Types of statin intolerance 57	
Anecdotal data 58	
Clinical features 58	
Evaluation of statin intolerance 59	
Management 60	
Alternative agents 61	
Indian experience with statin-induced muscle symptom 62	
11. Nonfasting Lipid Levels: Clinical Relevance and Implications for Practice	66
<i>Ajay K Sinha, Vikas Singh, Narendra Kumar</i>	
Rationale for requirement of a fasting sample 66	
Emergence of nonfasting levels measurement 66	
Lipid component measurement 67	
SECTION 3: DIABETES AND HEART	
12. Diabetes and Cardiovascular Disease: Implications of Recent Cardiovascular Outcome trials with Newer Anti-diabetic Drugs for Cardiovascular Protection	73
<i>Prakash Deedwania</i>	
Background 73	
Therapeutic strategies for control of cardiovascular disease in diabetes 74	
Role of antidiabetic (hypoglycemic) medications in cardiovascular protection 75	
13. Diabetes Classification New Dimensions	79
<i>Jugal Kishor Sharma, Amit Gupta</i>	
Diabetes classification: history 79	
Diabetes classification: why do we need a new classification system? 79	
New proposed classification of diabetes 80	

14. Prevention of Coronary Artery Disease in Diabetes Mellitus	83
<i>Ranjan Modi, Sunil Modi</i>	
Lifestyle modification	83
Lipid-lowering therapy	84
Antithrombotic medications	86
Bariatric surgery	86
Future or what is in horizon	86
15. Diabetes and Coronary Artery Disease: Prevalence and Mechanisms	89
<i>Satyanarayan Routray, Dipak R Das</i>	
Prevalence of diabetes and coronary artery disease	89
Diabetes and coronary artery disease: mechanisms	90
16. Management of Diabetes in Heart Failure	95
<i>Shashank R Joshi</i>	
The problem	95
Screening for heart failure in type 2 diabetes mellitus	95
Glycemia control and heart failure: choice of antidiabetic therapies	96
Metformin	96
Sodium-glucose cotransporter 2 inhibitors	96
Dipeptidyl peptidase-4 inhibitors	97
Glucagon-like peptide-1 receptor agonists	97
Sulfonylureas	97
Thiazolidinediones	98
Insulin	98
SECTION 4: HYPERTENSION	
17. Epidemiology of Hypertension in India: The Real Scenario	103
<i>Rajeev Gupta, Kiran Gaur</i>	
Systematic reviews of epidemiological studies	103
Association of hypertension with macrolevel risk factors	110
18. Primary Prevention of Hypertension	113
<i>Panniyammakal Jeemon, Dorairaj Prabhakaran</i>	
Classification of hypertension	113
The need for primary prevention of hypertension in India	113
Primary prevention	114
GAPS in knowledge and future research needs	116
19. Cutoff for Hypertension: Implications of 2017 Guidelines for Indian Patients	119
<i>Rajeev Narang, S Srikant</i>	
Other highlights	121

20. Initial Choice of Drugs in Uncomplicated Hypertension: Not Monotherapy Anymore but Combination	123
<i>C Venkata S Ram</i>	
Pharmacological treatment of hypertension	123
An abbreviated overview of drugs for initial combination therapy	125
Initial combination therapy not monotherapy is the answer for blood pressure control	126
21. Are ACE inhibitor and ARB Equal in Hypertension?	129
<i>SS Chatterjee, Arka Chatterjee</i>	
Mechanism of action	129
Efficacy in reducing blood pressure	129
Efficacy for surrogate clinical outcomes	130
Effects in select patient subsets	130
Adverse effects and patient compliance	131
Cost-effectiveness	131
22. Diuretics as Antihypertensive in Elderly	133
<i>Anunay Gupta, HS Isser</i>	
Issues with elderly population	133
Blood pressure goals and targets	133
Clinical trials in elderly population	134
Diuretics as first-line antihypertensive drug	135
23. Treating Resistant Hypertension: Stepwise Approach	137
<i>Binjo Vazhappilly, Julian Thottan, Mohanan Padinhare</i>	
Stepwise evaluation of resistant hypertension	137
24. Secondary Hypertension: When and How to Screen	142
<i>Anjan Lal Dutta, Soumik Chaudhuri</i>	
Who to screen?	142
What to do before screening for secondary hypertension?	143
Conditions requiring reevaluation, after starting antihypertensive therapy	143
Role of ambulatory 24-hour blood pressure monitoring	144
Role of echocardiography in secondary hypertension	144
How to screen?	144
Uncommon causes of secondary hypertension	146
When secondary hypertension may present as resistant hypertension	147
25. Managing Low Diastolic Blood Pressure in Elderly Hypertensive	150
<i>HK Chopra, AK Pancholia</i>	
Pathophysiology of the J-curve	150
Diastolic blood pressure control: how low is too low? Clinical trial evidences	151
Low diastolic blood pressure and atherosclerosis in elderly subjects	151
Isolated diastolic hypotension and incident heart failure in elderly	151

26. Ambulatory Blood Pressure Monitoring—When to Order and How to Interpret?	153
<i>Rajan J Manjuran, Sulthan R Salih</i>	
History and relevance of ABPM	153
Procedure	153
Indications	154
Merits and drawbacks	157
Future directions	158
27. Home Blood Pressure Monitoring: Current Status	160
<i>Vidyut Jain, Avani Jain</i>	
Review of literature	160
SECTION 5: CHRONIC CORONARY ARTERY DISEASE	
28. Best Method for Risk Stratification in CAD—Anatomy, Physiology, or Both	167
<i>Pawan K Sharma, Kewal C Goswami</i>	
Methods for risk stratification in CAD	167
Risk stratification using noninvasive methods	167
Risk stratification using invasive methods	169
Potential uses and limitations of the traditional syntax score	170
29. Screening for Coronary Artery Disease in Asymptomatic Adults	173
<i>Pratap Chandra Rath, Md Abdul Azeez Asad</i>	
Rationale for screening	173
Screening tests	173
Anatomic (imaging) techniques	175
Other methods for the assessment of cardiovascular risk	176
Safety of screening tests	176
30. Optimal Medical Management for Chronic Stable Angina in 2018	179
<i>Satyavan Sharma, Naresh D Munot</i>	
Lessons learnt from randomized trials	179
What constitutes optimal medical therapy?	180
Other drugs for angina	184
31. Beta-Blockers in Chronic Stable Coronary Artery Disease: Current Status	187
<i>J Shiv Kumar, M Sitaram, Sajith Pavitran, G Nagarjuna</i>	
Incidence and prevalence	187
Pathophysiology of coronary artery disease	187
Pharmacotherapeutics of beta-blockers	188
Newer generations of beta-blockers	188
Adverse effects of beta-blockers	189
Guidelines for use of beta-blockers in angina	189

32. Revascularization in Chronic Stable Angina—Current Status	191
<i>Parneesh Arora, Upendra Kaul</i>	
Evidence from trials	191
Current approach to revascularization for SIHD	192
Indications for coronary angiography	192
Choice of revascularization PCI or coronary artery bypass grafting	192
33. Revascularization in Diabetes: Rational Choices in 2018	198
<i>Rajiv Agarwal</i>	
Surgery or percutaneous coronary intervention	199
Freedom trial	199
Other randomized trials	199
Incomplete revascularization	200
Second-generation drug-eluting stents	200
Real world scenario	200
Registry data	200
Rational choice of revascularization strategy: evolving a consensus	200
New randomized trials needed	201
Comparison with medical therapy	201
Acute coronary syndromes	201
Type and duration of diabetes	201
34. Enhanced External Counterpulsation: Current Status	204
<i>Ashok Goyal</i>	
Enhanced external counterpulsion in coronary artery disease and heart failure treatment	204
Mechanism of action	205
Indications and contraindications	207
Enhanced external counterpulsion in extracardiac diseases	208
35. Cardiac Rehabilitation: The Road Less Travelled	210
<i>Satyendra Tewari, Raj Pratap Singh</i>	
Indications of cardiac rehabilitation	211
Inpatient cardiac rehabilitation	211
Barriers to cardiac rehabilitation in India	212

SECTION 6: ACUTE CORONARY SYNDROMES

36. Why Seek Vulnerable Coronary Plaques?	217
<i>Amir Ahmadi, Michael Valentine, Rick Chazal, Jagat Narula</i>	
What is a vulnerable plaque?	217
How is vulnerable plaque identified?	218
The quantitative extent of high-risk features	218
The number of adverse plaque characteristics	219
The evidence of plaque progression	219

37. Protecting Heart from Ischemia-Reperfusion Injury: Current Understanding	221
<i>Jabir Abdulkutty, Jimmy George</i>	
Mediators of myocardial reperfusion injury	221
Therapies to reduce ischemic injury	223
Reperfusion by primary percutaneous coronary intervention, thrombolysis, or both	223
Other therapies to reduce ischemic injury	223
Pharmacological interventions to reduce reperfusion injury	224
38. Risk Stratification in Unstable Angina/NSTEMI: A Current Approach	226
<i>Anoop Jain, CB Meena, Sahil Sareen</i>	
Epidemiology	226
Pathophysiology	226
Clinical and risk assessment	226
Noninvasive testing	228
Stratification of risk	228
Management	230
39. hs-cTroponin in Acute Coronary Syndrome: Current Status	235
<i>Amal K Banerjee</i>	
Clinical perspective	236
Clinical practice guidelines	236
Risk assessment and outcomes	237
40. Managing Acute Coronary Syndrome in Renal Dysfunction	240
<i>Parayoru K Asokan, Kailash K Goyal</i>	
Pathophysiology	240
Diagnosis of acute coronary syndrome in patients with renal dysfunction	240
Management	240
SECTION 7: ST-SEGMENT ELEVATION MYOCARDIAL INFARCTION	
41. Burden and Outcome of STEMI in India	249
<i>Santanu Guha, Avik Karak</i>	
Preamble	249
Burden of cardiovascular diseases in India	249
Burden of cardiovascular disease risk factors	250
Determinants of cardiovascular disease in Indians	250
Epidemiology of STEMI in India	250
Outcome of STEMI	251
42. Choosing Fibrinolytics in STEMI: Economics over Efficacy?	256
<i>Mullasari S Ajit, Meenakshi MS</i>	
Importance of early revascularization	256
Pharmacoinvasive strategy	256

Fibrinolytic drugs—classification and comparison	257
Efficacy of fibrinolytics—based on trials	257
Choice of fibrinolytic in ST-elevation myocardial infarction	258
43. Routine PCI after IV Thrombolysis—Is it Ready for Prime Time?	260
<i>Lekha Pathak, Ankur Jhavar</i>	
Strategy clock in STEMI	260
Treatment delay in STEMI	260
Reperfusion strategies	261
44. Revascularizing Nonculprit Artery in AMI: Uniform Strategy or Case-based Approach	265
<i>Ranjit K Nath, Kewal C Goswami</i>	
Approach to the management of nonculprit lesions in STEMI	265
45. Improving Outcomes of Primary Percutaneous Coronary Intervention: Technical Aspects	271
<i>Ambukeshwar Singh, Ayush Shukla, Nakul Sinha</i>	
Prehospital or patient preparation	271
Loading dose	271
Role of counseling	272
Angiography	272
Slow flow or no reflow	273
Deferred stenting	274
46. Late Presenters with STEMI: Which is the Best Strategy?	276
<i>Soumitra Kumar</i>	
Risk stratification in latecomers after STEMI	276
Reperfusion PCI in latecomers with STEMI	277
Nonreperfusion options for late presenters with STEMI	278
47. Acute Coronary Syndrome in Elderly	281
<i>Surender Deora, Kewal C Goswami</i>	
Challenges in elderly	281
Management	282
Medical management	282
Thrombolysis versus primary percutaneous coronary intervention	283
Cardiac rehabilitation	283
48. Right Ventricular Myocardial Infarction: An Update	286
<i>Shishu Shankar Mishra, Biswaranjan Mishra</i>	
Definition	286
Incidence	286
Pathophysiology	286
Clinical presentation	287
Differential diagnosis	287

Management	289
Prognosis	290
49. Cardiogenic Shock in Myocardial Infarction: Optimal Approach	292
<i>Siddharthan Deepti, Sandeep Singh</i>	
Definitions	292
Incidence, temporal trends, and etiologies	292
Outcomes	292
Management	293
50. Optimizing STEMI Care—Developing Regional Networks	298
<i>Sabarirajan Sokkaiyan, Thomas Alexander</i>	
Magnitude of the problem	298
Developing regional STEMI networks—the STEMI India experience	299
SECTION 8: DUAL ANTIPLATELET THERAPY	
51. Choice of Dual Antiplatelet Therapy in Acute Coronary Syndrome: Is There a Consensus?	305
<i>Hiremath MS, Deore RA</i>	
Aspirin	306
Ticlopidine	306
Clopidogrel	306
Prasugrel	308
Ticagrelor	308
52. Optimal Duration of Dual Antiplatelet Therapy after Acute Coronary Syndrome: Current Status	311
<i>Dhiman Kahali, Vivek Singh Rathore</i>	
Risk stratification tools for ischemia and bleeding risks	311
Type of P2Y12 inhibitor and timing of initiation	312
DAPT after percutaneous coronary intervention for ACS	313
DAPT in patients treated with CABG surgery for ACS	315
DAPT for patients with medically managed ACS	316
Resistance to drugs	317
Duration of DAPT after PCI in patients with peripheral artery disease	317
53. Switching Between DAPT Agents: The Right Strategy	320
<i>Harinder K Bali, Hiteshi KC Chauhan</i>	
Dual antiplatelet therapy clinical conundrum unraveled	320
Switching modalities	322
Switching between various oral P2Y12 Inhibitors	322
Switching between oral and intravenous P2Y12 inhibitors	329
Platelet function testing and switching of P2Y12 inhibitors	332
The way forward: what is the right strategy to switch DAPT?	332

54. Management of Bleeding in Planned or Unplanned Surgery in a Patient on Dual Antiplatelet Therapy 336

Sameer Dani

Dual antiplatelet therapy and pharmacology 336

Prevention of bleeding 337

Treatment of bleeding 339

SECTION 9: CORONARY INTERVENTION

55. History and Evolution of Coronary Intervention 345

Dev B Pahlajani, Akshay Mehta

Arrival of coronary angiography 347

New devices 349

History of fractional flow reserve, intravascular ultrasound, and optical coherence tomography 350

56. Bifurcation Stenting: Optimal Strategy in 2018 353

Ashwin B Mehta, Nihar Mehta

Definitions and classifications 353

Anatomical considerations 353

Relation between sizes of vessels: Murray's law and finet's law 355

Plaque shift versus carina shift 355

Threatened side branch morphologies: Preventing side branch occlusion 355

Stenting strategy in bifurcation lesions—one or two stents? 356

Tips and tricks 359

57. Left Main Coronary Artery Stenting in 2018 363

DS Gambhir

Stenting versus bypass surgery for left main coronary artery disease 363

Very long-term follow-up after left main coronary artery stenting 365

Current guidelines for left main coronary artery stenting 365

Selection of left main bifurcation stenting strategy 365

Role of adjust devices 366

Personal experience 368

58. Current Update in the Treatment of Calcified Lesions 370

Matthew I Tomey, Samin Sharma

Identification and classification of calcification 370

Patient and lesion selection 371

Wire selection 371

Modification of calcified lesions 371

Performance of atheroablation 373

Postatheroablation angioplasty and stenting 376

Comparative efficacy 376

Other devices 376

59. Protected Percutaneous Coronary Interventions: Treating the Complex Higher-risk Indicated Patients	379
<i>Mathew Samuel Kalarickal, Ramachandran Paramasivam</i>	
Complex high-risk indicated patients	379
CHIP PCI hospital	380
CHIP physician	380
Patient evaluation and procedure planning	380
Hemodynamic support devices	380
Post-procedure care	382
Current evidence	382
60. Ostial Coronary Lesions: Tips and Tricks for the Interventionist	384
<i>Pravesh Vishwakarma, Rishi Sethi</i>	
Morphology and histology	384
Diagnostic challenges	384
Selection of hardwares	385
Special techniques for ostial stent placement	388
61. Approach to Management of Chronic Total Occlusion	391
<i>Pravin K Goel, Roopali Khanna</i>	
Imaging of chronic total occlusion lesions	392
Predictors of chronic total occlusion-percutaneous coronary intervention success	392
Hybrid algorithm for chronic total occlusion-percutaneous coronary intervention	393
Chronic total occlusion-percutaneous coronary intervention techniques	393
Complications of chronic total occlusion-percutaneous coronary intervention	394
62. Hybrid Coronary Revascularization	396
<i>C Raghu</i>	
Benefits of coronary artery bypass grafting over percutaneous coronary intervention	396
Why percutaneous coronary intervention is preferred in practice?	396
In coronary artery bypass grafting, which is the preferred surgical conduit?	397
Which is better on-pump versus off-pump surgery?	397
Minimally invasive direct coronary artery bypass surgery	397
Robotic-assisted coronary artery bypass grafting	397
Endoscopic bypass grafting	397
Hybrid coronary revascularization	397
Hybrid outcomes	398
63. Should all Percutaneous Coronary Interventions be Radial Only?	400
<i>Tejas Patel, Surender Deora, Sanjay Shah</i>	
Background	400
64. Contemporary Coronary Stents: Implications for My Practice	404
<i>Neha Maddali, Kevin Marzo, Ramesh Daggubati</i>	
Design	405
Implications on clinical practice	407
Drug-eluting stent safety and efficacy in specific patient populations	408

65. Fractional Flow Reserve and Instantaneous Wave-free Ratio— Which Should Be the Gold Standard?	411
<i>Nagendra Boopathy Senguttuvan, Nitish Naik, Kewal C Goswami</i>	
Fractional flow reserve	411
Advantages of fractional flow reserve	412
Clinical utility of fractional flow reserve	413
Case study	414
Instantaneous wave-free pressure ratio	416
Comparison of invasive physiological indices to noninvasive physiology measured by positron emission tomography	416
Hybrid approach	417
Standalone instantaneous wave-free ratio approach	417
Merits and demerits	417
66. Optical Coherence Tomography in Coronary Artery Disease: A Review	419
<i>Ashwat S Dhillon, Leah Raj, Anil Kumar Mehra</i>	
Principles of optical coherence tomography	419
Preparation of imaging system and image acquisition	420
Optical coherence tomography interpretation in intracoronary imaging	420
Optical coherence tomography versus intravascular ultrasound	421
Correlation of optical coherence tomography with fractional flow reserve	422
Clinical utility of optical coherence tomography imaging	422
Stent selection (diameter and length)	423
Optimization after stent deployment	423
67. Stem Cells in Cardiovascular Disease: Is there an indication?	426
<i>Vijay Iyer</i>	
Challenges in cell therapy	426
Cell types and mechanisms	427
Clinical trials with stem cells	427
Nonischemic dilated cardiomyopathy	431
Future directions in cell therapy and lessons learned	431
68. Future of Interventional Cardiology	433
<i>VK Bahl, Dinkar Bhasin</i>	
Percutaneous mitral valve therapies	433
SECTION 10: INTERVENTION IN STRUCTURAL HEART DISEASE	
69. TAVR: Indications and Limitations in Clinical Practice	443
<i>Tarun Chakravarty, Matthias Raschpichler, Chinai Patel, Raj Makkar</i>	
Eligibility for transcatheter aortic valve replacement	443
Transcatheter aortic valve replacement for degenerative bioprosthetic aortic valves	444
Current generation commercially available transcatheter aortic valve	445
Indications for transcatheter aortic valve replacement	445
Limitations of transcatheter aortic valve replacement	445

70. Imaging for Transcatheter Aortic Valve Implantation: Practical Aspects	448
<i>Kinjal Banerjee, Nyal Borges, Parth Parikh, Samir Kapadia</i>	
Planning phase	448
Planning phase: procedural planning	449
Procedure phase	451
Postprocedure follow-up	452
71. Alcohol Ablation for HOCM: Progress over the Past Two Decades	455
<i>Hubert Seggewiss, Angelika Koljaja-Batzner</i>	
Historical development of percutaneous septal ablation	455
Indication for septal ablation	455
Technique of septal ablation	456
Acute results and complications	458
Follow-up results	459
72. Percutaneous Management of Paravalvular Leak: Patient Selection and Outcomes	462
<i>A Sreenivas Kumar, Ramakrishna Janapati</i>	
Etiology of paravalvular leak	462
Clinical diagnosis	462
Imaging	462
Indications for paravalvular leak closure	465
Devices for percutaneous paravalvular leak closure	465
Technique of transcatheter paravalvular leak closure	465
Outcomes and complications of paravalvular leak closure procedures	467
Medical therapy	467
73. Left Atrial Appendage Closure Device for Stroke Prevention in Atrial Fibrillation	468
<i>Balbir Singh</i>	
Existing options of stroke prevention in atrial fibrillation	468
Rationale for left atrial appendage occlusion	468
Identifying the right patient for device closure	469
Intolerance or contraindications to oral anticoagulant or new oral anticoagulants	469
Device implantation	470
Postprocedural treatment	470
Clinical trial results	470
Discussion	470

SECTION 11: CARDIAC IMAGING

74. Utility of Echo in Assessment and Management of Functional Mitral Regurgitation	475
<i>Gonzalo Luis Alonso Salinas, Marina Pascual Izco, José Luis Zamorano</i>	
Mechanism and etiology of mitral regurgitation	475

Ultrasound assessment of functional mitral regurgitation	475
Management of functional mitral regurgitation	479
75. Diastology Demystified	481
<i>Jagdish C Mohan, Vishwas Mohan, Madhu Shukla</i>	
Physiology of diastole	482
Factors contributing to diastole	482
Significance of diastolic function	483
Left atrial volume and diastolic function/dysfunction	488
Mitral inflow velocities	490
Mitral inflow measurements	491
Mitral inflow: acquisition and feasibility	491
Mitral annular velocities	492
Practical tips	494
Pulmonary vein flow and diastolic function	496
Acquisition of pulmonary vein flow signals	498
Pulmonary vein flow parameters	499
Mitral flow propagation by color M-mode	499
Longitudinal strain, rotation, and untwisting rate by acoustic speckle tracking	500
Diastolic stress test	500
The new guidelines on diastolic function	501
76. Echocardiographic Assessment of Right Ventricular Function	503
<i>K Tamilselvan, R Alagesan</i>	
Anatomical and physiological basis for right ventricular echocardiography	503
Right ventricular chamber dimensions assessment	503
Right ventricular anterior wall thickness assessment	504
Assessment of right ventricular hemodynamics	504
Assessment of right ventricular systolic function	506
Right ventricular myocardial performance index	506
Tissue doppler imaging of right ventricular	507
Right ventricular strain imaging	507
Assessment of right ventricular diastolic function	509
Right ventricular wall motion assessment	509
Transesophageal echocardiography	509
77. Longitudinal Strain Imaging: Is it a Clinical Tool?	511
An Echocardiographic Appreciation	
<i>G Vijayaraghavan, S Sivasankaran</i>	
Definition	511
Longitudinal strain	511
Speckle tracking for strain imaging	512
Longitudinal strain imaging protocol	512
Ejection fraction and global longitudinal strain	513
Ischemic heart disease and regional strain	513
Infiltrative diseases: amyloidosis	514
Left ventricular endomyocardial fibrosis	515
Hypertrophic cardiomyopathy	515

Left bundle branch, cardiac failure, and cardiac resynchronization therapy	515
Myocarditis	515
Strain imaging in rare situations	517
Limitations of strain imaging	518
78. Three-Dimensional Echocardiography—Current Indications	521
<i>Hardeep K Grewal, Ravi R Kasliwal</i>	
Left ventricle assessment	521
Right ventricle assessment	524
Left atrial assessment	525
Three-dimensional strain of left ventricle	526
Left ventricle dyssynchrony analysis	526
Valve assessment	527
Transcatheter interventions for valvular heart disease	534
79. Intervention and Fusion Echocardiography	542
<i>Shantanu P Sengupta</i>	
Problems during structural heart disease interventions	542
Understanding fusion imaging	542
Interatrial septal defect closure	543
Mitral valve interventions	545
Aortic valve interventions	545
80. Interpreting a Nuclear Stress Test	548
<i>GN Mahapatra</i>	
Approach to interpretation	548
81. Myocardial Viability Assessment: How Do We Apply in Clinical Practice?	559
<i>Nagendra Boopathy Senguttuvan, Kewal C Goswami</i>	
Energy and ischemia	559
Revascularization	560
Modalities of viability testing	560
Role of viability testing in the management of ischemic cardiomyopathy	563
Future direction	565
82. Computed Tomography Coronary Angiography—Essentials for Cardiologists	566
<i>Priya Jagia, Arun Sharma</i>	
Conventional angiography or computed tomography coronary angiography	566
83. Current Indications for Cardiac Magnetic Resonance Imaging	572
<i>Mona Bhatia, Shashank Jain</i>	
Technical aspects of cardiac MRI	572
Indications and applications	573
Future developments	579

SECTION 12: CARDIOVASCULAR PHARMACOLOGY

84. Newer Antianginals	583
<i>Kewal C Goswami, Anunay Gupta</i>	
Ranolazine	583
Nicorandil	584
Ivabradine	584
Trimetazidine	585
Fasudil	585
Allopurinol	586
Endothelin receptor blockers	586
Testosterone	586
High-dose statins	586
Molsidomine	587
Investigational drugs	587
85. Newer Antihypertensives	588
<i>TK Mishra</i>	
Newer drugs for hypertension	588
Emerging molecules	590
Future prospects	591
86. Newer Agents for Dyslipidemia	593
<i>Iyengar SS, Saleha N</i>	
Ezetimibe	593
Proprotein convertase subtilisin/kexin type 9 inhibitors	594
Inclisiran	595
Microsomal triglyceride transfer protein inhibitor: lomitapide	596
Antisense oligonucleotide against apolipoprotein B—mipomersen	596
Bempedoic acid	596
Gemcabene	596
CAT-2054	597
Novel drugs targeting high-density lipoprotein cholesterol	597
What are the recommendations of the medical societies on new nonstatin medications?	598
Safety of very low density lipoprotein cholesterol	599
Highest risk-highest benefit strategy	599
87. Choosing Between NOACS Wisely: Are They all the Same?	601
<i>Sandeep Bansal, Anunay Gupta</i>	
Pharmacokinetics and pharmacodynamics differences	601
Major differences in trials	602
Compliance	604

88. Newer Antihyperkalemic Drugs	606
<i>AK Pancholia</i>	
Clinical manifestations of hyperkalemia	606
Therapy for hyperkalemia	607
89. Drug Interactions in Cardiology	612
<i>Arunangshu Ganguly</i>	
Incidence	612
Mechanism of drug–drug interaction	612
90. Unsuspected Drug Toxicity in Cardiology Practice	620
<i>Ashish Tiwari, Sharad Chandra</i>	
Cardiotoxicity of cytotoxic drugs	620
SECTION 13: HEART FAILURE	
91. Heart Failure in India	627
<i>Sandeep Seth, Karishma Landge</i>	
Heart failure in India is reaching epidemic proportions	627
Causes	627
Severity of disease	627
Tackling the problem in India	628
92. Biomarkers for Heart Failure: Current Role and Relevance	631
<i>Anunay Gupta, Ambuj Roy</i>	
Natriuretic peptides: B-type natriuretic peptide and N-terminal prohormone	
B-type natriuretic peptide	631
Newer biomarkers	633
93. Practical Tips for using Beta-blockers, ACEI, ARBs, ARNI, Diuretics, Aldosterone Antagonists in Heart Failure	635
<i>Vijay Kumar Chopra, Sanjay Mittal</i>	
Beta-blockers	635
Angiotensin-converting enzyme inhibitor	636
Angiotensin receptor blockers	637
Angiotensin receptor neprilysin inhibitor	637
Diuretics	638
Aldosterone antagonists	638
94. HFrEF—How to Diagnose and Manage?	640
<i>Sanjeev Sanghvi, Swati Mahajan</i>	
Pathophysiology of HFrEF	640
Diagnosis of HFrEF	640
History and clinical examination	640

Investigations	642
Treatment	643
95. Heart Failure with Midrange Ejection Fraction—What is This?	647
<i>Arup Dasbiswas</i>	
Clinical characteristics	647
Predictors and outcomes of heart failure with midrange ejection fraction	648
96. Monitoring Therapy in Heart Failure with Reduced Ejection Fraction	650
<i>Soura Mookerjee</i>	
Trials of biomarker-guided therapy for heart failure	650
Multidisciplinary care approach to the management of heart failure patients	650
Remote monitoring of heart failure: tools and results	651
97. Stepwise Approach to Acute Decompensated Heart Failure	656
<i>BP Singh, Ravi V Prasad, Nirav Kumar</i>	
Pathophysiology	656
Evaluation of the patient with acute decompensated heart failure	656
Relevant investigations	658
Management goals	658
Treatment of acute heart failure	658
Management of patients with cardiogenic shock	661
98. Advanced Heart Failure Therapies—An Overview	664
<i>Rishi A Bhargava, Prafulla G Kerkar</i>	
Estimating prognosis in advanced heart failure	664
Advanced heart failure—treatment strategies	664
Advanced heart failure therapies—Indian scenario	669
99. Takotsubo Cardiomyopathy—An Update	671
<i>Pintu Nahata</i>	
History	671
Diagnostic criteria	671
Epidemiology	671
Etiopathogenesis	671
Clinical features	672
Variant	673
Management	674
Prognosis	674
SECTION 14: SYNCOPÉ	
100. Syncope: What is New?	679
<i>Satish K Kaushik, Surendra K Chutani</i>	
The new or revised concepts	679

101. Tilt Table Testing in Syncope	682
<i>Surender Deora, Kewal C Goswami</i>	
Pathophysiology of vasovagal syncope	682
Head-up tilt test	682
Response to head-up tilt test	683
Indications	684
Complications and contraindications	684
Future prospects	684
102. Implantable and External Loop Recorders: Indications in My Practice	686
<i>Praloy Chakraborty</i>	
Patients with syncope	686
Patients with palpitations	688
Nonestablished indications	688
103. Sudden Death in Dilated Cardiomyopathy—What is New in 2018?	690
<i>Kamal K Sethi, Ashish K Govil</i>	
Pathophysiology of dilated cardiomyopathy	690
Role of drug therapy in sudden cardiac death	690
Role of implantable cardioverter defibrillator	691
Risk stratification	693
104. Orthostatic Hypotension	696
<i>Siddharthan Deepthi, Kewal C Goswami</i>	
Definition	696
Epidemiology	696
Physiology of the normal orthostatic response	696
Etiology	698
Clinical presentation	700
Orthostatic testing and variants of orthostatic hypotension	700
Differential diagnosis	701
Management	701
Treatment	701
SECTION 15: ATRIAL FIBRILLATION	
105. Stroke Prevention in Atrial Fibrillation: New Oral Anticoagulants	705
<i>Sharad Agrawal</i>	
Epidemiology of stroke in atrial fibrillation	705
Risk stratification tools in atrial fibrillation	705
Antithrombotic management of atrial fibrillation	706
Current recommendations for antithrombotic therapy in atrial fibrillation	708
106. Catheter Ablation of Atrial Fibrillation	710
<i>Dinkar Bhasin, Gautam Sharma</i>	
Advantages of maintaining sinus rhythm	710

Pathophysiology of atrial fibrillation	710
Indications for atrial fibrillation ablation	711
Technique for pulmonary vein isolation	711
Adjunctive ablation strategies	713
Complications of atrial fibrillation ablation	713
Outcomes	714
107. Postoperative Atrial Fibrillation: Clinical Correlates and Management	715
<i>Krishnarpan Chatterjee, Naveen Garg</i>	
Incidence and time course	715
Pathogenesis	715
Clinical manifestations and diagnosis	716
Prevention of atrial fibrillation and complications	716
Management	718
Anticoagulation	718
108. Managing Antithrombotics after Percutaneous Coronary Intervention in Atrial Fibrillation: Current Recommendations	721
<i>Sundeep Mishra</i>	
Why risk of thrombosis after percutaneous coronary intervention?	721
Why risk of stroke after onset of atrial fibrillation?	722
How to prevent thrombosis in patient undergoing percutaneous coronary intervention?	722
How to prevent stroke in a patient with atrial fibrillation?	724
How to balance risks and benefits in patient of atrial fibrillation undergoing percutaneous coronary intervention	727
109. Treatment of Atrial Fibrillation in Heart Failure: Is It Any Different?	732
<i>Rajesh A Dhopeshwarkar</i>	
Goals of treatment in atrial fibrillation	732
Challenges in device management in patients with atrial fibrillation and heart failure	735
110. Managing Atrial Fibrillation in Acute Myocardial Infarction	736
<i>Jayagopal P Balagopalan, Sarjun Basha</i>	
Predictors of atrial fibrillation in acute myocardial infarction	736
Management of atrial fibrillation in acute myocardial infarction	736
SECTION 16: VENTRICULAR ARRHYTHMIAS	
111. Ventricular Arrhythmias in Acute Myocardial Infarction	741
<i>Rajesh A Dhopeshwarkar, Rakesh Yadav, Kewal C Goswami</i>	
Types of ventricular arrhythmias	741
Mechanism and pathogenesis of ventricular arrhythmias after acute myocardial infarction	741
Predictors of sustained ventricular tachycardia and ventricular fibrillation	741
Management of ventricular arrhythmias	743

112. Ventricular Arrhythmias and Sudden Death: Problems and Opportunities in Clinical Practice	746
<i>Kapil Kumawat</i>	
Mechanisms of ventricular arrhythmias and sudden cardiac death	746
Epidemiology	747
Therapies for ventricular arrhythmias and sudden cardiac death	747
Devices for treatment of ventricular arrhythmias and sudden cardiac death	748
Prevention, prediction, and treatment of VAS and SCD in specific disorders	749
113. Electrocardiography Clues in a Sudden Cardiac Death Survivor	756
<i>Ranjan Modi, Aparna Jaswal</i>	
Structural heart disease	757
Ischemic heart disease	758
Nonstructural heart disease: inherited	758
Nonstructural heart disease: noninherited	764
Electrocardiography-based tests	765
Common forms of sudden cardiac death	765
Multiple risk markers: cumulative risk	766
Importance of dynamic monitoring	767
114. Premature Ventricular Complex: When and How to Ablate?	771
<i>Joseph Theodore, Raja Selvaraj</i>	
When do premature ventricular complexes need to be treated?	771
To treat or not to treat a premature ventricular complex	771
How to treat?	772
Technique of premature ventricular complex ablation	772
Ablation of premature ventricular complexes	774
Outcomes	774
115. Epicardial Ventricular Tachycardia: Recognition and Approach	775
<i>Maki Ono, Walid I Saliba, Oussama Wazni, Mandeep Bhargava</i>	
Preoperative assessment and recognition	775
Approach to access the pericardial space	777
Mapping and ablation	778
Complications	779
116. Cardiopulmonary Resuscitation: What's New?	783
<i>Nitin Modi, Sunil Sharma</i>	
2015 American heart association guideline update for cardiopulmonary resuscitation and emergency cardiovascular care	783
SECTION 17: CARDIAC IMPLANTABLE ELECTRONIC DEVICES	
117. Improving Outcomes in Patients with Cardiac Resynchronization Therapy	791
<i>Rohit Malhotra</i>	
Patient selection	791
Preprocedure planning	794

118. CRT-D versus CRT-P—What should be the Standard of Care in Nonischemic Cardiomyopathy?	799
<i>TS Kler, Avinash Verma</i>	
Burden of sudden cardiac death in NICM	799
CRT-D in NICM—lack of benefit is consistent	800
Is the trial design at fault?	802
So which NICM patient needs icd or CRT-D?	802
119. ICD in HFrEF—When are They not Needed?	804
<i>Rajnish Sardana, Praloy Chakraborty</i>	
Early after myocardial infarction	804
Early after myocardial revascularization	805
Recent onset nonischemic cardiomyopathy	806
120. Leadless Pacemakers: Current Review and Future Directions	809
<i>Vanita Arora</i>	
Potential complications with conventional pacing system	809
Animal studies and technological advancements	809
Current leadless cardiac pacemakers	810
How the algorithm functions	813
SECTION 18: CARDIAC SURGERY	
121. Time to Embrace Total Arterial Revascularization	819
<i>Ramakanta Panda, Sunil Vanzara</i>	
Reason for low atherosclerosis in arterial conduits	819
Types of arterial conduits	820
Indications and contraindications to use total arterial revascularization	820
Techniques of harvesting	821
Factors influencing graft patency	822
Comparative patency data of arterial grafts	823
Survival benefit	823
Discussion	825
122. Surgery in Acute Myocardial Infarction	831
<i>Ganesh K Mani, Pramod K Sharma, Manju Mani</i>	
Coronary artery bypass surgery after failed PCI	831
Outcome of surgery within 6 hours	832
Optimal timing of coronary artery bypass surgery in acute myocardial infarction	832
Operative strategy (arrested or beating heart?)	833
Personal experience	833

Coronary Artery Disease Risk Factors

Smokeless Tobacco and Cardiovascular Disease

Surender Deora, Kewal C Goswami

INTRODUCTION

Tobacco has been used by human beings since 600 AD.¹ Columbus came to know about tobacco from Caribbean and introduced it in Europe. It was introduced in India in early 1600 AD by Portuguese traders mainly as a barter commodity to trade Indian textiles.² The harmful effect of tobacco was also known since the Mughal era and the Jahangir, the Mughal emperor of India, had even passed orders to ban it.³ The spiritual leader, Guru Gobind Singh, the 10th Sikh guru, prohibited smoking for the Sikh community. He said, "Wine is bad, Indian hemp (bhang) destroys one generation, but tobacco destroys all generations".⁴ Not only in India, the king James I of England and Shah Abbas of Persia were aware of the harmful effect of tobacco. King James described tobacco smoking as "a custom loathsome to the eye, hateful to the nose, harmful to the brain, and dangerous to the lungs". Initially, it was mainly used by affluent class but gradually penetrated at all socioeconomic strata in various forms.

The term "smokeless tobacco" (SLT) mainly refers to chewing, spitting, sniffing unburned tobacco in one or the other form either alone or mixed with other constituents. The

SLT is mainly obtained from *Nicotiana rustica* which contains more nitrosamines as compared to the tobacco for smoking obtained from *Nicotiana tabacum*. Mainly, it was consumed with betel quid (pan) for decades and later in the form of bidi (tobacco wrapped in dried leaves of special trees). Some people used for its presumed medicinal value which although has never been proved in any system of medicine being practiced in India.

The various forms and different names of SLT consumed in India are *Pan*, *Gutkha*, *Zarda*, *Naswar*, and *Mishri* or *Gul* (Table 1 and Figs. 1 to 3).

- *Pan* is a betel leaf containing mixture of tobacco, areca nuts, spices, and lime (to increase the bioavailability of nicotine)
- *Gutkha* is nothing but powdered form of scented tobacco, areca nut mixed with lime.
- *Zarda* is Indian chewing tobacco flavored with spices and flavored form of tobacco is also used in pan
- *Naswar* is a moist, powdered tobacco snuff consumed mostly in India, Pakistan, Afghanistan and neighboring countries. *Naswar* is snuffed in the floor of mouth, under

TABLE 1: Various types of smokeless tobacco

Common name	Ingredients
Gutkha	Tobacco, areca nut, condiments, flavoring agent
Khaini	Tobacco flakes, lime
Naswar	Tobacco, slaked lime, indigo, cardamom oil, menthol
Gul	Burned tobacco powder, molasses
Zarda	Boiled tobacco
Pan	Betel leaf, areca nut, tobacco, lime, spices
Moist snuff (US type)	Pulverized tobacco, fermented
Moist snuff or snus (Swedish type)	Pulverized tobacco, nonfermented

FIG. 1: Dried tobacco leaves and Zarda.

FIG. 2: Gul and Naswar in Indian market.

FIG. 3: Snuff and Tapkeer in Indian market.

the lower lip, or inside the cheek for prolong period to get desired effect

- *Mishri or Gul* is tobacco powder applied to teeth and gums with index fingers and used as dentifrices
- *Snuff* is a pulverized tobacco either fermented (US type) or nonfermented (Swedish type). The pattern of use of snuff is slightly different in these two countries where in Sweden it is placed under the upper lip and in United States between the lower gum and chin.⁵ It is usually inhaled or snuffed into the nasal cavity, delivering a swift hit of nicotine. It is usually in the flavored form.

Smokeless tobacco is not only common in middle income and poor countries but is also quite commonly used as snuff in North America and in Europe mainly Sweden. Inhalation of tobacco or snuff is relatively less common in India as compared to western countries

There are more than 350 million populations globally using SLT with the majority living in Southeast Asian region.⁶ The prevalence of SLT in this region is 1.3–38% in males and 4.6–27.9% in females.⁷ India is one of the largest consumers of tobacco products both in number and relative share. The prevalence of tobacco use in Indian population more than 15 years age is 34.6% (47.9% males, 20.3% females) and is

mainly consumed as SLT (49.3% males, 85.5% females).⁸ The average age of initiation was 17.9 years similar to that of smoking.⁹ It is specially increasing in younger children in India. A cross-sectional study in Delhi and Chennai (Project MYTRI) reported higher use of SLT in 6th grade students than 8th grade.¹⁰ Tobacco use in any form accounts for 6 million deaths globally every year which is expected to increase 8 million by 2030. According to Tobacco Control Policy (TCP) Indian cohort survey, Gutkha was the most common form of SLT used in India followed by chewing of tobacco (Fig. 4).¹¹

The association of tobacco consumption mainly in form of smoking and cardiovascular disease (CVD) is well established.¹² The historical trend of smoking and CVD in United States ran parallel in last century. The rate of smoking and CVD increased till first half of 20th century and later decreased gradually because increased awareness and well proven causation of various diseases.^{13,14} The use of SLT which was common in middle income countries became gradually increased in developed countries as the trends for smoking decreased whereas the smoking and SLT both increased in developing countries especially Southeast Asia.¹⁵ The main reason of increased use of SLT is because of its easy availability, lack of awareness of its harmful effect,

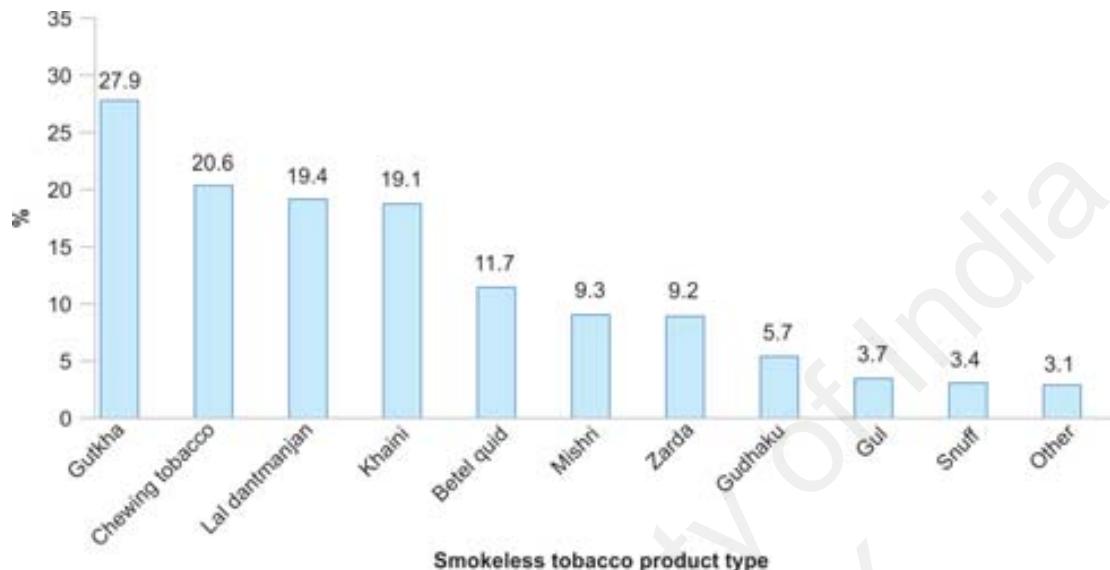

FIG. 4: Prevalence of smokeless tobacco used in India.

Source: Gravely S, Fong GT, Driezen P, et al. An examination of the effectiveness of health warning labels on smokeless tobacco products in four states in India: findings from the TCP India cohort survey. BMC Public Health. 2016;16:1246.

aggressive marketing by the companies, presumption of it being medicinal value, as mouth freshener, and dentifrices. Tobacco consumption is the most important preventable risk factor for premature death especially in young middle-aged adults.¹⁶

PHARMACOKINETICS OF SMOKELESS TOBACCO

Nicotine is the main constituent in tobacco causing addiction and most of its harmful effect. The level of nicotine in blood depends upon the concentration of tobacco in the product, its pH level, moisture level, and the size of tobacco cutting.^{17,18} It is water- and lipid-soluble weak base and readily crosses the mucosa in unionized form. If the pH of the SLT is higher, i.e., if it is more alkaline then more nicotine remains in unionized form, hence more absorbed resulting in higher nicotine blood level.¹⁹ The maximum level of nicotine is similar in both smoking and SLT but the level of nicotine is more sustained in SLT as compared to smoking where rapid peaks and troughs are seen.²⁰

SMOKELESS TOBACCO AND CARDIOVASCULAR RISK FACTORS

Nicotine increases the blood pressure (BP) and heart rate (HR) by enhancing the release of dopamine, epinephrine, norepinephrine, vasopressin, etc. and activation of sympathetic nervous system. The long-term effect of SLT on BP depends on many factors including the type and amount of SLT used and level of physical activity. Increase in BP is not only because of nicotine but also because of high sodium content of the tobacco product and licorice in SLT. This has been proved by measuring the urinary sodium content in

various types of SLT.²¹ The licorice increases the sodium level by inhibiting the metabolism of mineralocorticoids and thus increases the BP. The acute effects of SLT causes increase in HR and BP which in one of the study shows increase by 19 beats/min of HR and by 21/14 mm Hg of BP.²² In a population-based survey of more than 30,000 participants in Sweden, the chronic SLT users were more likely to have higher BP (>160/90 mm Hg).²³ More often it is the diastolic BP which is elevated as shown in a study of 135 middle aged healthy volunteers with ambulatory BP monitoring.²⁴ But in those who are physically active like baseball players, no significant elevation in BP and HR was noted in SLT users.²⁵ Use of tobacco has been shown to be associated with insulin resistance and incident diabetes. Higher serum level of insulin and fibrinogen was noted in SLT users as compared to non-users.²⁶ A prospective population-based study in middle aged Swedish men using snuff found significant risk of developing diabetes at follow-up of 10 years.²⁷ SLT has also been associated with abnormal lipid profile. A study conducted in Asians with regular tobacco chewing habits reported significantly high level of low-density lipoproteins cholesterol (LDL-C) and low level of high-density lipoproteins cholesterol (HDL-C).²⁸ Similarly, Tucker et al. in a population based study reported 2.5 times higher prevalence of hypercholesterolemia in SLT users.²⁹ Gupta et al. studied association between SLT and CV risk factors in a population based case control study in Bikaner region, India.³⁰ They found significant higher prevalence of hypertension, tachycardia, dyslipidemia and diabetes as compared to nontobacco users. All these studies were in isolation and in different regions of the globe where different types of SLT products with different tobacco content and other constituents were being used. The effect of SLT on vascular inflammation, atherosclerosis and thrombosis is still unclear and needs large studies with all types of SLT products.

SMOKELESS TOBACCO AND CARDIOVASCULAR DISEASE

Smokeless tobacco has been associated with various diseases including cancer of the oral cavity, esophagus, and pancreas.^{31,32} It has also been associated with low birth weight, preterm or stillbirth.³⁰ The association of SLT with CVD is not very well established as it is for smoking.³³ Various studies in different regions of the world produced different results depending upon the type of SLT consumed and their level of chemical constituents. Apart from the Southeast Asian countries, the main consumer of SLT although in different forms is in Sweden and United States. The SLT consumed in India have high levels of tobacco-specific nitrosamines as compared to that present in moist snuff available in European market.^{34,35} Also, the SLT available in India has varied methods of preparation, variable tobacco content and varied methods of using it which causes different effects as compared to SLT available in western countries. The meta-analysis by Boffetta and Straif calculated SLT-attributable fraction of CVD.³⁶ In their analysis, SLT use contributed 5.6% of fatal coronary heart disease (CHD) in Sweden and 0.5% in America. This meta-analysis included eight studies that evaluated the risk of fatal myocardial infarction and five studies that evaluated the risk of fatal stroke but this analysis did not include Asian studies. Three studies showed significant association of SLT and CV death (including stroke and CV death) but other studies did not show that strong association. But the overall cohort has shown positive association between CV death and SLT. The meta-analysis by Vidyasagar et al. has shown increased risk of fatal ischemic heart disease (IHD) and stroke with SLT.³⁷ Another study by Gupta et al. also known as Mumbai cohort study the results was mixed. At follow-up of 5 years, SLT use was associated with significant fatal CV event in females but not in males.³⁸ The study including patients from India, China, and Taiwan has shown insignificant association of SLT and CV mortality in India but significant association in China and Taiwan.³⁹ The incidence of nonfatal stroke did not show an increased risk in SLT users but most of the studies with this end point have been conducted in Nordic region like Sweden.⁴⁰ The incidence of nonfatal IHD shows significant heterogeneity depending upon the geographical area of study. The studies conducted in Nordic region did not show an increased risk for nonfatal IHD but those from the Asian region showed a 40% increased risk.⁴¹ No data available for this outcome from North American studies. There are limited data on the risk of CHD with different type of SLT products. Gupta et al. first time did a meta-analysis with different SLT products and risk of CHD.⁴² They found a significant association between snuff use or snus (most commonly consumed in Europe) and fatal CHD. But there was no significant association between chewing tobacco (most commonly consumed in Asia) and fatal CHD which may be due to small studies and significant heterogeneity between the studies. This study also analyzed the fraction of fatal CHD attributable to SLT in different regions where it was found to be highest in Sweden (5%) followed by Southeast Asia (0.77%), and least in United States (0.14%).

HEALTH POLICY IMPLICATIONS

Smokeless tobacco has not received much focus among policy makers and researchers because it is presumed to be less harmful than smoked tobacco. It is also thought to be a regional rather than global problem although the most population in developing countries consumes SLT rather than cigarettes. The problem in policy making is lack of concrete evidence against SLT because of its various types and composition. Moreover, the pattern of consumption of the various types of SLT differs in these countries therefore all studies have not shown consistent results. SLT is found to be equally detrimental as compared to smoking at least in Indian subcontinent with little data available with us. The tobacco specific nitrosamine available in the Indian SLT is much higher and varied as compared to that available in Sweden and hence more injurious to health.⁴³ Therefore, the policy needs to be as strict as that for smoking tobacco. Cigarettes and Other Tobacco Products Act (COTPA) 2003 prohibits all type of advertisement of any type of tobacco products. India is a signatory of WHO Framework Convention on Tobacco control (FCTC) and MPOWER package and has implemented tobacco control awareness programs.⁴⁴ The impact of the FCTC is that the prevalence of smoking has declined in the countries who have strictly implemented it.⁴⁵ But it is difficult to assess the effect of these measures in controlling the SLT use because of the little available quality data.⁴⁶ Continuous government efforts, effective advocacy by NGOs, and inclusion of harmful effect of tobacco in all forms in school curriculum are some of the ways in dealing with this problem.

CONCLUSION

In India, SLT is the dominant form of tobacco used and is equally dangerous to health as smoked tobacco. It causes more sustained raised nicotine level in blood as compared to smoked tobacco and hence is more addictive. It causes raised BP, impaired blood sugar level and dyslipidemia and hence is prone to cause CVD. The available literature from the Indian subcontinent shows an association of SLT and increased risk of fatal IHD and stroke. A multipronged approach is needed for the control of all types of tobacco use so that the younger and productive population of the country remains healthy.

Alcohol and Coronary Artery Disease: Fact versus Fiction

JPS Sawhney, Kushal Madan

INTRODUCTION

There has been a lot of controversy around the use of alcohol in coronary artery disease (CAD). Many studies are in favor of wine as advantageous as compared to other alcoholic beverages. Some studies suggest that type of drink was not important. Heavy drinking is associated with increased mortality, hypertension, and cerebrovascular hemorrhage on the other end light-to-moderate consumption of alcohol is shown to be cardioprotective. How much drink is safe? In fact the definition of heavy, moderate and light drinking is not standardized. It must be known that definitions of a "standard drink" are variable by article and country thereby leading to imaginary facts rather than facts.

The purpose of this chapter is to explore the link between drinking alcohol and CAD. This chapter will put forward the facts associated with alcohol consumption and cardioprotective effects. So if someone does not drink already, is his heart a reason to start?

UNDERSTANDING "STANDARD DRINK"

A standard drink (or "unit of alcohol" in UK) is a notional drink that contains a specified fixed amount of pure alcohol (ethanol). Different countries define standard drinks differently. That means one standard drink always contains the same amount of alcohol regardless of the container size or the type of alcoholic beverage, but does not necessarily correspond to the typical serving size in the country in which it is served. For example, in the United States, a standard drink contains about 14 g of alcohol. The lowest number of grams of alcohol in Europe is in UK unit at 8 g and the highest in Austria at 20 g. In absolute terms, amounts of alcohol consumed less than 30 g per day is considered as light-moderate drinking and alcohol consumed more than 30 g/day is considered as heavy drinking.

ALCOHOL AND CARDIOVASCULAR MORTALITY

Epidemiological data indicate that there is a J-shaped curve to describe dose-response between alcohol intake and mortality, i.e., low-risk in light-to-moderate drinkers as compared to nondrinkers and highest risk among heavy drinkers. In a meta-analysis of 34 studies Di Castelnuovo et al. concluded that low levels of alcohol intake (1–2 drinks/day for women and 2–4 drinks/day for men) provided maximum protection (13–22% in women and 15–19% in men). On the other hand, alcohol intake more than two drinks per day in women and more than three drinks per day in men are associated with increased mortality.²

Gaziano et al. in a prospective cohort study, studied 89,299 men (age 40–84 years) from Physicians Health study, who were followed over 5.5 years for mortality.³ They reported an L-shaped curve between light-to-moderate alcohol intake and cardiovascular (CV) mortality with decreased risk at 1 drink/week. It was also observed that there was decrease in CV mortality as compared with nondrinker even at more than or equal to two drinks per day.

Mukamal et al. studied 245,000 US adults and reported that alcohol intake of both light and moderate levels was associated with lower CV mortality compared with either heavy drinkers or nondrinkers.⁴

ALCOHOL AND CORONARY ARTERY DISEASE

Studies have reported that moderate consumption of alcohol is cardioprotective. Whether this cardioprotective effect is associated with lesser degree of coronary atherosclerosis was studied by Femia et al. in which association of alcohol with coronary atherosclerosis was assessed by coronary angiography in a large cohort of men (1,676) and women (465) from a coronary care unit.⁵ It was concluded that in a selected

high-risk population, moderate alcohol consumption was independently associated with less coronary atherosclerosis and lower risk for cardiac mortality. This conclusion cannot be extrapolated to the general population. To study the association between alcohol consumption and coronary atherosclerosis in asymptomatic subjects, study was performed on 1,795 individuals without coronary heart disease (CHD) using computerized tomography detected coronary calcium. It was concluded that the risk of extensive coronary calcification was 50% lower in individuals who consumed 1–2 alcoholic drinks per day than in nondrinkers.⁶

ALCOHOL AND CARDIOVASCULAR MEDICATIONS

Cardiovascular disease (CVD) patients are mainly taking lipid-lowering, antiplatelets or oral anticoagulant drugs. In such setting what are the interactions of alcohol and medications, how alcohol is metabolized or absorbed, whether alcohol affects the therapeutic effects of drugs, has not been sufficiently investigated. Moore et al. studied the risks of combined alcohol-medication use and reported that depending on type of medicine and amount of alcohol there could be aggravation of liver disease, dizziness, problems with coordination, insomnia, worsening of depression, and poor control of diabetes. Aspirin when combined with alcohol can raise the risk of gastrointestinal bleeding.⁷

However, more research is needed to determine the safety of alcohol consumption in combination with CV drugs.

POSSIBLE MECHANISMS FOR CORONARY ARTERY DISEASE PROTECTION BY ALCOHOL

It is hypothesized that moderate alcohol consumption reduces the risk of myocardial infarction (MI) through its effects on high-density lipoprotein cholesterol (HDLc), insulin sensitivity, thrombotic activity, and inflammation.

Effects on High-density Lipoprotein Cholesterol

Moderate alcohol intake is associated with increase in serum HDLc. This increase in HDLc is also associated with increase in apolipoproteins (A-I and A-II) which are the major HDL carrier proteins. According to Rimm et al. there will be 8 mg/dL increase in the plasma concentration of apolipoprotein A-I and a 16.8% reduction in CHD due to increased HDLc from 30 g alcohol per day.⁸

Antioxidant Effects

Alcohol intake may have antioxidant effect. There is a strong evidence from the observational studies that oxidation of low-density lipoprotein (LDL) is affected by the antioxidative effect of alcohol and thereby impeding the atherosclerotic process. It has been shown that grape-derived beverages are rich in nutritional polyphenolic antioxidants and hence have cardioprotective effects.^{9,10}

Enhanced Insulin Sensitivity

Alcohol consumption is also associated with reduced insulin resistance and increased insulin sensitivity. This effect is probably due to suppressed fatty acid release from adipose tissue and elevation of adiponectin levels during the Krebs cycle of skeletal muscles, thereby facilitating glucose metabolism.^{11,12}

Antithrombotic Effects

Alcohol promotes reduction in blood clotting and platelet aggregation, reduced levels of plasminogen activator inhibitor (PAI) activity, fibrinogen, plasma viscosity, von Willebrand factor and factor VII, and increased concentrations of tissue-type plasminogen activator (tPA) have been described.¹³

Anti-inflammatory Effects

Alcohol may confer cardioprotection by acting as an anti-inflammatory agent. Recent data show that alcohol consumption suppresses the production of proinflammatory cytokines such as tumor necrosis factor (TNF)- α , interleukin-5, interleukin-6, and C-reactive protein (CRP).¹⁴

DRINKING PATTERNS AND CORONARY HEART DISEASE

Not only choice of beverage but also the drinking pattern is an important factor of interest with respect to CAD and hypertension. Some of the studies mentioned in the report on moderate drinking from National Institute of Alcohol Abuse and Alcoholism assessed the differences between regular low per-occasion consumption and the same total weekly consumption all at once.¹⁵ In fact, the pattern of alcohol drinking is not assessed by many studies, thereby making the comparison and conclusions difficult across the studies.

To assess the influence of drinking pattern and type of beverage (beer, red wine, white wine, and liquor) on risk of MI, Mukamal et al. studied 38,077 males who were free of CVD at baseline. There were 1,418 cases of MI during 12 years of follow-up once in every 4 years. As compared to men who consumed alcohol 3–4 or 5–7 days per week had decreased risks of MI as compared to those who consumed alcohol less than once per week. Also there was an inverse association between the risk of MI and four types of beverage, strongest for beer and liquor, intermediate for white wine, and weakest for red wine.¹⁶

The most favorable drinking pattern is regular daily or almost daily light drinking, with avoidance of clearly harmful binge drinking.¹⁷

INFLUENCE OF AGE AND SEX ON CARDIOVASCULAR EFFECTS OF ALCOHOL

Recent reviews suggest that alcohol consumption is mainly associated with a decreased risk of MI among men over 45 years of age and women over 55 years of age. To study whether the beneficial effect of alcohol is influenced by age, Hvidtfeldt et al. conducted a pooled analysis of eight

prospective studies including 192,067 women and 74,919 men and showed an inverse relationship for both men and women for three age groups (≤ 50 , 50–59, ≥ 60 years).¹⁸ In a population-based study of 4,410 adults aged more than 65 years free of CVD at baseline, it was found that alcohol consumption was inversely associated with risk of CHD for men and women, and for different beverage types. Also it was concluded that moderate consumption (14 or more drinks/week) was associated with lowest risk of CHD.¹⁹

It has been reported that men and women have similar cardioprotective benefit especially in postmenopausal women. Nurse's health study,²⁰ studies from women's health initiative²¹ and Swedish women's lifestyle and health study²² have demonstrated an inverse relationship between moderate alcohol consumption and the risk of CAD and total mortality in women. But it is evident from the literature that women experience toxic effects of alcohol at approximately half the dose of men.²³ Overall evidence from epidemiological data indicates that alcohol consumption in women may be associated with an increased risk of breast cancer. Relative effect of moderate consumption of alcohol is lower than the increased risk of acquiring breast cancer especially for women with a family history of breast cancer. Although there has been a belief that alcohol enhances lactation but the scientific research does not support that alcohol consumption increases milk production but may actually decrease it.

THE GENETICS OF ALCOHOL AND CARDIOVASCULAR DISEASE

Alcohol dehydrogenase (ADH) catalyzes the oxidation of ethanol to acetaldehyde which is highly toxic affecting the myocardial structure and function. Any genetic variation in the activity of ADH enzyme can lead to excess acetaldehyde accumulation. Similarly cytochrome P450 2E1 (CYP2E1), is another enzyme which promotes conversion of ethanol to acetaldehyde.

Chen et al. identified a mitochondrial protein aldehyde dehydrogenase-2 (ALDH2) which plays an important role in alcohol metabolism.²⁴ ALDH2 activation is required for cardioprotection as it catalyzes the oxidation of acetaldehyde to a lesser toxic acetate. Therefore, it is the balance between the levels of ADH, CYP2E1, and ALDH activity that determines how much alcohol can be metabolized by liver, what are the byproducts and the underlying alcohol induced tissue injury including CVD.

The French Paradox

This term French paradox was first used in 1992 to describe the irony of the fact that in spite of high saturated fats in the diet, incidence of coronary events was less in French population. This was attributed to the fact that there was moderate consumption of red wine along with the meal.²⁵ Epidemiological studies indicate that the amount of alcohol consumed in France, i.e., 20–30 g/day can reduce risk of CHD by at least 40%.

Regular, moderate consumption of red wine has been associated with reduced CHD and mortality. Red wine has higher levels of polyphenols (flavonoids and nonflavonoids, which have antioxidant, antiendothelin-1, and antiplatelet effects) as compared with either forms of alcohol. But the cardioprotective effects are due to ethanol itself rather than a specific type of alcoholic beverage (wine, beer, and liquor). A differential cardioprotective effect of wine could be because wine is always consumed in moderation as compared to beer or liquor. Studies have shown equal protection from all types of alcohol suggesting that the specific alcoholic beverage is less important than the quantity and pattern of the alcohol intake.^{26,27}

Two components to understand the pattern of drinking are frequency and binge drinking. Mukamal et al. in a cohort study of 1,935 MI patients followed up for 3.8 years showed that binge drinkers (even light binge drinkers) had 2-fold high-risk of mortality than drinkers who did not binge.²⁸ There is also an indication from the literature that more frequent drinking (several days/week or daily) is more beneficial as compared to occasional drinking.^{29,30} Frequent drinking may also explain the so called "French Paradox." French people relate the beneficial effects of red wine to the frequency of drinking, i.e., every day with their meals.

POINTS TO CONSIDER FROM THE PAST STUDIES

- There have been no reported randomized controlled trials of alcohol consumption and CAD outcome data. This could be due to obvious ethical and logistical reasons
- *Errors in the past:* Shaper et al. in 1988 hypothesized the presence of systemic misclassification errors in the past studies associated with alcohol consumption and CHD.³¹ According to Shaper et al. people decrease their alcohol consumption as they get older. Heavy drinkers tend to reduce alcohol intake that have ischemic heart disease or high blood pressure. Inclusion of such population as abstainers might create bias which was not considered in past. Shaper's hypothesis was not further evaluated, but Fillmore et al. confirmed this and suggested that the cardiac protection by alcohol may have been overestimated.³² They classified the misclassification errors:
 - Former drinker misclassification error, i.e., failure to separate former drinkers from complete nondrinkers
 - Occasional drinker misclassification error, i.e., failure to separate occasional drinkers from complete non-drinkers.

In their meta-analysis, they concluded that the few studies without this error (i.e., those that did not contaminate the abstainer category with occasional or former drinkers) show abstainers and "light" or "moderate" drinkers to be at equal risk for all-cause and CHD mortality.³³

- As compared to heavy drinkers, moderate drinkers have a healthy lifestyle. It is presumed that heavy drinkers are likely to consume more tobacco, unhealthy diet and do less exercise and this unhealthy lifestyle could be the explanation for higher CV mortality in heavy drinkers

- Widespread belief that alcohol is beneficial in CAD could also induce selection bias in more recent studies
- Genetics can also influence the interindividual variations in the CV response to alcohol consumption.

ALCOHOL AND INDIAN POPULATION

There has been ample evidence from the literature to show that there exists a J- or U-shaped relation between alcohol consumption and CHD. That means CHD and mortality rates are lowest in light-to-moderate drinkers and highest among abstainers and heavy drinkers. However, there is paucity of data from India to support this concept. Limited data in Indians from the INTERHEART study, a case-control study of patients with incident acute MI, revealed that in South Asians alcohol consumption was not protective against CHD.³⁴ The odds ratio (OR) of having MI was 1.64 [95% confidence interval (CI) 1.21–2.27] among Indian alcohol users as compared to nonusers. Roy et al. conducted a surveillance study in ten industries across India to assess the CHD prevalence among 4,465 male subjects who were present or past alcohol users as compared to abstainers.³⁵ Consistent to INTERHEART study they did not observe any protective association between alcohol intake and the prevalence of CHD, rather suggested a possible harm of alcohol for coronary risk in Indian men, since there was significantly higher systolic blood pressure, diastolic blood pressure, and fasting blood sugar in alcohol users as compared to lifetime abstainers. The contradictory results could be due to differences in ethnicity, type of alcoholic beverage, and pattern of alcohol intake. The beneficial effect of moderate alcohol consumption is not a global finding because most of the research reported in literature is from western world where the climate, culture, and diet are so different from Asian countries. Similar to Indian population, it is reported that moderate alcohol does not confer cardioprotective effect on ischemic heart disease mortality among older Chinese population in Hong Kong.³⁶

DETRIMENTAL EFFECTS OF ALCOHOL INTAKE

Alcohol abuse, binge drinking has all been associated with harmful effects such as hepatitis, liver cirrhosis, pancreatitis, hypertriglyceridemia, stroke, injuries, and accidents.³⁷ Corrao et al., in a meta-analysis of alcohol consumption and the risk of neoplasms and non-neoplastic disease, reported strong trends in risk for cancers of oral cavity, esophagus, and larynx.³⁸

Ethanol at higher doses is associated with cardiotoxicity thereby developing alcoholic cardiomyopathy and heart failure.³⁹ Excessive alcohol uses can also precipitate cardiac arrhythmias typically atrial fibrillation.⁴⁰

A WORD OF CAUTION

Alcohol is classified as a human carcinogen (class 1) by the International Agency for Research on Cancer, with a dose-related increase in prevalence of several cancers either

exponentially (e.g., oral cavity and pharyngeal cancers) or linearly (e.g., esophageal and breast cancer), beginning at the level of the first to second drink per day.

Keeping this fact in mind it seems cardioprotective benefits are relatively less than increasing the risk of cancer.

The term “moderate drinking” is inappropriately used and should be avoided in scientific literature. Public health advocates suggest “nonharmful” or “drinking at low-risk” are more useful terms.

Complete abstinence is easier than perfect moderation.

—St. Augustine

CONCLUSION

Present available literature about the beneficial effects of alcohol is substantial and contradictory, so it is less likely to make a straightforward recommendation regarding the optimal limit of consumption of alcohol. Caution in making general recommendations is needed.

Based on the epidemiological and clinical evidence, as compared to nondrinkers, “moderate alcohol use” should not be interpreted as “healthy alcohol use” (Masters, 2003).

However, it is not suggested to initiate drinking if you do not already because alcohol certainly has well-established neurotoxic, hepatotoxic, and carcinogenic risks. There are safer and healthier ways to protect your heart.

Thus, we encourage people to discuss alcohol use with the physician and make an individualized decision about appropriate consumption.

Vitamin D and Cardiovascular Disease: Indian Perspective

Ramu Adela, Rajesh Khadgawat

INTRODUCTION

Vitamin D

Vitamin D, a secosteroid (steroid with open or broken ring), is fat-soluble vitamin involved in maintenance of calcium metabolism as well as musculoskeletal health. It exists in two forms, ergocalciferol (D₂, from plant origin) and cholecalciferol (D₃, from animal origin). With limited sources in diet except for seafood, main source of vitamin D in humans is synthesis from cholesterol in epidermis by exposure to the UV radiation (sunlight). Exposure to sunlight for sufficient duration bring out chemical change in structure by opening a double bond which further initiates series of structural changes resulting in formation of cholecalciferol (also known as "Calciol"). Once formed, cholecalciferol, an inactive form, undergoes hydroxylation in liver and converted to 25-hydroxycholecalciferol [(25(OH)D) also known as "Calcidiol" or "Calcifediol"] which is further, hydroxylated in kidney to form active form of vitamin D, 1,25-dihydroxycholecalciferol [(1,25(OH)₂D) also known as "Calcidiol"]. Vitamin D receptors (VDRs) are intracellular receptors and found in all tissues of the body, including vascular smooth muscle, endothelium, and myocardium. The active metabolite 1,25(OH)₂D binds with the vitamin D receptor in cytoplasm in the targeted cell and form a heterodimeric complex (VDR-RXR) with retinoid receptor (RXR). Further VDR-RXR complex translocate to the nucleus where it binds with vitamin D responsive element (VDRE) in the DNA and exert its biological function through transcriptional regulation of targeted genes in targeted cells (Fig. 1).¹

ASSESSMENT OF VITAMIN D NUTRITIONAL STATUS

Nutritional status of vitamin D is assessed by measuring serum levels of 25-hydroxyvitamin D. Although measurement of 1,25(OH)₂D, active form is also possible but

measurement is cumbersome and at the same, not useful in providing nutritional status of vitamin D. One of the most debatable issues about vitamin D is cutoff used for defining vitamin D deficiency (VDD). Many societies suggest serum vitamin D levels between 12 and 20 ng/mL to define VDD; however, most widely used cutoff, all over the world is less than 20 ng/mL while levels between 20 and 30 ng/mL are considered as insufficient and levels more than 30 ng/mL is used to define vitamin D sufficiency. Further, levels of VDD (<20 ng/mL) are divided into severe (<5 ng/mL), moderate (5 ≤ 10), and mild VDD (10 ≤ 20 ng/mL).² These cutoffs are based on the physiological fact of occurrence of secondary hyperparathyroidism with decrease in vitamin D levels.

VITAMIN D NUTRITIONAL STATUS IN THE WORLD AND IN INDIA

High prevalence of VDD has been recognized very early at the start in 19th century (1920s) especially in causing rickets, which led to initiation of food fortification programs in most of the developed countries.³ Over the years, vitamin D food fortification has resulted in improvement in vitamin D status of general population. However, errors in fortification (fortification of large amount of vitamin D by mistake) had raised concerns about these fortifications, which resulted in many countries converting universal fortification to optional fortification with vitamin D. Vitamin D food fortification program could not be started with wider success in our country.

In spite of food fortification, high prevalence of VDD has been reported all over the world, across all age groups and both sexes.^{4,5} VDD is considered to be pandemic with report of widespread deficiency coming from every part of the world with maximum prevalence reported from Middle East and South Asian countries in spite of availability of sunlight throughout the year. Prevalence of VDD has been estimated to be approximately 30–60% in the general population.⁶

In spite of geographical location of India (located at 28° 36.8' N and 77° 12.5' E in the northern hemisphere of the

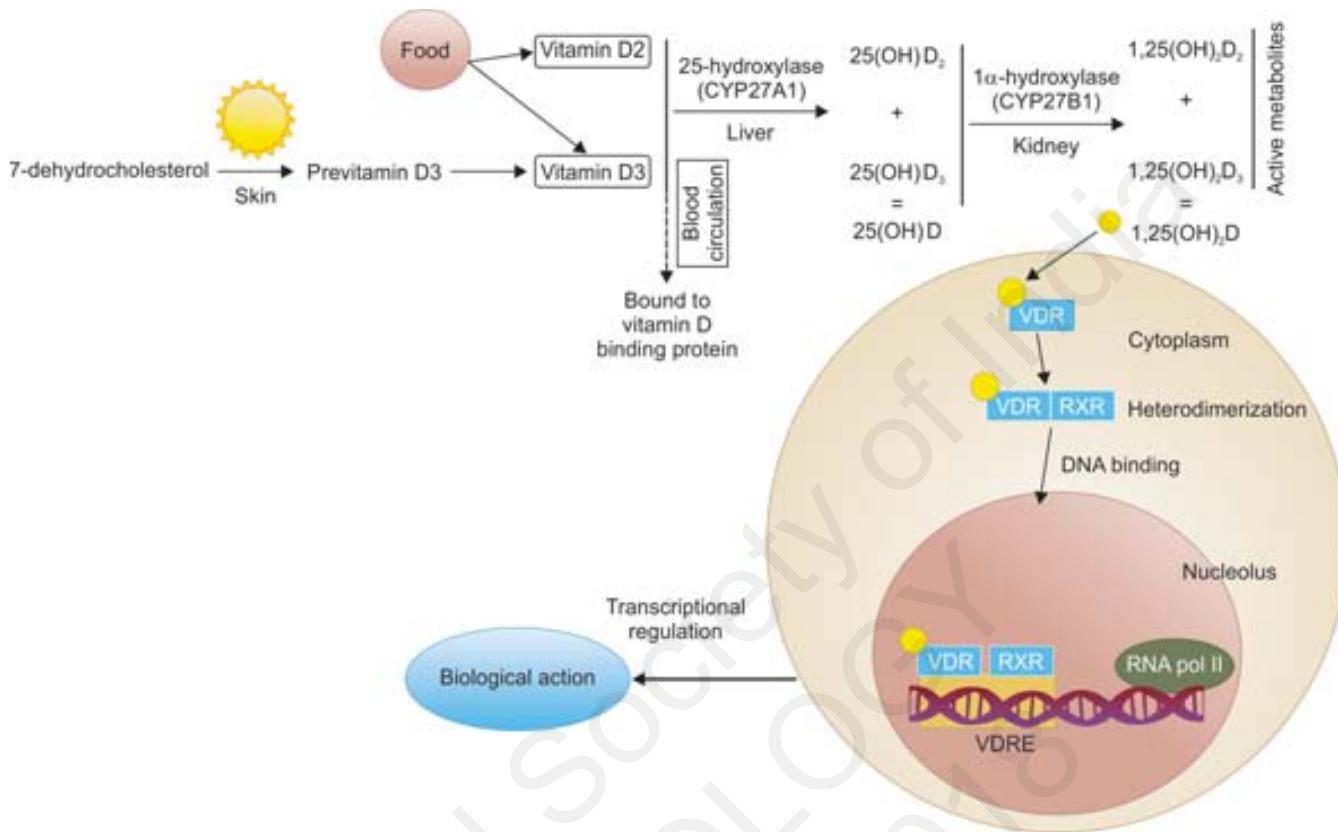

FIG. 1: Vitamin D synthesis, metabolism, and cellular action.

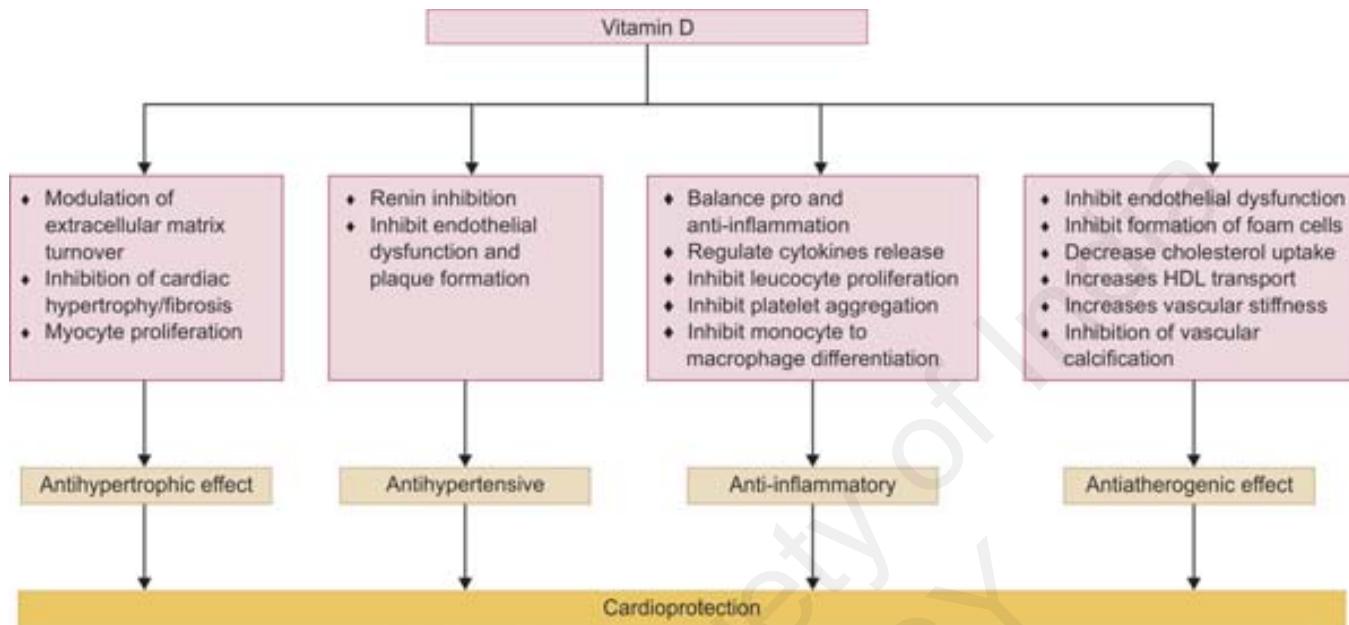

globe) which provides plenty of sunlight throughout the year, VDD was never a concern among Indians. Contrary to this assumption, high prevalence of VDD has been reported throughout the country for all age groups including neonates, infants, school going children, adolescents, adults, pregnancy, lactating women, and senior citizens. This is probably a result of poor sun exposure, dark skin complexion, atmospheric pollution, vegetarian foods habits, absence of food fortification with vitamin D, and poor intake of vitamin D supplements.⁷ The most of the published studies on vitamin D status of general population report that very high prevalence to the extent of 70–95% using a cutoff of less than 20 ng/mL.

VITAMIN D AND NONSKELETAL EFFECTS

One of the major functions of vitamin D is maintenance of musculoskeletal health. However, over the years, association studies of levels of serum vitamin D with many chronic diseases has given a newer concept of role of vitamin D in nonskeletal diseases especially, noncommunicable diseases. Vitamin D has been reported to influence not only insulin sensitivity or resistance but also insulin secretion.⁸ There are several studies, including data from the Framingham Heart Study,⁹ demonstrating an inverse association between insulin resistance and serum 25-hydroxyvitamin D levels.

VITAMIN D AND CARDIOVASCULAR DISEASES

Vitamin D status has also been linked to cardiovascular (CV) risk factors, morbidity, and mortality.¹⁰ VDD state has been shown to be associated with cardiovascular diseases (CVD) risk factors such as obesity, hypertension, hyperlipidemia, and diabetes mellitus. In a random sample of 6,784 subjects in the age group of 30–60 years, high serum levels of vitamin D was reported to be associated with lower incidence of metabolic syndrome and lipid profile favorable to CV health; however, no association between vitamin D level and blood pressure was found.¹¹ In one of the largest study, population-based sample of 16,603 men and women aged 18 years or older (Third National Health and Nutrition Examination Survey, 1988–1994). Subjects with CVD had a greater frequency of 25(OH)D deficiency (<20 ng/mL) than those without VDD. Even after adjustment of all CV risk factors, subjects with VDD had an increased risk of prevalent CVD with odds ratio 1.20.¹² Another large study of 18,225 US men (Health Professionals Follow-Up Study), low vitamin D status was found to be associated with increased risk of myocardial infarction (MI) as compared to subjects with vitamin D sufficiency.¹³ Another data base study of 41,504 subjects, VDD was associated with highly significant ($p <0.0001$) increases in the prevalence of diabetes, hypertension, hyperlipidemia, and peripheral

FLOWCHART 1: Proposed mechanisms for cardioprotection with vitamin D.

vascular disease. Serum vitamin D levels were also found to be significantly associated with coronary artery disease (CAD), MI, heart failure (HF), and stroke. Even in subjects without risk factors but with severe deficiency, also had increased likelihood of developing diabetes, hypertension, and hyperlipidemia.¹⁴ In a recently published meta-analysis of 19 prospective studies with 66,000 participants, a linear and inverse association was found between circulating vitamin D level and risk of CVD.¹⁵ Similarly, VDD has also been reported to be associated with subclinical markers of atherosclerosis like intima-media thickness (IMT), arterial stiffness, and coronary calcification.

MECHANISM OF VITAMIN D AND PROPOSED CARDIOPROTECTION

The exact mechanism of role of vitamin D in proposed cardioprotection has not been elucidated well. The most of the information is coming from individual studies assessing effect of vitamin D on cellular, molecular, and biochemical parameters associated with CVD. Vitamin D has shown to inhibit proliferation of vascular smooth muscle cells and increases calcification of smooth muscle cells.¹⁶ It has also been shown to regulate the growth and proliferation of smooth muscle cells and cardiomyocytes. It has been reported to inhibit renin-angiotensin-aldosterone system (RAAS) and inhibit the endothelial dysfunction, the initiation step of plaque formation.¹⁷ Similarly, vitamin D has also been found to be affecting the immune balance by suppressing proinflammatory and increasing anti-inflammatory cytokines and chemokines and inhibits endothelial dysfunction, leukocyte proliferation, cytokine release, and platelet aggregation the process involved in the atherosclerosis

development.¹⁸⁻²¹ It also shows antiatherogenic function by inhibiting the formation of foam cells, cholesterol uptake by the macrophages, and enabling high-density lipoprotein (HDL) transport.²²

VITAMIN D AND CARDIOVASCULAR DISEASE: EVIDENCES FROM OBSERVATIONAL STUDIES

High prevalence of VDD has been reported from all ages in Indian population all across the country. Details of the Indian observational studies mentioned in table 1. Most of the studies reporting association between vitamin D and CAD had recruited patients admitted in hospital setting for management of CAD. Priya et al. reported high prevalence of VDD (80.4% using cutoff of <20 ng/mL) in North Indian hypertensive subjects in comparison to controls with 67.7%.²³ Another study reported VDD (<30 ng/mL) in 53.3% hypertensive pregnant women while only 3.3% healthy pregnant women without hypertension had VDD. In the same study, lower vitamin D levels were also found to be associated with hypertension disorders in pregnancy and circulatory cytokine and chemokine levels.²⁴ Cross-sectional studies have also reported higher prevalence of VDD in subjects with CAD patients and found to be independent predictor of CAD.²⁵⁻²⁷ Multiple studies have also reported high prevalence VDD in patients admitted with MI patients.²⁸⁻³⁰ Similarly, higher prevalence of VDD has also been reported in patients with ischemic stroke and is independent predictor of ischemic stroke.³¹ Higher prevalence of VDD in patients with dilated cardiomyopathy has been reported and found to be correlated with cardiac function.³²

TABLE 1: Indian studies exploring vitamin D status of subjects with coronary artery disease

Cardiovascular disease; reference	Study type and place	Study population and size	Outcome parameter assessed	Serum 25-hydroxyvitamin D level	Conclusion
Acute myocardial infarction (AMI) ²⁸	Observational study, Delhi	Healthy controls: 120 AMI cases: 120	Compared vitamin D status of AMI cases with healthy controls	Controls: 11.1 ng/mL Cases: 6.0 ng/mL	High prevalence of vitamin D deficiency among cases of acute MI as well as controls
AMI ²⁹	Observational study, Delhi	Control cases: 50 AMI cases: 50	Compared vitamin D status of AMI cases with healthy controls and correlation between FMD and vitamin D	Controls: 25.4 ng/mL AMI cases: 14.5 ng/mL	Majority of AMI cases were vitamin D deficient FMD was positively correlated with vitamin D
AMI ³⁰	Observational study, Bangalore	AMI: 314	Compared vitamin D deficiency among AMI patients	67.5% patients were vitamin D deficient and 16% were insufficient, 83.5% patient had abnormally low vitamin D	Vitamin D deficiency is common in patients with AMI
CAD ²⁶	Observational study, Uttar Pradesh	Control: 101 CAD: 140	Compared vitamin D status in CAD cases with controls	Controls: 28.8 ng/mL CAD: 18.2 ng/mL	Significantly low vitamin D levels observed in CAD Vitamin D deficiency was found to be an independent predictor of CAD
CAD ²⁵	Observational study, Andhra Pradesh	Healthy controls: 50 T2DM: 71 CAD: 28 T2DM + CAD: 38	Compared vitamin D status among study groups	Controls: 38.0 ng/mL T2DM: 32.0 ng/mL CAD: 30.8 ng/mL T2DM + CAD: 20.1 ng/mL	Low vitamin D levels observed in the T2DM, CAD and T2DM + CAD groups, compared to healthy controls
CAD ²⁷	Observational study, Chandigarh	Patients who underwent coronary angiography: 315	Compared vitamin D status of CAD patients with normal coronary artery	Normal coronary artery 11.3 ng/mL CAD: 14.1 ng/mL	Prevalence of vitamin D deficiency is very high in CAD, but it does not correlate with the angiographic severity of CAD
Hypertensive disorders in pregnancy ²⁴	Observational study, Hyderabad	Healthy pregnant: 30 Hypertension disorders in pregnancy: 30	Compared vitamin D status between the two groups	Healthy pregnant: 50.2 ng/mL Hypertension disorders in pregnancy: 28.64 ng/mL	Vitamin D levels decreased in severity of hypertensive disorders in pregnancy
Hypertension ²³	Observational study, Lucknow	Controls: 99 Hypertension cases: 102	Compared vitamin D status between the two groups	Controls: 33.5 ng/mL Hypertension cases: 15.1 ng/mL	Vitamin D deficiency is more prevalent with hypertension
Elderly subjects visiting cardiac checkup camp ⁴⁷	Observational study, Rajasthan	Control: 47 CAD: 53	Correlation between serum vitamin D level and cardiovascular morbidity	Vitamin D deficiency CAD: 28.3%; Controls: 25.53% Vitamin D insufficiency Cases: 49.05%; Controls: 23.40% Vitamin D sufficiency Cases: 22.64%; Controls: 51.04%	Vitamin D deficiency is common in elderly persons
Ischemic stroke ³¹	Observational study, Hyderabad	Controls: 250 Ischemic stroke: 250	Compared vitamin D status between the two groups	Vitamin D deficiency Stroke cases: 48.8%; Controls: 31.6%	Vitamin D deficiency is an independently associated with ischemic stroke
Dilated cardiomyopathy (DCMP) ³²	Observational study, Lucknow	Controls: 60 DCMP: 56	Compared vitamin D status between the two groups	Controls: 28.2 ng/mL DCMP: 14.5 ng/mL	DCMP subjects had lower vitamin D levels than controls

FMD, flow-mediated dilatation; T2DM, type 2 diabetes mellitus; CAD, coronary artery disease; MI, myocardial infarction.

VITAMIN D AND CARDIOVASCULAR DISEASE: EVIDENCES FROM INTERVENTIONAL STUDIES

International Studies

Results of cross-sectional studies of association of vitamin D with CAD have not been verified in interventional studies with vitamin D. In a randomized, double-blind, placebo-controlled clinical trial of 5,108 community-residents aged 50–84 years, oral vitamin D in an initial dose of 200,000 IU, followed a month later by monthly doses of 100,000 IU, or placebo for a median of 3.3 years did not prevent CVD compared with placebo.³³ Another randomized trial, also did not show a reduction of mortality in patients with advanced HF received a daily vitamin D of 4,000 IU compared with placebo.³⁴ Study of 112 patients receiving 3,000 IU cholecalciferol daily for 20 weeks did not result in a significant reduction in blood pressure.³⁵ However, study with female subjects aged over 69 years who received vitamin D3 (800 IU) and calcium (1,200 mg) daily for 8 weeks' supplementation resulted in borderline yet significant decrease in systolic blood pressure ($p = 0.04$).³⁶ Witte et al. conducted a study on 229 chronic heart failure (CHF) and VDD [cholecalciferol (<20 ng/mL)]. Participants were allocated to 1-year of vitamin D supplementation (4,000 IU/daily) or placebo. The study showed improvement in cardiac function like LV ejection fraction and reversal of LV remodeling like LV end-diastolic diameter and LV end-systolic diameter.³⁷ Dalbeni et al. conducted a randomized double-blind placebo-controlled study on CHF patients, high-dose 800,000 IU (4,000 IU/daily) of cholecalciferol for 6 months. The study revealed that 25(OH)D levels and ejection fraction were increased and systolic blood pressure decreased after 6 months treatment.³⁸ Similarly, another research group reported that vitamin D supplementation (100,000 IU) in subjects with baseline vitamin D insufficiency did not improve CVD risk factors profile.³⁹ Tomson et al. reported data of vitamin D supplementation in BEST-D (Biochemical Efficacy and Safety Trial of vitamin D) double-blind randomized placebo-controlled trial (4,000 IU/day for 12 months) did not show any improvement on blood pressure, arterial stiffness, and cardiac function.⁴⁰ Another recently conducted single-center, double-blind, randomized, placebo-controlled study with vitamin D dosage of 2,800 IU per day did not show any favorable effect on lipid metabolism.⁴¹ Chowdhury et al. conducted a meta-analysis with observational and interventional studies and concluded that in observational studies, serum 25(OH)D level was negatively associated with death due to CVD, cancer, and other causes; however, supplementation studies did not support role of vitamin D supplementation in improving clinical outcomes.⁴² Recently, published systematic review with meta-analysis by using placebo-controlled randomized trials of at least 4 weeks of vitamin D supplementation, did not show any significant effect of vitamin D supplementation on CV function, i.e., flow-mediated dilatation (FMD), carotid-femoral pulse wave velocity.⁴³ Although, it would be difficult to compare results

of these studies because of many limitations like lack of randomization, placebo-controlled design, use of hospital admitted population, small sample size, shorter duration of intervention, and absence of VDD in study subjects at baseline, but still most of the studies have not reported any significant positive impact on outcome parameters. Multiple meta-analyses published assessing effects of vitamin D supplementation in various CADs, suggest no beneficial role of vitamin D supplementation in established CAD. However, pooling of results of all intervention studies would be not very logistic as design, duration, and dose of supplementation of vitamin D is highly heterogeneous.

INDIAN STUDIES

The most of the studies published from India are of observational design with only three interventional studies have been conducted so far. Details of these studies are given in table 2.

Abid et al.⁴⁴ randomized 72 subjects with HF (NYHA class II or more) with vitamin D level less than 30 ng/mL into two groups, group I, subjects received cholecalciferol 60,000 IU weekly for 12 weeks while in group II, subjects received optimized medical therapy but not vitamin D. Although, there was a significant improvement in echocardiographic parameters, but the extent of change from baseline did not differ significantly between the two groups.

Narasimhan et al.⁴⁵ in an open label randomized controlled design, supplemented a single dose of 600,000 IU of cholecalciferol intramuscular injection in patients with ischemic stroke, and compared with patients who did not receive vitamin D. Using Scandinavian Stroke Scale (SSS) as outcome parameter, it was found that vitamin D supplemented group had significantly higher SSS than patient who did not receive. Even in supplemented group, higher scores were seen in subjects who had VDD at the time of screening in comparison to subjects who did not have. The sample size was small (30 in each group) and not double blind design but requires further exploration of results in larger studies.

Another recently published randomized, double-blind, placebo-controlled study,⁴⁶ effect of cholecalciferol supplementation on vascular function was assessed in 120 patients aged 18–70 years, with nondiabetic chronic kidney disease (CKD) stage 3–4 and VDD (≤ 20 ng/mL).

Intervention group received two oral doses of cholecalciferol (300,000 IU) at baseline and 8 weeks, compared with matching placebo. In comparison to placebo group, cholecalciferol supplementation significantly increased endothelium-dependent brachial artery flow-mediated dilation at 16 weeks. Intervention also led to significant favorable changes in pulse wave velocity and circulating interleukin (IL)-6 levels.

However, another interventional study, i.e., Indian Polypill study [The International Polycap Study 3 (TIPS-3)] which was initiated to study vitamin D supplementation effect on reducing major adverse CV events (ClinicalTrials.gov Identifier NCT01646437), is still ongoing.

SECTION 1

Coronary Artery Disease Risk Factors

TABLE 2: Indian studies assessing effect of vitamin D supplementation on cardiovascular outcomes

Cardiovascular disease, reference	Study type	Dose of vitamin D supplementation and frequency dosage	Duration of supplementation	Outcome parameters of intervention	Diseases groups and no. of subjects	Serum vitamin D levels before and after supplementation	Conclusion
Heart failure ⁴⁴	Nonrandomized	60,000 IU/ week	3 months	Association between vitamin D levels and echocardiographic parameters	Group 1: n = 38, vitamin D supplemented Group 2: n = 36, no supplementation	Before: Group 1: 18.14 ± 6.07 ng/mL Group 2: 20.48 ± 5.86 ng/mL After: Group 1: 34.7 ng/mL Group 2: 20.5 ng/mL	No improvement in left ventricular function, serum vitamin D levels increased following supplementation
Ischemic stroke ⁴⁵	Nonblinded and randomized, placebo	Single dose 600,000 IU	3 months	Stroke outcome	Group 1: n = 30, supplemented with vitamin D Group 2: n = 30 patients received placebo	Baseline: Group A: 17.98 ± 3.81 ng/mL Group B: 18.44 ± 4.69 ng/mL vitamin D levels were not measured after intervention	Improvement in the stroke outcome and EF and decreased systolic blood pressure
Cardiovascular risk in CKD ⁴⁶	Randomized, double-blind, placebo-controlled trial	300,000 IU at baseline and 8 th weeks	16 weeks	Cardiovascular risks	Group 1: Placebo: 59 Group 2: Vitamin D: 58	Before: Group 1: 13.21 ng mL Group 2: 13.4 ng/mL After: Group 1: No change Group 2: 23.4 ng/mL	Increased endothelium-dependent brachial artery flow-mediated dilation and favorable changes in pulse wave velocity and circulating IL-6 levels

CKD, chronic kidney disease; IL-6, interleukin-6; EF, ejection fraction.

CONCLUSION

Based on the observation studies, association between VDD and CVD has been well reported. However, studies of supplementation of vitamin D did not show improvement in any of the clinical outcomes studied so far.

Hormone Replacement Therapy and Cardiovascular Diseases

Geetha Subramanian, Aviraj Choudhary, Kamaldeep Bansal

INTRODUCTION

Cardiovascular disease (CVD) is one of the leading causes of death in women globally. In industrialized countries like UK, Northern Europe, and North America coronary heart disease (CHD) is the most common cause of death in women, whereas stroke is more common in Southern Europe. As cardiac events are very uncommon in premenopausal females which in itself shed the light over the protective influence of ovarian sex hormones inherent to menstruation cycle. After menopause however this protective influence begins to decrease and the risk for CVD tend to increase gradually equating itself to the male risk in eightths decade of life.^{1,2} The estrogen deficiency that ensues after menopause is considered the main culprit in increasing the risk of CVD. Estrogen deficiency exerts its metabolic, hemodynamic, and vascular effects which influence the cardiac risk factors directly or indirectly. In some observational studies it has been shown that the hormone replacement therapy (HRT) in postmenopausal women had a lower rate of CVD and cardiac death than those not receiving HRT. However, randomized studies, Heart and Estrogen/progestin Replacement Study (HERS) and Women's Health Initiative (WHI) showed that HRT may actually increase the risk and events of CVD in postmenopausal women.

MENOPAUSE-INDUCED CHANGES IN CARDIOVASCULAR FUNCTIONS

Adverse changes in lipids and lipoproteins and in glucose and insulin metabolism accompany the onset of the menopause^{3,4} encouraging the development of atheroma. There is also negative impact on vascular function, which results from the loss of ovarian hormones. As the female sex hormone concentration declines, there is a significant increase in the level of total cholesterol, low-density lipoprotein (LDL) cholesterol, and triglycerides whereas the high-density lipoprotein (HDL) cholesterol shows a declining trend. Indirect effects are also seen in alterations of blood pressure, obesity,

body fat distribution, clotting factors, and glucose metabolism which are all independent risk factors for CVD as well. In 1976, the Framingham investigators reported a 2.6-fold higher incidence of cardiovascular events in age-matched postmenopausal women compared with premenopausal women.⁵ Surgical menopause was associated with 2.7-fold higher risk of CHD compared with premenopausal women of the same age, and women with a natural menopause had 2.2-fold higher risk of CHD compared with premenopausal women of the same age.⁵ Estrogen-deficient state in postmenopausal women can account for changes in the cardiovascular function.

Menopause shifts the overall balance toward atherogenic lipids and lipoprotein profiles. Lipoprotein(a) has been shown to have significantly increased in postmenopausal patients which is an important marker of cardiac risk.^{6,7} Elevated levels of lipoprotein(a) has been associated with premature atherosclerosis, stroke, and myocardial infarction in various case control studies.⁸⁻¹⁰ Further the role of coagulation factors, anticoagulation substances, and a balance between fibrinolytic and antifibrinolytic elements of the blood play a major role in development of atherosclerotic plaque. Elevated levels of fibrinogen and factor VII in postmenopausal than in premenopausal women of the same age has been shown in various population-based studies.¹¹⁻¹³ Also increased incidences of thromboembolic phenomenon¹⁴ and CHD¹⁵ have been found in congenital deficiencies of the coagulation inhibitors antithrombin III, protein C, and protein S. Increased plasma concentrations of plasminogen activator inhibitor-1 (PAI-1) and tissue plasminogen activator (tPA) antigen ultimately causes a reduced function of fibrinolytic system and increases the chances of CHD (Box 1).^{16,17}

EFFECTS OF HORMONE REPLACEMENT THERAPY ON CORONARY HEART DISEASE RISK

The administration of HRT induces variable amount of significant metabolic changes in women's body. The actual effect of administered therapy depends upon a number of factors like type of steroid used, dose of steroid, mode of administration, duration of therapy, and most importantly patients response is also individual. Estrogen substantially lowers the LDL cholesterol in turn lowering the total cholesterol and this effect is more evident by oral route of administration rather than transdermal route.¹⁸ Other protective roles (Box 2) of estrogen include increasing the levels of HDL cholesterol particularly the HDL2 subfraction. Similarly, it also lowers the levels of lipoprotein(a) an important cardiovascular risk marker. The most notorious particles causing atherosclerosis are the small and dense LDL particles because of their capacity to get retained in the arterial wall leading to production of foam cells and generating atheromatous plaques. Oral HRT increases the overall clearance of small LDL particles from the circulation and is thus protective against CVD.¹⁹ These benefits are however not observed with transdermal route of HRT.²⁰ Endogenous triglycerides are another important CVD risk parameter which is also influenced by the dose, route, and duration of HRT. Thus, transdermal estrogen decline triglyceride levels but oral estrogens increase their level because of first-pass metabolism.^{18,21}

Addition of progestogens to HRT does not lower LDL. By increasing hepatic lipase activity androgenic progestogens such as norgestrel, attenuate the HDL-raising effect of estrogen.²¹ While certain nonandrogenic progestogens, such as dydrogesterone, do not attenuate estrogen-induced increases in HDL²² others, such as medroxyprogesterone acetate (MPA), have negative impact on estrogen-induced increases in HDL. Levonorgestrel being an androgenic progestogen decreases triglyceride levels by reducing the secretion of very LDL. Increase in triglycerides induced by oral estrogens is not prevented by addition of C21 progestogens. Thus, dual estrogen/progestogen HRT can increase HDL and triglycerides, or it can decrease triglycerides, but at the same time causes a decrease, or no increase, in HDL. Which change in lipid profile is more important in terms of CHD benefit remains unknown. In certain situations, it has been postulated that the some HRT regimens can benefit more than others.

BOX 2 Important cardiovascular benefits of estrogens

- Reduces atherosclerosis
 - Increases HDL cholesterol
 - Lowers LDL cholesterol
 - Prevents platelet aggregation
 - Promotes coronary artery vasodilatation
 - Decreases lipoprotein(a) and inhibits LDL cholesterol oxidation
- HDL, high-density lipoprotein; LDL, low-density lipoprotein.

Estrogen affects the metabolism and levels of insulin as well. The dynamics of glucose and insulin concentrations in postmenopausal women changes, usually improving insulin resistance after oral administration of 17-estradiol whereas, estradiol when given transdermally does not exert much effects.²³ In contrast, raised insulin levels and impair glucose tolerance have been linked with alkylated estrogens such as ethinylestradiol, and conjugated equine estrogens (CEE).²⁴ Addition of progesterone to HRT regime affects insulin metabolism as androgenic progestones produce more insulin resistance whereas nonandrogenic progestones does not have much effects. Oral estrogen reduces certain prothrombotic clotting factors like fibrinogen and factor VII, and also reduces the antifibrinolytic factor PAI-1, still producing increase in thrombogenesis.²⁵ A continuous combined transdermal HRT resulted in a significant decrease in factor VIIc, and an increase in fibrinolytic activity. Estradiol also exerts beneficial effects in terms of CVD by maintaining endothelial function and reducing angiotensin converting enzyme activity which has been reported with both oral and transdermal HRT.²⁶

CLINICAL STUDIES OF HORMONE REPLACEMENT THERAPY AND CORONARY HEART DISEASE

Observational studies done worldwide have consistently shown that HRT is associated with a reduced incidence of CHD and total mortality in postmenopausal women. Five randomized controlled trials (RCTs) which have used total mortality and morbidity as end point was conducted (Box 3). Out of five, three were secondary prevention trials²⁷⁻²⁹ and two were primary prevention.³⁰⁻³² RCTs conducted on HRT failed to show any beneficial effect on CHD and mortality in postmenopausal women. In contrary to RCT, observational studies have shown a 30–50% reduction in CHD and total mortality when analyzed among all women regardless of age. This difference between observational studies and RCTs is best exemplified within the WHI that evaluated HRT in both an observational cohort and in RCTs. The WHI observational study arm conducted in 53,054 women showed a 50% reduction in CHD in women who used estrogen + progestin (E+P) in contrast with women who do not. Whereas in RCT arm, the risk of CHD was increased 18% in women on combined CEE 0.625 mg + MPA 2.5 mg relative to

- WHI-E (Women's Health Initiative Estrogen Trial)

HRT, hormone replacement therapy.

placebo in the Women's Health Initiative estrogen-progestin (WHI-EP) trial.³⁰ This difference in clinical outcomes between observational studies and RCTs is mostly because of the different characteristics of the cohorts. In observational studies, women who used HRT were relatively young (30–60 years old), had recent menopause, were thin [approximate body mass index (BMI) of 25 kg/m²] and were having typical menopausal symptoms for which HRT initiated. HRT in these patients was continued for longer periods (10–40 years). On the other hand, in RCTs women who used HRT were much older (>90% of women older than 55 years) and on average more than 10 years beyond menopause (average 13–23 years). Patients having predominant menopausal symptoms were excluded from RCT arm. Mean duration of HRT (1–6.8 years) in RCT arm was also considerably less than that of the HRT users in observational studies. Also, women in RCT arm were overweight (approximate BMI of 29 kg/m²). It has been shown that the characteristics of women in RCTs were markedly different from those studied in observational studies. Thus, accounting for the discordance of the HRT effects on CHD and mortality from observational studies compared to RCTs among women regardless of age.

Although, in RCTs the effect of HRT on CHD over all ages is null, these trials also showed that there are beneficial effects of HRT on CHD according to the timing of initiation of HRT relative to age and menopause.³³ The largest RCT WHI had shown that compared to placebo, women who were randomized to CEE + MPA within 10 years of menopause had a 12% decrease in CHD events whereas women between 10 and 20 years after menopause had a 23% increased risk of CHD and women more than 20 years after menopause had a 66% increased risk of CHD ($p = 0.05$).³⁴ In WHI trial, only one-third were less than 60 years old and less than 5% were within a few years of menopause, representing the subgroup of women found in observational studies who had reduction in CHD with HRT. Whereas, older women (>60 years old) who were given HRT many years after menopause (>10 years) thus not representing the women in observational studies had increased risk of CHD with HRT. The standard dose of estrogen used for relief of vasomotor symptoms in women aged around 50 years may be inappropriately high for women some 15–20 years older.²⁷ The enormous data available after meta-analysis of RCTs emphasize that young postmenopausal women who started HRT in close proximity to menopause have reduced CHD and total mortality. These results are also in accordance with the results seen in observational studies where almost all the women started HRT in close proximity to menopause, typically within 6 years. Large RCTs (HERS and WHI-EP), observational studies, arterial imaging studies, and case-control studies consistently showed reduction in CHD risk with prolonged HRT use (>6 years).

Majority of adverse outcomes associated with HRT as shown in WHI and other RCTs are rare (<1 event per 1,000 treated women).³⁵ Younger women who started on HRT had lower adverse outcome as compared to older women who started on HRT later. Adverse effects like stroke

and venous thromboembolism are rare and having incidence similar to commonly prescribed drugs. In WHI, the breast cancer risk differ with CEE alone associated with a reduction in breast cancer risk³⁶ and combined CEE + MPA associated with an increased risk,³⁷ the magnitude of risk seen with statin therapy is comparable to that of CEE + MPA therapy.³⁵

CONCLUSION

The combined data from various RCTs and observational studies indicate that the effect of postmenopausal HRT on CHD and total mortality is influenced by the timing of initiation (age and time since menopause) and the duration of therapy (>6 years of use). The adverse events associated with HRT are rare (<1 additional event per 1,000 women) and even rarer in younger age women (<60 years or within 5 years of menopause). The adverse risk with estrogen alone is quite rare. In women with confirmed CHD, HRT should not be initiated for preventing future cardiovascular events. Women who are already taking HRT for noncardiac conditions, if develops CVD, can continue to take it if they are stable. If HRT is to be given for the sole purpose of preventing future cardiovascular events in postmenopausal women who do not have pre-existing CHD post should be considered only after a careful risk assessment. At present, the indications for HRT use are relief of menopausal symptoms, maintenance of quality of life and prevention of osteoporosis. Prevention of CHD has never been a licensed indication. It is, however, clearly possible to use appropriate HRT regimens safely in women at increased risk of CHD or with established disease. Patient preference as well as noncardiovascular risks and benefits should guide any decision regarding such therapy. In the final analysis, the difference in CHD and total mortality outcomes between observational studies and RCTs is reflected by the differences in the study design and the characteristics of the populations studied. In fact, data from RCTs and more than 40 consistent observational studies indicate that the young postmenopausal women with menopausal symptoms who use HRT for long periods of time have lower rates of CHD and total mortality than comparable postmenopausal women who do not use HRT.

SECTION 2

Lipids and Diet

Cholesterol and Coronary Artery Disease Controversy

Rajiv Bajaj

INTRODUCTION

Our understanding of diseases of civilization and modern lifestyle have undergone a sea change over the last 50 years. Cholesterol has become synonymous with heart attacks. There is widespread anxiety about good and bad cholesterol. Cholesterol dictates current food preferences.

CHOLESTEROL AND CORONARY ARTERY DISEASE CONTROVERSY

Diseases of Civilization and Modern Lifestyle

Over the last 50 years, cholesterol has become synonymous with heart attacks. There is widespread anxiety about good and bad cholesterol. Cholesterol dictates current food preferences. Alcohol is often recommended for raising high-density lipoprotein (HDL) cholesterol. Butter and eggs are feared. Before the war, glucose was blamed for diabetes, obesity, atherosclerosis, cancer, and all other diseases of modern lifestyle.¹ These diseases were called saccharine diseases.² The original connotation of modern lifestyle was adopting agriculture, living on crops rich in glucose, being prone to glucose diseases.

Medical journals, textbooks, and conferences emphasize cholesterol, but some landmark research work and a few popular books oppose this view. Clearly, both sides cannot be entirely right or wrong. When we weigh the evidence for and against cholesterol, and look at its chemistry, we can discern its role, and the cause of confusion.

Cholesterol Hypothesis

Cholesterol has been implicated in pathogenesis of atherosclerosis because of rabbit experiments, cholesterol in atheroma, premature coronary artery disease (CAD) in familial hypercholesterolemia (FH), population studies of blood lipids, efficacy of statins or PCSK9 inhibitors; and diet

studies like Oslo Diet-Heart Study and Lifestyle Heart Study (Dean Ornish).

Rabbits are herbivores, and plants do not contain cholesterol. Unlike rabbits, omnivores tolerate high-cholesterol diets. Their natural diet contains animal products, and excess cholesterol can be excreted in bile.

Cholesterol is suspected because of its presence in atherosomas. Low-density lipoprotein (LDL) reaches wherever there is tissue damage and cell multiplication. Serum cholesterol levels therefore fall after infarction, stroke, fracture, sepsis, burns, and cancers. Low-grade vascular injury and inflammation attracts circulating LDL to vessel walls, their association is akin to that of wounds and bandages.

Familial hypercholesterolemia predisposes to atherosclerosis. There are fewer hepatic LDL receptors in FH, and the catabolism of LDL is slow. When Framingham statisticians found no relation between circulating cholesterol level and infarctions in their population, younger men were divided into cholesterol quartiles after excluding older men and all women. The highest quartile was a distillate of premature infarctions due to FH. This is the epidemiological evidence that implicates cholesterol.

Circulating lipids levels correlate with atherosclerotic risk because LDL and HDL levels change with diet. These changes are largely caused by dietary carbohydrates, as these are converted into triglycerides, VLDL, and then small dense LDL by body. Diets rich in unsaturated fatty acids do shift cholesterol from blood stream to cell membranes, but this is related to cholesterol's role in structural strength, not to atherosclerosis.

PURE and Other Contradictory Studies

Two recent studies have raised concerns about low-fat, low-cholesterol diet (LFLC) for preventing heart disease, and reopened an old controversy that was never fully resolved. PURE, a large prospective cohort study³ identified a strong positive correlation between carbohydrate content of diet

and hard end points. PREDIMED, both initial and recent revised versions, too showed that adding nuts and olive oil is better than a LFLC diet. Initial diet trials had repeatedly raised similar concerns. In anticoronary club trial, and Minnesota Coronary Survey,⁴ mortality was higher with LFLC diet. These results had even precipitated a change in design of subsequent diet studies of 1970s. Multiple risk factor intervention trial (MRFIT), WHO factories study, and many others, therefore employed multiple preventive measures simultaneously. Thus the treatment arm stopped smoking, controlled blood pressure with antihypertensive drugs, exercised, and adopted LFLC diet. Despite a design that maximally favored the LFLC diet, these trials too, were negative. Curiously, lessons from the preceding diet trials began to hit their authors' blind spots. MRFIT blamed antihypertensive drugs for killing the LCFC diet group, and WHO factories study opined that stopping smoking is lethal! Later, the randomized Harvard's nurses' health study reported that increasing fruits, vegetables, olive oil, whole grains, and decreasing red meats, butter, sugar, etc. did not protect the heart. Currently, these randomized controlled trials are discounted, and fruits and vegetables are vigorously promoted based on statistical association found in inter heart case-control survey.

The studies that implicate dietary cholesterol are fewer. Oslo is a small *post-hoc* subanalysis of a negative trial, Ornish's even smaller trial could not be reproduced in subsequent studies, Lyon's heart study⁵ a single center publication claimed 80% reduction in events with Mediterranean diet. Like its daughter, Indo-Mediterranean study, it crumbled under scrutiny. The celebrated diet was regular food cooked in canola margarine, and India's mustard oil version lost all its raw data to termites.

Nevertheless, there is a definite association between cholesterol and atherosclerosis, and biochemistry clarifies its role.

FUNCTIONS OF CHOLESTEROL

All nucleated animal cells synthesize cholesterol. In addition, dietary cholesterol is absorbed, and delivered to liver. Eating cholesterol does not affect blood levels in humans, since synthesis and excretion are regulated. Requirements increase in illnesses and during cell multiplication.

Animals have cholesterol for the same reason that plants have cellulose. Cholesterol stabilizes cell membranes, provides structural strength, and regulates membrane permeability.

Circulating lipoproteins have immune functions. They adsorb, internalize and isolate circulating bacterial endotoxins and all other injurious fat soluble debris, and deliver these to liver for catabolism. Liver secretes fresh, buoyant, cholesterol-rich LDL, and removes old, toxin-laden small dense LDL (sdLDL). LDL is not a blood pollutant, it is body's blood and tissue cleansing device.

Soluble Nutrients and Very-low-density Lipoprotein Synthesis

After digestion, water-soluble nutrients like amino acids go via portal vein to the liver; insoluble nutrients like

triglycerides and cholesterol form chylomicrons, and directly enter general circulation.

The foremost health difference between modern and primitive diets is in their glucose content. Modern crops like sugarcane, grains, and tubers contain mostly glucose. Blood levels of glucose and amino acids are tightly regulated. Excess amounts, and all miscellaneous soluble nutrients like pentose, organic acids, alcohols, etc. are mostly converted to triglycerides, enter circulation as very low density lipoproteins (VLDL). Although conversion of dietary glucose to triglycerides prevents hyperglycemia, VLDL does not adsorb endotoxins efficiently. VLDL is LDL that has been reassigned to transport of soluble calories from intestine to liver to adipose cells. VLDL becomes sdLDL. LDL is not homogenous; assorted particles are collectively measured as LDL. Fresh LDL from liver is healthy, VLDL remnants, and aged-LDL require elimination by liver.

Thus, the body sends fats directly into blood stream as chylomicrons, and converts all soluble nutrients including milk and fruit to triglycerides before permitting them to enter the circulation.

Lipoproteins

Triglycerides of food reaches tissues in chylomicrons (apolipoprotein B48). Depleted chylomicrons (remnants) containing dietary cholesterol, fat soluble vitamins, etc. are internalized by hepatocytes. Fasting chylomicronemia occurs when peripheral lipase activity is diminished (e.g., obese, alcoholic diabetics), and produces severe hypertriglyceridemia. High levels of circulating remnants promote atherosclerosis. This happens in rabbit experiments, and rarely in humans (broad beta disease). Genetic chylomicron clearance disorders are aggravated by high-fat diets.

Very-low-density lipoprotein and LDL (apolipoprotein B100) are synthesized in liver. On a natural "forest" diet, the triglycerides come from food (animal fat), and glucose is manufactured in liver. Synthesis of triglycerides in liver is meagre. Blood level of VLDL and sdLDL is low. Liver secretes cholesterol-rich large LDL.

Modern livers are kept busy synthesizing triglycerides from glucose, secreting VLDL and removing VLDL remnants. This predisposes to fatty liver, and elevates blood VLDL and sdLDL.

Apolipoprotein A is secreted by intestine and liver. It interacts with circulating lipoproteins and tissues, adsorbs lipids, and delivers them to LDL and to liver. It is a mop for toxins and a mobile service station for plasma lipoproteins. Its levels therefore vary inversely with VLDL levels.

Theories of Atherosclerosis

According to cholesterol theory synthesis of LDL by liver is excessive, and this is due to fat or cholesterol in diet. High levels of LDL clog the arteries. This theory ignores the role of glucose in VLDL synthesis, the formation of sdLDL from VLDL, and does not explain the absence of atherosclerosis in primitive tribes, (targets for primordial prevention), presence in ancient Egyptians; equivocal mortality benefits of second line antilipid drugs and exercise.

Endothelial injury by hypertension, cigarette smoke, uremic toxins, hyperhomocysteinemia, pollutants, etc. leads to local inflammatory response. Glucose too, causes endothelial injury. It is a reactive aldehyde. It glycosylates numerous proteins like hemoglobin, endothelial adhesion protein, etc. Injury leads to inflammation and healing. Arteries, like other tissues, have stereotyped response to diverse injuries. Chronic low-grade endothelial injury leads to atherosclerosis.

Ancient Egyptians were wheat and barley farmers, they had adopted the modern, glucose-rich diet. Neel and many others have shown that glucose-naïve populations are very susceptible to glucose injury. (Neel conclusively disproved his own "thrifty gene" hypothesis).

Statins deplete hepatic cholesterol. This increases hepatic LDL receptors, and sdLDL uptake. Thus, statins and PCSK9 inhibitors help by removing toxic sdLDL. Low hepatocyte cholesterol marginally depresses VLDL synthesis, and therefore raises blood sugar. Removal of old, spent, toxin-laden small dense LDL is helpful, removal of fresh buoyant LDL cannot be. Fanciful and illogical extrapolations of "LDL targets" are advocated for "eradicating atherosclerosis" despite evidence that aggressive LDL lowering increases nonvascular adverse events.

Advantages and Disadvantages of Glucose

Glucose is the explosive, emergency fuel for phagocytosis, sprinting, and anoxic tissues. Natural diet has very little glucose, the liver synthesizes it. Blood levels are 50–80 mg, rising moderately in fever, injury, and other emergencies.

Carbohydrates increase serum insulin and somatomedins, they are growth factors. Lactose produces rapid growth in breast-fed infants. Human body size is diminutive without cooking (pygmies), small with cooked natural diet, gigantic in glucose fed modern humans as it is in farmed animals.

When rice and flour entered India, physicians documented that they cause diabetes (*madhumai*).¹ Carbohydrate reduction was standard treatment for thousands of years. Current advice is riddled with contradictions. Fats are curtailed, forcing diabetics to take a high-glucose diet. Whole grains are recommended for lowering glycemic index, though they cannot match the spectacularly low glycemic index of fats. Voglibose and sodium-glucose cotransporter-2 (SGLT2) inhibitors are prescribed for blocking absorption of glucose by intestines and kidneys, though fat is the one that is feared.

Rapid weight loss occurs in type 1 diabetes because low blood insulin promotes catabolism of body fat. Conversely, hyperinsulinemia promotes fat synthesis. Carbohydrate restriction is therefore effective in obesity, calorie counting is not.

Cancer cells have damaged genes. They lack the complex organization essential for oxidative phosphorylation, are prone to cell death. On a high-glucose diet, they survive by anaerobic glycolysis and cause cancer. *In vitro* cancer cell lines require glucose and insulin, and glucose PET (positron emission tomography) scanning locates various cancers.

A simple rule has long existed, if diabetes predisposes to any condition, its cause is probably dietary glucose. Glycosylation of lens causes cataracts; joint cartilage, osteoarthritis; advanced glycated-end products, dementia.

The long list of modern diseases needs further additions like glaucoma, hypothyroidism. Diabetic mothers get eclampsia, dystocia, cesarean sections; their babies macrosomia, growth retardation, congenital defects. Even many cardiac arrhythmias may be due to altered autonomic function. Do autoimmune diseases, allergies, and many infectious diseases result from abnormal immune responses to innocuous environmental chemicals and microbes?

Lipid Profile

Absolute risk estimation is needed for calculating sensitivity, specificity and receiver operator curves. Lipidology emphasizes relative risk. Sensitivity, specificity, etc. are never calculated. The various risk calculators combine all risk factors like age, diabetes, tobacco apart from lipids, to separate 20% 10 year risk from 10%. Even this modest achievement is suspect.

There are equally significant inverse relationships between serum cholesterol and neuropsychiatric problems, cancers, and even lifespan.

Remnant chylomicrons (B48), fresh LDL from liver, spent LDL, and VLDL, are all measured together as LDL. Atherogenic spent particles are lumped together with healthful fresh LDL.

Low-density lipoprotein is emphasized; triglycerides are discounted, though LDL changes are downstream effects of triglyceride synthesis in liver. High triglycerides and low HDL are the commonest findings in diabetes and infarctions ("atherogenic dyslipidemia"). The obvious triglyceride/HDL ratio, which is automatically the most robust, is ignored.

EARLY RESEARCH ON CHOLESTEROL

The cholesterol saga started immediately after England won World War-2 and "dissolved" the Empire.⁶ Diagnosis of myocardial infarctions had increased with availability of electrocardiogram (ECG). In USA, this was projected as an epidemic of heart disease. Government announced grand investment in research for rapid action against "the number one killer", as "its cause was unknown". A Harvard doctor prepared a list of all known and suspected associations like diabetes, smoking, etc., and an observational study began in Framingham. Decades were consumed in prospectively obtaining "p" values for already listed associations. This was then projected as extensive research, which lamentably, "failed to find the cause, but identified risk factors". The weak association between cholesterol and infarctions appeared very late, and only by excluding all women, and most men from analysis. This toehold triggered relentless campaigning on dangers of cholesterol. Diabetes had the strongest association, but it was discounted for another decade. These decades of cholesterol education gradually

obscured the common knowledge that dietary glucose causes diabetes.

The original promises of world class research under the guidance of leading authorities and reputed medical bodies were renegaded. Start-ups like American Heart Association were handed over reins and finance to dominate. At Framingham, a group of statisticians worked under a single, unknown, and disillusioned internist for 6 years. Kannel, a young war veteran next became the sole medical expert of the haloed Framingham Study. He is hailed as "father of prevention"! The treatment research limb of the government's war against heart disease was shifted to Bethesda, over 400 miles away. It kept busy conducting lengthy trials of cholesterol. Their negative results were vigorously massaged to obtain some favorable p values. Those negative studies are still quoted as evidence in favor of cholesterol hypothesis.

Even as Framingham and National Institute of Health (NIH) began their slow charade, an army strongman started marketing dietary cholesterol as the cause of heart disease. Ancel Keys had no background of research or heart diseases, but he was an old friend of the government, he had helped to slash costs of feeding US soldiers by developing and summarily approving the infamous K ration. He imposed cholesterol as the cause of heart problems, concealing or trashing all research that suggested the opposite, and showcasing his six and seven countries Studies. Both were fudged and silly. After his retirement his juniors exposed his duplicity by publishing his large randomized trial that showed the opposite of what he preached, a trial he had deliberately buried.⁴ Immediately, almost on cue, Ornish, a Californian nonentity with unreliable data, became the messiah of preventing heart disease by reducing fat in diet. In Europe, a single obscure author claimed stupendous benefits of "Mediterranean Diet", spawning the humbug of "Indo-Mediterranean Diet".

Cholesterol lobby promotes weak statistical associations a causal, projects unreliable studies, but buries strong studies, biochemistry and physiology. Till recently, Inter Heart emphasized that over 90% of the risk is "accounted for" by conventional risk factors, and asserted that these, therefore, cause atherosclerosis. PURE study implicates carbohydrates. By analogy, if studies are conducted of why cars breakdown, we may discover many risk factors like number of dents, presence of carburetor, absence of GPS, tampered mileometer, age and financial status of owner, etc. and these may identify 95% of all cars that stop. Old cars tend to breakdown after running hundred thousand miles. To "discover" this we require analysis of car mileage; not complex statistics.

DIET AND HEALTH

To understand food, we must focus on nutrients that enter the body after digestion and absorption. Speed of assimilation matters less; physical appearances, antioxidants, etc. are mostly irrelevant. Biochemically, logical guidance about food has been replaced by charts that curtail fat and cholesterol, optimize blood lipids, and glorify obscure trace substances.

Confusion abounds: (1) Indigestible items (fiber) have been declared healthy. (2) Almonds, honey, bottle gourds, pomegranates, etc. are ascribed mystical health effects. (3) Jargons like "junk foods", empty calories, fast food, anti-oxidants abound. (4) Very similar foods are ascribed opposite health effects, e.g., apples healthy, mangoes unhealthy; almonds good; and cashew bad.

Cooking oils have spawned an elaborate pseudoscience. All triglycerides are nutritionally almost identical, providing nine glucose-free calories per gram. Their glycerol is identical. Unsaturated fatty acids decrease phospholipid bilayer rigidity, necessitating cholesterol redistribution from blood to cell membranes. On a diet rich in unsaturated fatty acids, cholesterol shifts out of plasma, and serum levels are transiently depressed. Though projected as barometers of heart health, these shifts are irrelevant to atherosclerosis.

Beliefs about dietary sodium are equally illogical. Glomeruli filter over 1,200 g of salt daily, of which over 99.5% is reabsorbed in tubules. Glomerular and tubular functions are under exquisite, independent and multiple controls. Beliefs that 4 g of salt daily is healthy, seven is dangerous, amounts to believing that if glomeruli filter 1,252 g salt daily, and tubules reabsorb 1,250, it is healthy, but altering these loads by even 0.1% is deleterious.

Modified Heart Healthy Diet

Since, glucose toxicity is important in atherosclerosis and health, current diet recommendations can be modified. Food should provide calories and all essential nutrients in adequate quantities. Vitamin B12 and iron require special attention in vegetarians. The diet should be palatable and affordable.

Adults: Basic rules are: do not be scared of eating; calorie counting is not needed for calories that come from fat; fats are healthier than glucose, especially in sedentary lifestyle; high-fat, low-glucose diet is good for heart; quantity of fats should be increased, quality (olive oil, cold pressed oils, cows ghee, walnuts, etc.) adds more expense than value; trans-fats of vanaspati ghee, margarine, bakery, sometimes eatery or party food, should be avoided; high protein is not very good, so consider protein a nutrient, not fuel; reduce glucose by curtailing sugar, jaggery, and by increasing fat in food; restrict glucose to amounts that can be stored as glycogen. Thus, physically active people may increase starchy foods, but match their intake to their expenditure from day-to-day, perhaps from meal-to-meal. These rules will prevent heart disease, cancers, various surgeries, and ensure longevity.

Poor man's heart healthy diet would have liberal amounts of cheap fats; (refined vegetable oil, palm oil, palm oil saturated fraction), starch titrated to activity levels, cheapest vegetables and animal foods (eggs, and milk), small multiple meals, and frugality of sugar, jaggery, and total calories to avoid hyperinsulinemia.

Ovo-lacto vegetarians should think of animal foods as healthy, reduce sugar and increase fat. There can be no single diet for children. Those planned for sumo wrestling, basketball, equestrian jobs, etc. would require tailored diets

from conception to adulthood. Geriatric diets should be palatable, and easy to digest. Instead of adding years to life, emphasis should be on enjoyment and affordability. Since a long life would be almost invariable, society will have to keep seniors happy and affordable, address legal rights and protection during long second childhoods.

Benefits of Low Fat, Low Cholesterol Diets

Cholesterol education, like animal rights and agriculture department's food pyramid, makes social sense. Carbohydrates make us large. Six feet humans are now common. Forest tribals are much smaller.

Cholesterol is present in animals, it is absent in plants. Cholesterol education leads to descending down in the food chain, from animal foods to plant foods. It greatly reduces the costs of feeding the population, the manpower and hectares required for production of food. It releases surplus manpower for urbanization, infrastructure, and businesses. Massive urbanization is possible; a world populated by dependent, compliant city folk. Exercise is essential for preserving health on a glucose-rich diet. The body has limited capacity for storing glycogen. In sedentary lifestyle, muscles contain glycogen and are insulin resistant. This predisposes to metabolic syndrome, diabetes, obesity, and thrombosis. Exercise depletes muscle glucose and improves insulin sensitivity, though it also increases wear and tear. The need for rest is equally important for health, but it is now seldom mentioned, even to patients discharged after myocardial infarction, congestive heart failure or major surgery. There are numerous publications on value of exercise in heart failure, but not of rest. Thus, cholesterol education leads to gigantic, hard-working, city dwellers maintained on cheap food; to a productive, docile, innocent workforce. The cholesterol myth fuels our prosperity.

PRESENT AND FUTURE

Structural integrity of cell membranes and isolation of lipophilic toxins from blood stream are vital functions of cholesterol. Cholesterol occurs in atherosomas because it reaches wherever there is tissue injury. A high-glucose diet engages hepatocytes in triglyceride synthesis, and toxin clearance slows. Excessive dietary glucose can cause many other direct harmful effects, glycosylation of proteins, hyperinsulinemia. Reducing glucose in diet, SGLT2 inhibitors, or even exercise, may provide greater benefit than mere reduction of toxic sdLDL with drugs.

Medical establishments, governments, and media have not resolved the cholesterol controversy. Clearly, some higher power enforces the confusion. Its rise soon after the Empire won the war, and the proactive role of the United

States government, suggests that above the three branches of modern states, are other, bigger powers. The cholesterol myth is kept alive by an all-powerful, but invisible, super-government. If doctors were paid well for knowledge, scientifically sound opinions, longevity of their patients, and very little for ordering or conducting hi-tech procedures, the cholesterol myth would collapse. The myth is deliberately kept alive by financial clout, and by other invisible influences.

Sodium-glucose cotransporter-2 trials can be expected to show benefits for arteries, veins, myocardium, dementia, cataracts, glaucoma, autoimmune diseases, cancers, glomeruli, etc. They will simultaneously show adverse effects on renal tubules and urinary tracts from excess urinary glucose, and little effect on dental caries, dyspepsia, and constipation. These trials may bring home the message of glucose toxicity, ending the cholesterol era. But will the next generation have the skills to make the post cholesterol world a better place than our prosperous, financially governed, global human farm?

CONCLUSION

Animals cell membranes contain cholesterol, it makes us flexible and mobile. Plants use cellulose. LDL and HDL work together like mop and pail for cleaning the circulation of endotoxins, cellular debris, etc. Fresh LDL and HDL are therefore both good, and old lipoproteins are bad because they contain endotoxins. High glucose diets change LDL to VLDL, and this becomes small dense LDL, which is atherogenic. Glucose is a reactive aldehyde that causes glycosylation of endothelial adhesion proteins. Glucose, smoke, etc. cause endothelial dysfunction, inflammation, and adhesion and deposition of small dense LDL causing atherosclerosis. High levels of old LDL or old HDL (familial hypercholesterolemia, alcohol, torcetrapib) predispose to atherosclerosis, and statins help by clearing small dense LDL from blood.

Indian Dyslipidemia: Challenges in Management

Saumitra Ray, Sumanta Chatterjee

INTRODUCTION

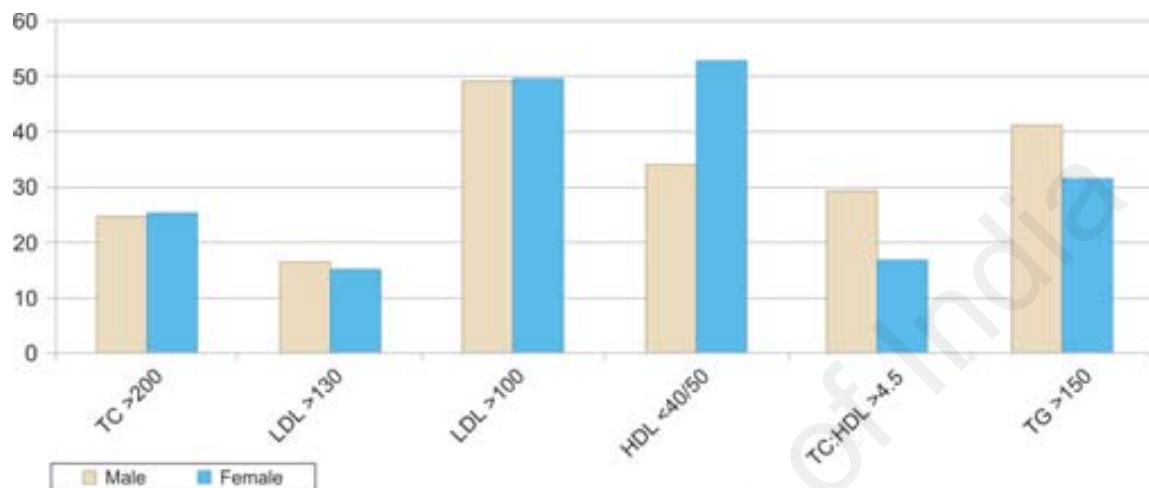

Abnormal values of lipoprotein lipids such as high total cholesterol (TC), low-density lipoprotein (LDL) cholesterol, very-low-density lipoprotein (VLDL) cholesterol, and triglycerides (TG) and low high-density lipoprotein (HDL) cholesterol are important coronary heart disease (CHD) risk factors. Many trials have shown that raised-LDL cholesterol (LDL-C) is the most common risk factor which leads to initiation and progression of coronary atherosclerosis. Robust data are available that show that lowering its levels can regress and stabilize atherosclerotic vascular disease.¹ Therefore, management of dyslipidemia is of paramount importance to reduce cardiovascular disease (CVD). In 2013, the National Heart, Lung, and Blood Institute (NHLBI), the American College of Cardiology (ACC), and the American Heart Association (AHA), released a joint guideline focusing on the risk of atherosclerotic cardiovascular disease (ASCVD). However, as evident by various studies, dyslipidemia in Indian population is characterized by low HDL cholesterol (HDL-C) and high TG. High TC and LDL-C are less common in Indian patients. Moreover, there are significant lifestyle, genetic, socioeconomic, and cultural differences in Indians versus European population. All these factors demand different treatment approaches for optimal management of dyslipidemia and CVD. Also, prevalence and the pattern of various risk factors that decides the category of CV risk differ from European population and therefore, risk assessment score varies. Apart from this, economical constraints on healthcare expenditure and delayed availability of newer agents also leads to different treatment approaches amongst treating physicians. Moreover, the side effect profile of the drugs used to treat dyslipidemia, notably statins, also varies from the European to the Indian population. No evidence-based Indian guidelines for dyslipidemia management considering all these factors have been developed and therefore, Indian physicians are forced to follow international guidelines for their patients. Hence, there is a need for adapting international guidelines for Indian patients through

expert consensus for guiding Indian physicians. Though Indian guidelines for the management of dyslipidemia are not currently available, a consensus statement on the management of dyslipidemia in Indian subjects was published in 2014. And that is why it is a challenge to manage dyslipidemia in India especially in the absence of India-specific guidelines.^{2,3}

INDIAN EPIDEMIOLOGICAL STUDIES ON DYSLIPIDEMIA

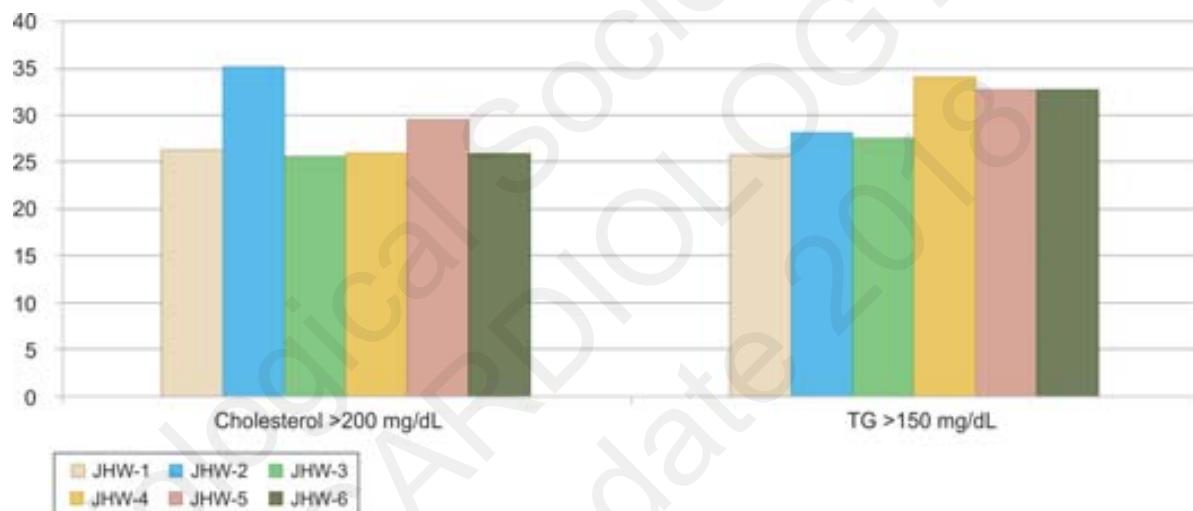

Heterogeneous data were showing an increasing secular trend in TC levels, but in view of various limitations and biases in data, robustness of this trend could not be confirmed. Prevalence of dyslipidemia in India is not adequately documented. However, India Heart Watch study was a big epidemiological survey of urban middle class subjects from 11 major cities of India. Prevalence in men and women, respectively were, TC more than 200 mg/dL in 25.1% (men) and 24.9% (women), LDL-C more than 130 mg/dL in 16.3% (men) and 15.1% (women) and more than 100 mg/dL in 49.5% (men) and 49.7% (women), HDL-C less than 40 mg/dL (men) and less than 50 mg/dL (women) in 33.6% and 52.8%, TC:HDL-C ratio is more than or equal to 4.5 in 29.4% and 16.8% and TG is more than or equal to 150 mg/dL in 42.1% and 32.9% (Fig. 1).⁴

India is undergoing a rapid epidemiological transition with increasing population, economic prosperity, urbanization and aging with associated risk factor transition. Adverse lifestyles such as greater smoking and tobacco use, change in nutritional habits with greater intake of unhealthy diets and increasing sedentary lifestyle are also responsible factors for development of CHD.⁵ In the Jaipur Heart Watch (JHW) studies (six in number), 20-year mean cholesterol and other lipid parameters were evaluated. Total 712 people of 20–59 years were evaluated in JHW-1, 558 in JHW-2, 374 in JHW-3, 887 in JHW-4, 530 in JHW-5, and 1,100 in JHW-6.

HDL, high-density lipoprotein; LDL, low-density lipoprotein; TC, total cholesterol; TG, triglyceride.

FIG. 1: Prevalence (%) of dyslipidemia in India Heart Watch multisite study, N = 6,123.

JHW, Jaipur Heart Watch; TG, triglyceride.

FIG. 2: Twenty-year trends in prevalence of hypercholesterolemia and hypertriglyceridemia among urban subjects in Jaipur Heart Watch.

There was high prevalence of overweight, hypertension, and lipid abnormalities. Age- and sex-adjusted trends showed significant increases in mean body mass index (BMI), fasting glucose, TC, HDL-C, and TG (quadratic and log-linear regression, $p < 0.001$). There was increase in overweight and obesity ($p < 0.05$) and hypertriglyceridemia but insignificant changes were observed in truncal obesity, hypertension, hypercholesterolemia and diabetes (Fig. 2).⁵

ASSOCIATION BETWEEN LIPID LEVELS AND RISK OF HEART DISEASE IN INDIA

In the INTERHEART study, relative importance of different lipid components in acute coronary syndrome is highlighted in which South Asian population was showing highest risk of myocardial infarction (MI) with high cholesterol level.⁶

In India, there are limited studies available which have prospectively evaluated importance of various cholesterol lipoproteins. In one study, done in the pre-statin era, a linear relationship of increasing TC levels with increasing mortality in various age-groups was observed (Fig. 3).⁷

Familial hypercholesterolemia (FH) is an important coronary risk factor with varying prevalence from 1:200 to 1:500 globally. It is commonly seen in young patients who have a history of MI. Many studies show that there is a relatively low prevalence of mild to moderate hypercholesterolemia in both population- and hospital-based subjects in India.⁸

A panel of Indian experts felt that QRISK®2 risk calculator for estimating CV risk in Indian subset of dyslipidemia is more appropriate than ASCVD risk score developed for the Americans.³

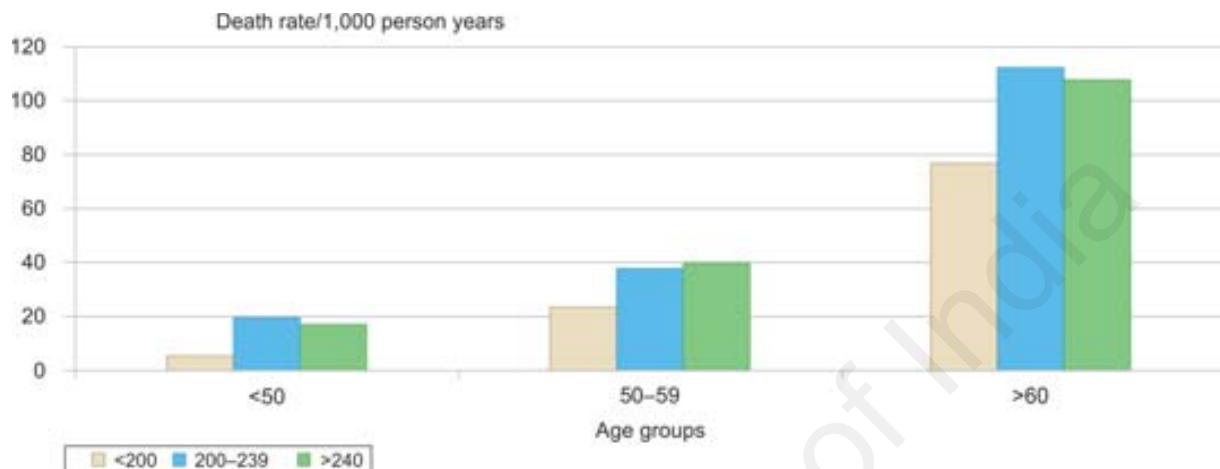

FIG. 3: Prospective study of association of cholesterol levels with cardiovascular mortality with preexisting coronary heart disease in India.

LABORATORY PARAMETERS ASSESSMENT

Assessment of lipid profile is crucial to assess CV risk and to decide on the treatment. Traditionally, assessments are done in fasting state. European Society of Cardiology (ESC) dyslipidemia guideline opined that both fasting and nonfasting assessment of TC, LDL-C, and HDL-C shows similar levels, whereas higher TG levels (by 27 mg/dL) are observed in nonfasting state depending on time and composition of the last meal. In Indian setting, this is even more due to higher content of carbohydrates in meal. The increase in TG levels in nonfasting state was seemed important as TGs are considered as strong CV risk factors for Asian Indians and is a characteristic dyslipidemic component in Indians.^{9,10} Nonfasting assessments were considered helpful so that overcrowding of laboratory in morning will be reduced and patients' preference to perform lipid assessment increases. However, nonfasting lipid assessment has disadvantage of unclear evidence on time of assessment after meal (whether 1 h, 1.5 h, 2 h, and so), meal load or composition before assessment, and nonfasting cut-off levels for each of lipid components. Thus, fasting lipid assessment is still the gold standard, to be performed whenever feasible with nonfasting assessment reserved for those with CV risk assessments, in diabetic patients, distant residence patients (first-hand opportunity to screen for dyslipidemia with follow-up fasting evaluation at 3 months). It was suggested that for a LDL-centric management, i.e., when physicians treating dyslipidemia has kept the target of achieving LDL-C to a goal irrespective of the other lipid levels, a nonfasting measurement may prove equally useful.³ This was also recommended by the European atherosclerosis society and European federation of clinical chemistry and laboratory medicine.

European Society of Cardiology recommended apolipoprotein B (ApoB) as an alternative marker for risk assessment especially in those with elevated TGs.¹¹ However, ApoB is expensive for Indian setting. Hence, it was suggested

that ApoB should not form a part of routine dyslipidemia management in Indian setting.³

Lipoprotein-a [Lp(a)] was advised by ESC guideline as marker for estimation in patients with history of premature CV disease in family and in those with borderline CV risk. Routine Lp(a) estimation is felt to be inappropriate in Indian setting. Further, as Lp(a) estimation techniques are not validated in most laboratories in India, Lp(a) testing is liable to technical errors giving false positive or false negative results. A recent evaluation from Banerjee et al.¹² reported nonsignificantly higher trend for elevated Lp(a) association with ischemic heart disease (IHD) in Asian Indians [odds ratio (OR) 2.0] and Chinese (OR 4.8) than non-Hispanic Whites (OR 1.4). Lp(a) assessment should be restricted to premature (at age <40 years) or recurrent CVD, FH, history of premature CVD in family, and borderline high risk of CV disease.³

INADEQUATE MANAGEMENT OF DYSLIPIDEMIA IN INDIA

Epidemiological studies of hypercholesterolemia and dyslipidemia are important for developing strategies for prevention of CHD. In Indian Heart Watch study awareness about dyslipidemia and its consequences among dyslipidemic population was in 17.5% men and 13.2% women and statins was given to 7.5% men and 6.7% women, while control to targets of TC less than 200 mg/dL was in 4.5% men and 3.7% women (Fig. 4).¹ The PURE study also found low use of secondary prevention drugs and healthy lifestyle practices in low income countries including India. A study has also reported that availability of statins is no longer a problem, still the use is low in India.⁴

INDIAN GUIDELINE RECOMMENDATION ON DYSLIPIDEMIA MANAGEMENT

Management of dyslipidemia is a difficult task as not only the prevalence of dyslipidemia is constantly increasing, particularly at a younger age, but also the pattern of dyslipidemia

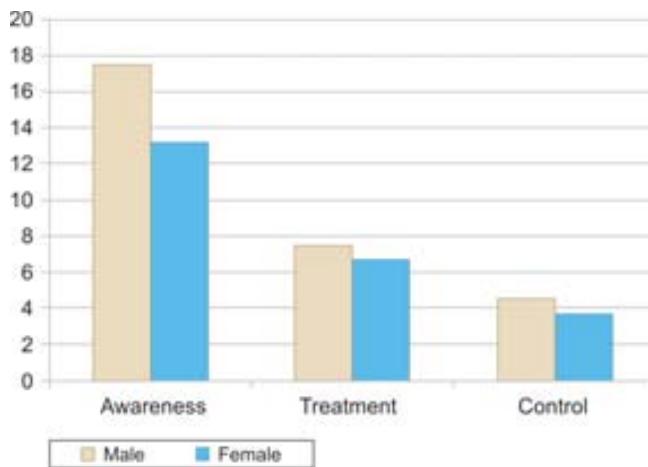

FIG. 4: Hypercholesterolemia awareness, treatment, and control among urban adults in India. (percentage prevalence): Indian Heart Watch Study.

is also different as compared to the Western populations. Furthermore, overall awareness about dyslipidemia and prevention of ASCVD, cultural beliefs, socioeconomic conditions, etc. are also different. For these reasons, there is a need to formulate a guideline recommendation for dyslipidemia and coronary artery disease (CAD) prevention for Indian patients which can be best suited for Indian conditions as well.

CARDIOVASCULAR RISK STRATIFICATION OF INDIAN PATIENT

Cardiovascular risk stratification is very much important for primary and secondary prevention of CAD, especially in high ASCVD score patients who do not have prior history of MI or any vascular condition. This is required to cater the

appropriate statin to appropriate patients. This avoids both under treatment and over treatment with statins. Moreover, the awareness of the risk of ASCVD improves patients' health behaviors and improve the compliance to treatment (Table 1).¹³⁻¹⁵

TREATMENT GOAL ACCORDING TO ASCVD RISK STRATIFICATION

This outline recommends target goal of lipid levels and thresholds for statin therapy initiation based on risk categories (Table 2). It should be noted that therapeutic lifestyle change is also recommended in all individuals who have LDL-C or non-HDL-C values above the desired goals, and preferably in everyone regardless of their cholesterol levels.¹⁵

CARDIOVASCULAR DISEASE PREVENTION: LIPID TARGETS

European Society of Cardiology recommends cessation of tobacco use, healthy diet, body weight maintenance, physical activity (moderate-vigorous 2.5–5 h per week), blood pressure, and glycemic control (HbA1c <7%).¹¹ However, healthy diet is one of the most deficient means in CV disease prevention in India. Reducing carbohydrate intake was suggested. Indian Council of Medical Research National Institute of Nutrition Research recommends visible fat intake of 50 g per person per day. It is suggested to limit the use of coconut oil, vanaspati, and animal fats on the account of high amount of saturated fatty acids present in these sources. Further, it is advised to avoid olive oil for cooking in India as it has lower smoking point and may get denatured at cooking temperatures (deep frying) employed in routine.³ In India, lower waist circumference (WC) cut-off for males (<90 cm) and females (<80 cm) are recommended contrasting to ESC

TABLE 1: Atherosclerotic cardiovascular disease risk categories in Indians

Risk category	Conventional risk markers	Nonconventional risk markers
Very high-risk	<ul style="list-style-type: none"> Pre-existing ASCVD DM with end organ damage or 2 or more major ASCVD risk factors FHH 	<ul style="list-style-type: none"> None
High-risk (>15% risk of ASCVD death/MI/stroke over 10 years)	<ul style="list-style-type: none"> 3 or more major ASCVD risk factors DM other than above category CKD stage 3B or 4 FH (except FHH) LDL >190 mg/dL/ heavy smoker/ strong family history of premature ASCVD 	<ul style="list-style-type: none"> CAC score >300 A Carotid plaque (nonstenotic) Lp(a) >50 mg/dL
Moderate-risk (5–15% risk of ASCVD death/MI/stroke over 10 years)	<ul style="list-style-type: none"> 2 major ASCVD risk factors 	<ul style="list-style-type: none"> CAC score 100–299 Raised carotid IMT/ aortic PWV Lp(a) 20–49 mg/dL Metabolic syndrome
Low-risk (<5% risk of ASCVD death/MI/stroke over 10 years)	<ul style="list-style-type: none"> 0–1 major ASCVD risk factor 	<ul style="list-style-type: none"> None

ASCVD, atherosclerotic cardiovascular disease; CKD, chronic kidney disease; CAC, coronary artery calcium; DM, diabetes mellitus; FHH: familial homozygous hypercholesterolemia; LDL, low-density lipoprotein; MI, myocardial infarction; PWV, pulse wave velocity; IMT, intima media thickness; Lp(a), lipoprotein(a).

TABLE 2: Treatment goals and statin initiation according to atherosclerotic cardiovascular disease risk categories

Risk category	Treatment goal		Initiation of drug therapy	
	LDL mg/dL	Non-HDL mg/dL	LDL mg/dL	Non-HDL mg/dL
Very high-risk	<50	<80	>50	>80
High-risk	<70	<100	>70	>100
Moderate-risk	<100	<130	>100	>130
Low-risk	<100	<130	>130	>160

HDL, high-density lipoprotein; LDL, low-density lipoprotein.

recommendation of less than 94 cm and less than 82 cm, respectively.¹¹ Also, BMI cut-off was opined to be less than 23 kg/m² against ESC recommendation of 20–25 kg/m².³ Alcohol was not found to be cardiac friendly for Indian population as opposed to most other ethnic groups.

LOWERING OF LOW-DENSITY LIPOPROTEIN REDUCES RISK OF CARDIOVASCULAR EVENTS

Low-density lipoprotein is a major culprit for development of atherosclerosis and causes CAD. Many studies have shown that as much as low LDL is better for CV event reduction. In a meta-analysis of 175,000 participants in 27 randomized trials of statins, the Cholesterol Treatment Trialists, (CTT) collaborators found that a reduction of 1 mmol/L (38.7 mg/dL) in LDL-C levels produced a 21% reduction in major vascular events over 5 years, irrespective of age, sex, base line LDL-C levels and presence or absence of vascular disease.¹⁶

DRUGS FOR MANAGEMENT OF DYSLIPIDEMIA

Statins remain the cornerstone for treatment of dyslipidemia. Statins are recommended in highest recommended or tolerated dose to reach the goal lipid levels and was agreed unanimously by the panel. However, panel identified three potential statins—(1) atorvastatin, (2) rosuvastatin, and (3) pitavastatin for clinical use in India. Descriptive studies in India have reported maximum utilization of atorvastatin and rosuvastatin to large extent (over 95% of prescriptions) than other statins.¹⁷

In the JUPITER trial, 106 people with no prior ASCVD or diabetes with baseline LDL-C less than or equal to 130 mg/dL and high sensitivity C-reactive protein more than or equal to 2 mg/L were treated with rosuvastatin 20 mg/d. The median LDL-C level attained was 55 mg/dL, as compared to 108 mg/dL at baseline. Those who achieved LDL-C less than 50 mg/dL had 65% reduction in the risk of major CV events and 46% reduction in total mortality. Approximately, 23% of the subjects reached LDL-C level of less than 40 mg/dL. In a *post hoc* analysis, no adverse effects were seen in this group.¹⁸

The ESC recommends use of ezetimibe, bile acid sequestrant, and cholesterol absorption inhibitors in a sequential manner as additional agents if the goal is not reached with statin alone. In cases with very high-risk who failed to achieve treatment goal, addition of proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors should be considered. Panel suggested when lipid goals are not reached, causes of secondary dyslipidemia should be ruled out.¹¹

In the IMPROVE-IT (Improved Reduction of Outcomes: Vytorin Efficacy international Trial), with ACS patients mean level of LDL-C was 69.9 mg/dL in the simvastatin group and 53.2 mg/dL in the simvastatin ezetimibe combination group. The median follow-up was for 7 years. Primary endpoint of CV death, MI, hospitalization for unstable angina, coronary revascularization (>3 days), or stroke occurred in 34.7% of the simvastatin group and 32.7% of the simvastatin plus ezetimibe group. The absolute risk reduction was 2% (numbers needed to treat-50) and relative risk reduction was 6.4% (hazard ratio 0.936; CI 0.887–0.988; p = 0.016). There was no safety signal.¹⁹

As per experts, to achieve LDL-C target, statins are first-line agents. In India, rosuvastatin (5–40 mg), atorvastatin (10–80 mg), and pitavastatin (1–4 mg) may be used as first choice. In case of failure to achieve goal LDL-C with statin alone, add ezetimibe (10 mg) as second agent followed by bile acid sequestrant, and cholesterol absorption inhibitors as needed. A combination of statin (in lower doses—e.g., atorvastatin 40 mg instead of 80 mg or rosuvastatin 20 mg instead of 40 mg) with ezetimibe may be considered in patients who have significant adverse effects with statins or who are diabetic or at high CV risk.

DRUGS FOR MANAGEMENT OF HYPERTRIGLYCERIDEMIA

The ESC recommended that statin should be given to all high-risk patients with TG more than 200 mg/dL and addition of fenofibrate to statin to be considered if target TG of less than 200 mg/dL is not reached with statin alone.¹¹ The risk of CV disease morbidity and mortality is increased significantly in case where estimated glomerular filtration (eGFR) is less than 15 mL/min/1.73 m². Using fenofibrate with statin thus demands lower dosage (75 mg/day) of fenofibrate. Further, reported prevalence of chronic kidney disease (CKD) in Indians is 17.2% with further increase in diabetic subset (18.8%) suggests significant burden of CKD. Panel opined that when eGFR is less than 60 mL/min/1.73 m², dose of fenofibrate should not be increased. In patients who have TGs more than 200 mg/dL, panel recommends use of fenofibrate in a low-dose with caution in CKD cases and strict implementation of lifestyle modification as a treatment strategy. In CAD cases, who have LDL-C less than 70 mg/dL with TG more than 200 mg/dL and HDL-C less than 35 mg/dL, panel suggested use of fenofibrate (75 mg/day) in addition to statin. Use of higher dose needs monitoring of eGFR in patients. Where fibrate is contraindicated or not tolerated, there is some evidence of biochemical benefit with saroglitazar, a dual PPAR agonist. This is safe in combination with statin but there is no evidence of its clinical outcome benefit.^{12,20}

FAMILIAL HYPERCHOLESTEROLEMIA IN INDIA

Familial hypercholesterolemia, a common genetic disease not diagnosed, especially in Asian countries.²¹ In India, sporadic case reports of FH are available in literature. However, the panel felt there is need to prospectively screen patients for FH and suggested use of clinical criteria for screening of FH in India. Panel stressed on assessing arcus cornealis before the age of 45 years especially in upper cornea as simple tool to start screening FH. In association with raised LDL-C (>250 mg/dL), these criteria can provide a clue to the diagnosis of FH. Genetic screening may be positive in ~ 60% cases which were classified as definite FH by clinical criteria. Target LDL-C in FH recommended by ESC guidelines is less than 100 mg/dL and less than 70 mg/dL without or with CVD, respectively. In high risk cases or in those with CVD or statin intolerance, PCSK9 inhibitor is recommended as treatment.¹¹

DYSLIPIDEMIA IN TYPE 2 DIABETES AND METABOLIC SYNDROME

The ESC guidelines recommend non-HDL-C is less than 130 mg/dL and less than 100 mg/dL in high-risk and very high risk cases, respectively. In treating dyslipidemia, statins are recommended in all type 1 diabetes and in presence of microalbuminuria and/or renal disease irrespective of baseline LDL-C. LDL-C is less than 70 mg/dL (primary) and non-HDL-C is less than 100 mg/dL (secondary) are recommended in type 2 diabetes and CVD/CKD as well as in patients aged more than 40 years without CVD but with one or more CVD risk factor. Further, LDL-C is less than 100 mg/dL (primary) and non-HDL-C more than 130 mg/dL (secondary) is advised in type 2 diabetes without any risk factor and/or evidence of target organ damage.¹¹

DYSLIPIDEMIA IN ACUTE CORONARY SYNDROME

The ESC recommends early high-dose statin for all cases with ACS and undergoing percutaneous coronary intervention (PCI) despite normal baseline LDL-C levels. Addition of ezetimibe and PCSK9 inhibitors should be considered, if LDL-C target is not reached with statin alone. In statin-intolerant cases, the latter two may be used alone or in combination. A goal LDL-C is less than 70 mg/dL or 50% reduction from the baseline value. Re-evaluation at 4–6 weeks is recommended. A loading of high-dose statin before elective PCI or in patients with non-ST elevation ACS should be considered when patients are already receiving statins. Panel suggested when baseline LDL-C is less than 100 mg/dL in any ACS patients, a target should be 50% reduction from baseline. When the target of less than 50 mg/dL is desirable and is not achieved with statin alone, addition of ezetimibe may be considered.¹¹

DYSLIPIDEMIA IN MODERATE-TO-SEVERE CHRONIC KIDNEY DISEASE

The ESC guidelines identified that CKD stage 3–5 are high or very high-risk for CV disease. Statin with or without ezetimibe is recommended in nondialysis-dependent CKD. In dialysis-dependent CKD cases without any CV disease, statins are not to be used. Statin, ezetimibe, or their combination should be continued at the time of dialysis initiation in all and especially in CV disease cases. Amongst two statins commonly used in India, atorvastatin dose was advised as 20 mg/day by NICE guidelines for primary or secondary prevention of CVD in CKD cases. These guidelines further advocate consultation of nephrologist if eGFR is less than 30 mL/min/1.73 m² and higher dose of atorvastatin is to be used. But, as recommended by ESC guidelines and opined by the panel, any dose of statin may be initiated to achieve the target LDL-C is less than 70 mg/dL.¹¹

DYSLIPIDEMIA AND STROKE PREVENTION

For primary prevention of stroke, statin treatment is recommended to achieve desired goals in high-risk and very high CV risk cases. For secondary prevention of stroke, intensive statin treatment is recommended by ESC guidelines. ESC guidelines recommend high-dose statin for both primary as well as secondary stroke prevention.¹¹

SAFETY ASSESSMENT DURING PHARMACOTHERAPY IN DYSLIPIDEMIA

In consideration of safety of statins, ESC guidelines recommend liver enzyme assessment especially alanine aminotransferase (ALT), at baseline, and once 8–12 weeks post-treatment or after increase in dose. Routine monitoring with ALT, thereafter is not recommended during therapy. If elevation of liver enzymes is over 3 times the upper limit of normal (ULN), reduce the dose or stop the drug and recheck liver enzymes in 4–6 weeks. Reintroduction should be cautiously done after ALT has returned to normal with lower dose at the start and then gradual increase with enzymes monitoring. Persistent elevation in enzymes excludes lipid lowering therapy as a culprit for liver damage. With regards to muscle damage, guideline recommends creatine kinase (CK) assessment at baseline. If elevation of CK is 4xULN, do not start treatment. Routine monitoring is not necessary except when patients complain of myalgia. Elevation of CK during therapy to 10x ULN demands discontinuation of drug and bimonthly monitoring of CK and renal function. Asymptomatic CK elevation to less than 10x ULN, continue treatment and monitor CK bimonthly whereas in symptomatic elevation of CK to less than 10x ULN, discontinue treatment, monitor CK and restart at lower dose after CK is normalized. Panel agreed to these recommendations and suggested for cautious use of statins in cases of hypothyroidism and vitamin D deficiency.¹¹

CONCLUSION

Cardiovascular disease is a major disease burden in India and as it is observed more commonly in young population compared to western population. Dyslipidemia is perhaps the most important risk factor for CVD, particularly for premature CVD. LDL-C is the primary target; but TGs and non-HDL-C can be considered for intervention in patients with grossly deranged levels. LDL-C less than 70 mg/dL is target for all ASCVD cases with optional reduction to less than 50 mg/dL in very high-risk cases. Optional lipid targets that can be considered in India include HDL-C less than 40 mg/dL and TGs less than 150 mg/dL (<100 mg/dL in very high-risk cases).

Statins are first-line drugs for dyslipidemia. Rosuvastatin, atorvastatin, and pitavastatin are commonly used in India. Ezetimibe should be second agent to statin to achieve the desired lipid targets. Low-dose statin in combination with ezetimibe may be considered in patients with significant statin related side effects. Addition of fenofibrate should be considered to statin to lower TGs less than 200 mg/dL, but with close follow-up for liver and kidney derangement.

For treatment of FH, statin, and ezetimibe combination is the primary treatment in India until PCSK9 inhibitors become readily available for clinical use.

In diabetes with high CV risk, LDL-C goal is less than 70 mg/dL. Combination of modest dose statin with ezetimibe should be considered to control dyslipidemia in diabetes.

In acute coronary syndrome and in patients undergoing PCI, LDL-C goal is less than 70 mg/dL with optional lowering to less than 50 mg/dL in very high-risk cases. High-dose statin with addition of ezetimibe, if necessary, is suggested to achieve these lipid targets.

In nondialysis dependent CKD, statin ± ezetimibe is advised to achieve LDL-C goal of less than 70 mg/dL, eGFR should guide the dosing choice. Use of high-dose statin in those with eGFR less than 30 mL/min/1.73 m² requires consultation with nephrologist. For primary and secondary stroke prevention, high-dose statins are advised. Follow-up monitoring is advised every 12 weeks till goals are reached and then annually. Liver function assessment at baseline and post-treatment (after 4–6 weeks) should be done. CK levels should be assessed in patients with myopathy or in those at high-risk of muscle damage.

Indian Diet and Coronary Artery Disease

Abhishek Gupta, MP Girish, Mohit D Gupta

"Food is more powerful than any pill. The food that we eat can make us fat or thin"

INTRODUCTION

Cardiovascular diseases (CVDs), especially coronary heart disease (CHD), are epidemic in India. The World Health Organization (WHO) and Global burden of disease study also have highlighted increasing trends in years of life lost (YLLs) and disability-adjusted life years (DALYs) from CHD in India. In India, studies have reported increasing CHD prevalence over the last 60 years, from 1% to 9–10% in urban populations and less than 1% to 4–6% in rural populations.¹

This increase has been largely attributed to rapid westernization. Westernization has made food calorie rich and convenient for the common man, but because of the various ethnic, epigenetic reasons, and the high prevalence of sarcopenic adiposity, Indians are vulnerable to adverse effects of these dietary changes.

The present article attempts to provide, evidenced based strategies for a cardioprotective diet in Indian context.

PREVALENCE OF DISEASE—IS THERE UNDERESTIMATION OF ACTUAL PROBLEM?

Coronary heart disease is a major cause of mortality and morbidity all over the world. While the prevalence and mortality due to CHD is declining in the developed nations there has been an alarming increase over the past two decades in the prevalence of CHD and cardiovascular mortality in India and other South Asian countries.¹

India is in a phase where it is going through an epidemiologic transition whereby the burden of communicable diseases has declined slowly, but that of noncommunicable diseases (NCD) has risen rapidly, thus leading to a dual burden.

The prevalence of ischemic heart disease (IHD) has increased sevenfold to about 14% by 2013. Similarly, it is more than quadrupled in rural areas, from 1.7 to 7.4% between 1970 and 2013.²

The Global Burden of Disease study estimate of age-standardized CVD death rate of 272 per 100,000 population in India is higher than the global average of 235 per 100,000 population. Some aspects of the CVD epidemic in India are particular as its accelerated build up, the early age of disease onset in the population, and the high case fatality rate.² The higher case fatality among Indians following acute coronary syndrome (ACS) could result in the underestimation of actual problem.

DIET AND CORONARY ARTERY DISEASE: EVIDENCE

Global disease burden of CVD is increasing across the globe including India, which is experiencing a rapid health transition. Diet and nutrition have been extensively investigated as risk factors for major CVDs in various studies like The INTERHEART study, The Lyon Diet Heart Study, The Framingham and offspring Study;³ these studies are conducted within and across populations, to link several nutrients, minerals, food groups, and dietary patterns with an increased or decreased risk of CVD.³⁻⁵

INDIAN DIET

Diversity of Indian Diet—Is It Sufficient to make us Healthy?

India has a rich and highly varied cuisine, and its various diets are strongly related to social identity, religion, and other cultural factors, as well as local agricultural practices and availability of diverse foods. Indian food is paradoxically considered strongly vegetarian, but it is actually lacking in vegetable content rather, is centered on wheat, in the north, and rice, in the south with daal being the second most important element. One can have an entire South Indian vegetarian meal without encountering even a single vegetable. The most important vegetable that is consumed

TABLE 1: Westernized diet and risk patterns

	Evidence	Conclusion
Dietary pattern with added fats, fried food, eggs, organ, and processed meats, and sugar-sweetened beverages (Southern dietary pattern)	There was a 56% increase in cardiac events over 6 years with the Southern pattern, which was eaten more frequently by residents of the Stroke Belt who were male, black, smokers, less educated, physically inactive, and overweight or obese. ⁷	A dietary pattern characteristic of the Southern United States (animal products and sweets) was associated with greater hazard of CHD, and is more common in overweight, Southern black men with lower levels of education and economic status

CHD, coronary heart disease.

is highly starchy aloo. Whatever amount of greens is taken is deeply fried which kills its nutrient content.⁵

Westernization of Indian Diet

The prevalence of CVDs increased by threefold in India as compared to west by the turn of 20th century⁶ which is attributed to rapid westernization. Westernization is correlated with increase in consumption of sugar, salt, high fat dairy products, eggs, red meat, and oils with their trans-fat content (Table 1).

Various methods of improving the taste and prolonging the shelf life of food substances like salting, refining, hydrogenation, and frying increases the energy density of the food materials. The harmful components of the westernized diet are because of in its energy density and its ability to have a long shelf-life.

CONTAMINATED VEGETARIANISM

Vegetarianism prevalent in India is aptly criticized as the contaminated vegetarianism, consuming large amounts of fried foods, excess of salt, sugar, and ghee. Hence, the protective components in the vegetarian diet are considerably lacking in our diet.

Cholesterol and Diet

Since, cholesterol can be synthesized in the body, all recommendations advice to restrict dietary cholesterol consumption to be less than 300 mg/day, which is the average amount found in an ordinary egg yolk.

In typical omnivorous diets, the relationship of intake of cholesterol in low doses and blood cholesterol is linear. At higher cholesterol intakes, the relationship is curvilinear; changes in dietary cholesterol have less of an effect on serum cholesterol.

The also the magnitude of the effect differs from one person to another, largely from differences in the baseline diet as well as genetically determined intestinal cholesterol absorptive capacity (Table 2).

OIL CONSUMPTION

Oil is a cooking medium which makes food more palatable. The water content of food gets replaced by the oil, which makes the food energy dense (Fig. 1).

TABLE 2: Dietary cholesterol in India diet

	Evidence	Conclusion
Dietary cholesterol	Meta-analysis including 27 studies using prepared diets and assessing effect on cholesterol ⁸	Added dietary cholesterol increases serum cholesterol; the effect is greatest when baseline intake is low Each 100-mg increment in dietary cholesterol increases TC by 2.2 mg/dL and increases the TC:HDL ratio by 0.02 units

HDL, high-density lipoprotein; TC, total cholesterol.

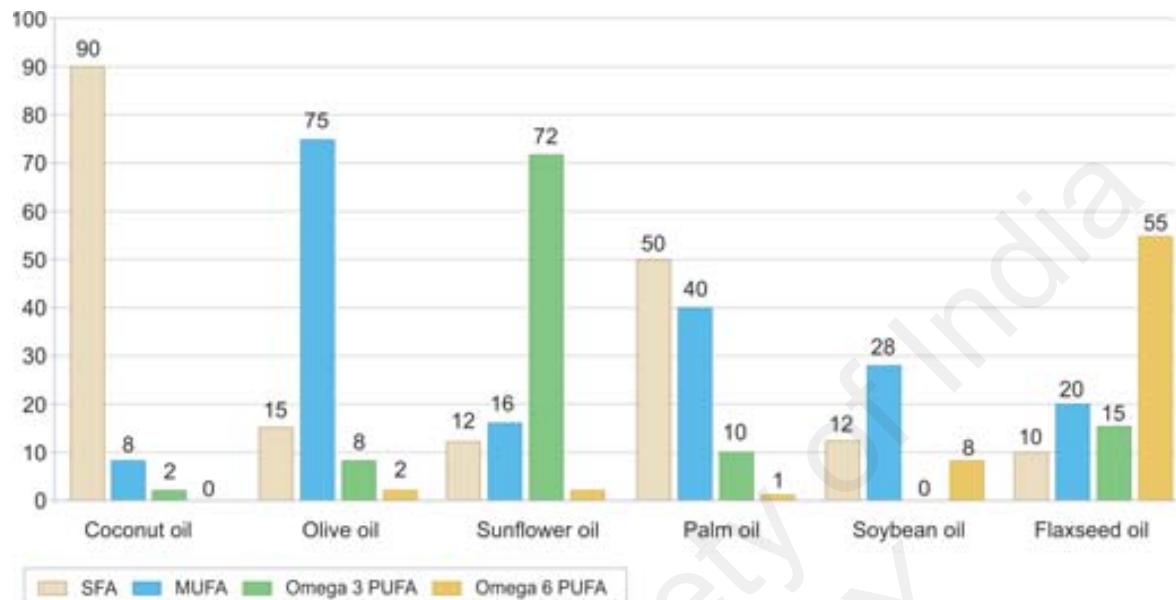

The invisible fat content of the cereals and pulses contribute to 3–5% of their weight. The person who consumes at least one nonvegetarian dish a day does not require additional oil in his diet. The invisible fat content of the Indian diet almost matches the daily requirement of 40–60 g/day. Therefore, only vegans and people involved in heavy manual labor requires up to one to two table-spoons of oil and that too only if they are unable to consume the recommended daily need of 30 g of nuts.⁹

The beneficial effect of fish and marine products in Indian diet is marred by the widespread deep-frying habit which oxidizes the cholesterol and transforms lipid contents making them more atherogenic.

Myth of Polyunsaturated Fatty Acid

Polyunsaturated fats contain essential fatty acids (FA), but have a short shelf-life, and thermal instability. It is better to use them as spreads or as seasoning. Most of refined oils with high polyunsaturated fatty acid (PUFA) can degrade easily at high temperatures to toxic component like free-radicals, trans-fats and malondialdehyde which are atherogenic, hence oil which are stable at high temperature like ghee, coconut oil, unrefined oil with high smoke point like mustard oil should be preferred for frying.

Widely advertised ω -6-polyunsaturated (mainly linoleic acid) cooking oils like sunflower oil, may not be heart friendly, since the prostaglandins derived from such oils are more thrombogenic than the ω -3-polyunsaturated oils (mainly ALNA) like canola, soybean, and rapeseed oil, so in diet n-6 to n-3 ratio should not be more than 5–10:1. There is also evidence, that if we keep n-6 FA intake lesser, n-3 FA can be converted into long chain n-3 FA like [2-ethylhexanoic acid (EHA) and dehydroepiandrosterone (DHEA)].¹⁵

MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids.

FIG. 1: Various fraction of fatty acids in different oils.

Which Oil to be Preferred for Cooking?

The sterol for the plant kingdom is ergosterol and any plant product, therefore can be labelled as cholesterol free. Solid fats (at room temperature), including coconut oil and palm oil, have deleterious effects on atherosclerotic cardiovascular disease (ASCVD) risk factors. Liquid vegetable oils have beneficial effects on lipids and lipoproteins. As noted, they decrease low-density lipoprotein cholesterol (LDL-C).

The evidence base for olive oil [monounsaturated fatty acids (MUFAs) rich] is the most comprehensive, with clear evidence for a benefit in ASCVD risk reduction. As olive oil is expensive and out of reach for most of Indian population other alternative with equal benefit is mustard oil (MUFA rich).

Replacement with MUFAs or n-6 PUFAs lowered fasting serum total cholesterol (-8.4% and -9.2% , respectively), LDL-C (-11.3% and -13.6%), and total cholesterol to high-density lipoprotein cholesterol (HDL-C) ratio (-5.6% and -8.5%) ($p \leq 0.001$).

The sterol for the animal kingdom is cholesterol and the recognition of oxidized cholesterol as an atherogenic moiety made the fats and oils of animal origin unacceptable choice as a cooking medium (Table 3).

Controversies on Saturated Fatty Acids—Are They Really Bad? What should be Optimal Replacement Fatty Acid?

Saturated fatty acid (SFA)-rich foods (e.g., meat, butter, and cheese) increase LDL-C, HDL-C, and decreases triglycerides. Unsaturated fatty acids (for example, vegetable oils and fatty

fish) decreases the amount of LDL-C and triglycerides in the blood and raises HDL-C.¹⁶

A recent meta-analysis of observational studies suggest that saturated fat intake is not associated with CVD, ischemic stroke, type 2 diabetes mellitus and all-cause mortality. In particular, a diet high in stearic acid appears to lower levels of unhealthy LDL-C.¹⁷

Available evidence from adequately controlled randomized trials suggest replacing SFA with mostly n-6 PUFA is unlikely to reduce CHD events, CHD mortality or total mortality.¹⁸

FRUIT AND VEGETABLES IN INDIAN DIET—MORE PRODUCTION BUT LESS CONSUMPTION

The WHO recommends a daily intake of at least 400 g (or five daily servings with an average serving size of 80 grams) of fruits and vegetables, excluding potatoes, cassava, and other starchy tubers to prevent diet-related chronic diseases and micronutrient deficiencies. But according to the India's Phytonutrient Report (2016) notes that Indians consume quite less than the norms.¹⁹ Lifestyle factors such as long working hours and junk food consumption and other factors like high costs, lack of availability of the product throughout the year were some of the reasons attributed to low consumption.

Dark green vegetables reduces arterial stiffness and blood pressure, because of inorganic nitrate, which undergoes salivary bacterial conversion to nitrite, followed by gastrointestinal acidification to nitrous oxide (NO).²⁰

SECTION 2

Lipids and Diet

TABLE 3: Summary of types of oils, content, and current evidence

	Evidence	Conclusion
Canola oil (MUFA-rich)	Canola oil reduces LDL-C but has no effect on HDL-C, lipid peroxidation, inflammation. But there are no data on CVD outcomes ¹⁰	Canola oil can be used as plant-based oil that is rich in unsaturated fat, to replace other fats
Coconut oil (SFA-rich)	Many Reviews have shown definite cholesterol-raising effect of coconut oil. There are no data on CVD outcomes ¹¹	Because coconut oil is rich in SFA, its use is not recommended
Sunflower oil (PUFA-rich)	Sunflower oil reduces LDL-C with no clear effect on HDL-C when replaced with other fats/oils ¹²	Sunflower oil is rich in MUFA and PUFA so can be used to replace other fats
Olive oil (MUFA-rich)	In the PREDIMED, a Mediterranean diet supplemented with extra-virgin olive oil reduced incident CVD by 30% compared with a lower-fat control diet	Extra-virgin (unrefined) olive oil is rich in MUFA and polyphenols and there is consistent evidence of its beneficial effect on CVD risk markers and CVD morbidity and mortality
Palm-oil (SFA-rich)	Meta-analysis of RCTs comparing palm oil to other vegetable oils demonstrates a cholesterol-raising effect ¹³	Of all vegetable oils, palm oil is among the highest in SFAs and, consequently, increases risk of CHD. Consumption should be discouraged
Mustard oil (MUFA-rich)	Collaborative study with USA, AIIMS, and St. Johns Medical College, Bangalore has proved that use of mustard oil as cooking medium reduces the risk of coronary heart disease by almost 70% in comparison to sunflower oil ¹⁴	Mustard oil is healthier than olive oil because it does not have trans FA, has low saturated fat and high in MUFA and PUFA such as ω-3FA and stable at high temperature which makes it ideal cooking oil and even deep frying oil

AIIMS, All India Institute of Medical Sciences; CHD, coronary heart disease; CVD, cardiovascular disease; FA, fatty acids; LDL-C, low-density lipoprotein cholesterol; HDL-C, high-density lipoprotein cholesterol; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; RCTs, randomized controlled trials; SFA, saturated fatty acids.

ANTIOXIDANTS—DO THEY HAVE ANY ROLE IN OUR DIET?

Antioxidant phytochemicals like flavonoids are richly concentrated in blueberries, strawberries, raspberries, red cabbage, red radishes, and eggplant (purple vegetables) and have potent anti-inflammatory properties.

Multiple subsequent randomized controlled trials (RCTs) of antioxidant supplements reported either neutral or negative results, including the GISSI trial of vitamin E, the Physicians Health Study of beta-carotene, and the National Institutes of Health (NIH)—AARP Diet and Health study of multivitamin supplementation (Table 4).

A process known as hormesis is hypothesized to explain the neutral or negative effects of excess antioxidant supplementation. Hormesis is a biphasic dose response to a stressor (toxic chemical, thermal, or radiological) in which a substance is beneficial at low doses but harmful at higher doses. Low doses of oxidant stressors induce endogenous antioxidant production that seems to be protective (Table 4).²¹

PROTEIN SOURCE—INDIAN FOOD/CUISINE IS HIGH IN CARBS, STARCH, AND FAT

If we look at veg high proteins—paneer/cottage cheese, milk, nuts are expensive. Second-grade vegetarian proteins are dals/lentils, green leafy vegetables are relatively cheap. Nonvegetarian proteins are eggs, chicken, fish which again are expensive (Table 5). Common Indian can't afford to consume them every day. So, carbs—roti/bread and rice—are consumed more to fill up your stomach.

TABLE 4: Vegetables and fruits in diet: Current evidence

	Evidence	Conclusion
Green-leafy vegetables	In the NHS and the HPFS it was found that 3 servings/ day of green leafy vegetables, combined with a low carbohydrate diet results in a 24% reduced risk of CVD ²⁰	Green-leafy vegetables (three servings daily) reduce the risk of incident T2DM and CVD
Antioxidant-rich fruits and vegetables	NHS II evaluated the relationship between anthocyanin intake and the risk of myocardial infarction during an 18-year follow-up ²¹	A 32% reduced risk of myocardial infarction was observed in those with the highest vs. lowest quintile of anthocyanin intake (especially blueberries and strawberries)

CVD, cardiovascular disease; HPFS, Health Professional's Follow-up Study; NHS, Nurses' Health Study; T2DM, type 2 diabetes mellitus.

TABLE 5: Role of protein from plant sources

	Evidence	Conclusion
Protein from plant sources	Participants from the Nurses' Health Study were studied from 1980 to 2012 and the Health Professionals Follow-up Study were studied from 1986 to 2012	Plant protein intake was associated with lower cardiovascular mortality (HR: 0.88 per 3% energy increment) ²²

HR, hazard ratio.

TABLE 6: Role of nuts in diet

	Evidence	Conclusion
Nuts	The PREDIMED RCT demonstrated that a high vegetable fat Mediterranean diet supplemented with mixed nuts at 30 g/day for 5 years, reduced CVD incidence by 30% compared with a lower-fat control diet ²³	Nuts are rich source of nutrients and also heart friendly and have favorable effect on fatty acid profile

CVD, cardiovascular disease; RCT, randomized controlled trial.

Concepts like “feed your children with more rotis only then they will get healthy” make our diet highly imbalanced.

Nuts—Do They Still have Bad Rap in Nutrition Circle?

While it is true that nuts are relatively energy dense, meaning that they contain a relatively high number of calories per unit weight. But they are actually an important part of a healthy diet. This paradox is because of satiating effect of nuts combined with incomplete digestion and reduction in metabolizable energy (Table 6).

Juices—Are They Really Elixir of Health in Present World?

Juicing of fruits and vegetables has gained popularity in modern world due to its ease and convenience. However, the process of juicing concentrates calories, which makes it much easier to ingest excessive energy. Though, phytochemical nutrients, such as lycopene, exhibit greater bioavailability in a liquid form versus the whole food, the clinical benefit of the same has not been proven yet. Hence, until more evidence come juicing primarily reserved for situations when daily intake of vegetables and fruits is inadequate.²⁴

Gluten-free Diet—Are They Really Beneficial in Providing Weight Loss?

Gluten-free diet comprises of rich amount of fruits and vegetables, legumes and dried beans, lean protein sources, nuts and seeds, low-fat dairy or nondairy alternatives of calcium and vitamin D, and healthy fats, including ω-3-fatty acids. There is no evidence that avoidance of gluten in diet by normal population will result in weight loss. There is limited information about CV outcomes benefit of this dietary pattern.²⁵

Dairy Products—Are They Enough to Meet Vitamin B12 Requirement?

Milk is an essential food item in Indian diet. The RDA of milk for Indian vegetarians is 300 g/day as compared to 200 g/day for nonvegetarians. In addition to milk, 80 g of meat, eggs or fish will provide rest of necessary vitamin B12. Although this recommended level of milk in lacto-vegetarians intake

will provide adequate quantities of protein (0.4 g), calcium (360 mg), vitamin A, many B vitamins, and minerals, but it will be deficient in vitamin B12 (0.45 µg as against the RDA of 1.0 µg).

Cow's milk is a good source of vitamin B12, with 100 g of the milk containing 0.5–1.0 µg of vitamin B12. One glass of cow's milk (250 g) provides 2.5 µg of vitamin B12, adequate to meet the RDA for an adult man. But, it has been shown that the dilution with water, storage or boiling (all of which are common household practices) may reduce vitamin B12 to 2.1 µg (21% decrease).²⁶

SUSCEPTIBILITY OF INDIANS

Small Body Frames

Salt and sugar are easily absorbed and get distributed in the total body water. Therefore, the amount consumed per drink/meal, per day needs to be matched with the body water content. The usual content of sugar in Indian diet is often high, which necessitates an intense insulin response to maintain euglycemia. Such diet which is high in sugar, when consumed by children may not have any immediate clinical manifestations, but led to early onset of dysglycemia in adult life.²⁷

Postprandial Metabolic Issues

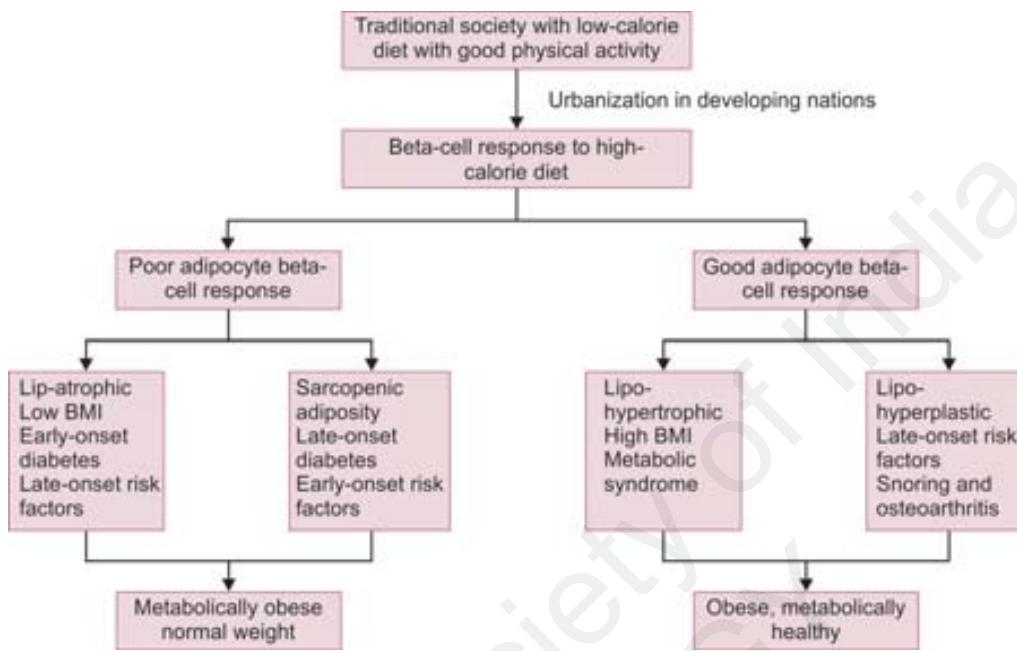

Postprandial lipid abnormalities and oxidant stress are preventable components of dietary modification. Insulin response of food depends upon route, i.e., enteral versus par enteral and race. Indians have more intense plasma insulin levels in response to an oral glucose load compared to Europeans.²⁸

Sarcopenic Adiposity

Sarcopenic adiposity refers to the situation of less muscle mass and more adipose tissue for the same body mass index, which is a risk factor for the premature onset of cardiovascular risk factors. Smaller body volume of Indians necessitates a hyper insulinemic response which is further intensified by the insulin resistance caused by sarcopenic adiposity. This vicious cycle of intense hyperinsulinemia is a reason for the early onset of all the risk factors at a low body mass index in Indians noted in various studies (Flowchart 1).²⁹

PREVENTIVE MEASURES TO REDUCE THIS EPIDEMIC

- Try to reduce intake of fried fast-food and processed foods
- Try to include variety of oils (extra virgin olive oil, canola, peanut, unrefined mustard oil) and foods containing natural fats (nuts, seeds, avocado, olives, soy, fish) in your diet. And use oil rich in SFA as ghee for deep frying which is common in India
- Emphasize on low-fat or nonfat dairy products
- Increase the amount and variety of plant foods consumed—eat more unrefined vegetables, fruits, and

FLOWCHART 1: The spectrum of body response to diet and physical activity.

wholegrain cereals. Reduce intake of refined sources of carbohydrates with higher glycemic indices

- Increase consumption of legumes (like baked beans, soybeans, lentils and tofu) in your diet
- Have a handful of a variety of raw, unsalted nuts on most days of the week, especially walnuts and almonds
- Eat oily fish at least once per week
- Check consumption of alcohol less than two drinks per day
- Avoid visible fat in your meal
- Avoid added salt in your food
- The increased consumption of high-salt, high-SFA, high-energy processed foods promoted by large industries led to detrimental effect on cardiovascular health. There is a need to address these concerns and find sustainable solutions
- The production of oils for mass consumption, with respect to SFA, MUFA and PUFA content as well as preferential pricing of low-SFA oils are areas of policy which need early attention and action.

CONCLUSION

Choose your food wisely and stay healthy

Things to be included:

- MUFA-rich oil like mustard oil and olive oil
- Daily serving of nuts
- Green leafy vegetables and fruits
- Plant-based proteins
- Blueberries and strawberries
- Southern diets (added fats and oils, fried foods, eggs, organ and processed meats, sugar-sweetened drinks).

Things to be avoided:

- Coconut oil and palm oil rich in SFA
- Juicing should be avoided
- Animal based protein should be restricted
- Antioxidant supplement have no clear benefit
- Gluten free diet as a diet to reduce weight.

Edible Oils: What is Right and What is Wrong?

Sonia Arora, Vitull K Gupta, Meghna Gupta

INTRODUCTION

During the past decades, the world, particularly the developing countries like India have witnessed rapid changes in diets and lifestyles. General improvement in the standard of living has been accompanied by unhealthy dietary patterns and insufficient physical activity resulting in increased prevalence of lifestyle and diet-related chronic diseases worldwide. WHO states that by 2020 the place of the largest causes of death and disability will be occupied by cardiovascular diseases (CVDs) and prevalence of obesity, type 2 diabetes mellitus (T2DM) and hypertension (HTN) which are considered to be chronic diseases related to the diet and lifestyle is also increasing.

Diet includes foods and nutrients which provide energy and are essential for normal metabolism, physiologic and biochemical processes, growth and physical well-being. Diet essentially comprises of macronutrients like proteins, carbohydrates, fats, and micronutrients like vitamins and minerals which are required in small quantities. Triglycerides (TGs) are components of fat comprising of esters of alcohol glycerol and fatty acid (FA) chains. Generally, the words "lipids", "oils", and "fats" are used interchangeably. Fats that are liquid at room temperature are called "oils" and generally have unsaturated or short FA chains. Word "fats" broadly means solid fats at room temperature and word "lipids" include all oils and fats in general. Fat supplies more than double the calories as compared to carbohydrate or protein making it an important dietary component with concentrated source of energy. Fat intake gives taste to diet, is metabolically important constituent of the body, helps absorption of fat soluble vitamins A, D, E, and subcutaneous fat helps insulates the body.

COMPOSITION OF FATS¹

Fats or lipids consist of FAs which are of two types as discussed here.

Saturated Fatty Acids

Saturated fatty acids (SFAs) are saturated with hydrogen atoms as carbon atoms have no double bonds in the fatty acid chain comprising of lauric acid, palmitic acid, and stearic acid which provide stability to saturated fats (SFs) and are usually solid at room temperature because single bonds between the carbon atoms are more stable than double bonds. Fat intake increases total cholesterol (TC) and low-density lipoprotein (LDL) cholesterol which is an important risk factor for cardiovascular diseases (CVDs), certain cancer and also impairs insulin sensitivity. SFAs are present in milk products (cream, ghee, butter, khoya, and paneer), animal tallow, palm oil, coconut products, and oil, etc. Results of ecological studies investigating the relation of coronary heart disease (CHD) to dietary intake of SFs suggested that development of CHD was related to higher intake of total fat content and SFs. In a study, it was seen that percentage of calories intake comprising of SFs was correlated strongly with coronary death rates in several defined populations in seven countries.²

Moreover correlation between the CHD incidences was weaker when compared to percentage of calories from total fat. Analysis of follow-up data from Nurses' Health Study showed that a 5% of calories from SF were associated with 17% more risk of CHD as compared to ingestion of equivalent percentage of calories from carbohydrates. Dietary intake of short- and medium-chain SFAs was shown to have insignificant CHD risk where as small CHD risk was observed with intakes of longer-chain SFAs.³ Different SFAs have different effects on plasma lipid and lipoprotein levels that increase total plasma cholesterol and LDL cholesterol levels were observed with SFAs containing 12–16 carbon atoms.⁴

Unsaturated Fatty Acids

Unsaturated fatty acids (USFAs) comprise of monounsaturated fatty acids (MUFA) and polyunsaturated fatty acids (PUFA). MUFA contain one double bonds and PUFA contain more than one double bonds within the fatty acid chain.

Monounsaturated Fatty Acids

Lipid peroxidation occurs to a lesser degree in MUFA as compared to PUFA as MUFA contain one double bond only, e.g., oleic acid, erucic acid. Studies have shown decrease in total mortality and CHD deaths with increased intake of MUFA.⁵ It is suggested that MUFAs are useful because it helps decrease free cholesterol by promoting cholesterol esterification in liver, promote receptor-mediated LDL uptake, lower LDL, and increase high-density lipoprotein (HDL). Recent evidence stresses on exploring the role of SFA, PUFA, and MUFA ratio in diet and intake of individual fat components as they influence LDL/HDL ratio and lipoprotein metabolism. Dietary sources of MUFA include almonds, peanuts, fruits like olives and avocados, olive oil, rice bran oil (RBO), groundnut oil, canola oil, and mustard oil.

Polyunsaturated Fatty Acids

Polyunsaturated fatty acids have a carbon–carbon double bond in a final N-6 position and are prone to lipid peroxidation because it has greater number of double bonds. Examples are linoleic acid, linolenic acid, arachidonic acid, eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA). Dietary sources include invisible fats present in pulses and cereals, sunflower oil has 50% PUFAs, corn oil 60%, cottonseed 50%, and safflower oil contain 70% PUFAs.

Results of another study suggested a substantial reduction in CHD risk when trans fat (TF) were replaced by polyunsaturated fat in the diet or other foods high in trans fatty acids (TFAs).⁶

Omega-3 and Omega-6 Fatty Acids

Omega-3 [α -linolenic acid (ALA), N-3] and omega-6 (linoleic acid) fatty acids are unsaturated “essential fatty acids” (EFAs) because human metabolism cannot create them.

Omega-6 Fatty Acids (Linoleic Acid, N-6)

At N-6 position there is double bond between carbon–carbon atoms and more number of double bonds make omega-6 fatty acids more prone to lipid per oxidation. Omega-6 fatty acids (N-6) are also important for health. PUFA intake decreases LDL and increases insulin sensitivity. A study concluded that a significantly lower incidence of type 2 diabetes mellitus (T2DM) was associated with higher intake of N-6 and substantial reduction of CHD risk was observed when long chain SFs was replaced by polyunsaturated fat.⁷ But the beneficial effect of N-3 is reduced by intake of more quantity of N-6. Dietary sources include invisible fat in cereals and pulses, margarine, safflower oil corn oil, sunflower oil, kardi oil, etc.

Omega-3 Fatty Acids(Alpha-Linolenic Acid, N-3)

N-3 consists of double bond at N-3 carbon atom and is precursors to anti-inflammatory products in the body. Dietary sources include legumes, green leafy vegetables, citrus fruits, nuts, and fish, especially fatty fish. Mustard oil has 6–11% of N-3, canola/rapeseed 7%, hemp oil 20%, flax (linseed) oil has 55%, the richest plant-based source. Hemp

and flax oils are not commonly used as table or cooking oil. Most of the N-3 available from plant sources is in form of ALA. Decrease platelet aggregation and formation of proaggregatory thromboxane A₂ was observed when dietary consumption of ALA was increased.⁸ Several epidemiologic studies showed that increase in linolenic acid intake was associated with a decreased risk of CHD mortality^{9,10} but in these studies other dietary factors like dietary vitamins, other fats, vegetables, and folate were not adequately adjusted. Based on strong data to support favorable effect of N-3 on prevention of CVD, it was suggested that diet rich in N-3 can be beneficial.¹¹ Evidence suggested that the protective effects of fish oil based N-3 may involve multiple mechanisms, like decreasing TG levels, reducing platelet aggregation, antiarrhythmic effects, improving endothelial dysfunction so decreasing atherosclerosis as well as improving endothelial-dependent vasomotor function.¹²

Omega 6 (N-6) to Omega 3 (N-3) Ratio

Balanced ratio of N-6 and N-3 is important for efficient body functions. N-6 and N-3 are converted into biological active components by competing for the common enzymes so when one component is consumed more than the other, it leads to imbalance in the metabolism of N-6 and N-3 gradually affecting several metabolic processes. Recommendations suggest that level of adequate intake of N-6 and N-3 depends on several factors like age, gender, and life style, etc. and several organizations have recommended different ratios like N-6:N-3 of 4:1 (Institute of Medicine) 5:4 (World Health Organization) and several suggest that ratio near 1:1 may be considered as optimal ratio.¹³ Several foods are good sources of both N-6 and N-3 and ratio may be different like N-6:N-3 ratio is 4:1 in walnuts, 1689:1 in almonds. In green leafy vegetables the ratio is less than 1, so to improve the ratio several food combinations are suggested to get the ratio of at least 10 to 1. The best N-6:N-3 ratio was found in mustard oil (1.2:1) and canola oil (2.2:1) and adverse ratio was found in olive oil (12.84), corn oil (46.01), and peanut butter (225.63).

TRANS FATTY ACIDS OR PARTIALLY HYDROGENATED FATTY ACIDS

Incomplete hydrogenation of vegetable oils results in formation of TFs and complete hydrogenation results in formation of SFs. TFs may confer texture to food and structural stability. Lamb and beef contain small quantity of natural TFAs. A review suggested that even low consumption of 1–3% of total calorie intake of TFs leads to increased risk of coronary artery disease (CAD) and TFs are more dangerous to CV health than any other macronutrient even on a per-calorie basis.¹⁴ Increased intake of TFs can increase the risk of CVD because it can lead to increase in LDL, TGs, lipoprotein (a) and decrease in HDL adversely affecting metabolism of EFA and prostaglandins promoting thrombogenesis and insulin resistance.¹² In a land mark study, it was found that the risk of CAD nearly doubled with 2% increase in intake of TF calories and to produce similar risk of CAD about 15%

increase in SF calories were required. It was found that risk of CHD decreased by more than half (53%) by replacing 2% of food energy from TFAs with nontrans unsaturated fats.³ Sources of TFs include dalda and vanaspati ghee, margarines, baked foods, readymade mithais and processed foods, and ready to eat snacks.

CHOLESTEROL

Cholesterol, an essential component of animal life, is found in animal fats including dairy products and nonvegetarian foods. Chemically cholesterol is a waxy sterol of fat. Very small amount of cholesterol is present in plants so generally plant oils are devoid of cholesterol. It is thought that absorption of cholesterol from intestine is decreased by phytosterols, a plant product because both phytosterols and cholesterol compete with each other for absorption in intestine. It is recommended to restrict the cholesterol consumption to less than 200 mg by decreasing animal fat consumption. Adverse effects of increased consumption of cholesterol are because it increases TC and LDL¹⁵ but the adverse effects are relatively less as compared to increased consumption of SFAs and TFAs¹⁶ and different individuals responded very differently to the effects of dietary fats.¹⁷ Cholesterol broadly is of two types, LDL and HDL. LDL is considered as "bad cholesterol" responsible for atherosclerosis and CAD whereas HDL is "good cholesterol" help prevent and retard progression of atherosclerosis.

Ghani

Ghani is a traditional method of oil processing in India in which oilseeds and subsequently the expressed oil are held in a scooped circular pit in the exact centre of a circular mortar made of stone or wood with a stout, upright pestle descending from a top curved or angled piece, permitting the pestle to rotate as the animal moves in a circular ambit, exerting lateral pressure on the upper chest of the pit, first pulverizing the oilseed and then crushing out its oil. There are regional variations in ghani design in India like large graniteghanis of Southern India (capacity 35–40 kg), wooden ghani of Western India (capacity 8–15 kg), Bengal ghani (capacity 5–10 kg), and Punjab ghanis (small capacity with a short pestle). Sesame, rapeseed, mustard, coconut, groundnut, and safflower oils were produced from mild ghani crushing and oils produced are known as "Kachi Ghani ka Tel".

Cold Pressed Oils

Cold pressed oils are called when ancient methods of hydraulic press is used to produce oils and oils such produced are in natural state retaining natural odor, taste, color, flavor, and nutrition. This process avoids exposing the oil to chemical solvents or high temperatures during extraction.

Refined Oils

Refined oil are produced using mechanical and chemical extraction methods from seeds and vegetable products and

these methods affect taste, destroy antioxidants, generate free radicals and are more susceptible to turn rancid but refined oils are relatively pure.

Unrefined Oils

Oils which are extracted from seeds or other vegetable material by exerting continuous pressure at high temperature of 200–250 °C are called unrefined oils and these are different from "cold pressed" oils called "expeller pressed" oils. Unrefined oils retain antioxidants, other nutrients, and flavor; so these oils are considered better and recommended for use.

Rancidity

Rancidity is the term used for development of unpleasant odor or flavor in fats and oils. Rancidity is classified according to the method of its production like hydrolytic, oxidative, and ketonic.

Smoke Point or Flash Point

Smoke point is the temperature at which decomposition and nutritional degradation of fats or oils occur resulting in formation of glycerol, free fatty acids (FFA), and bluish smoke giving an unpleasant and disagreeable flavor to the food. So, it is an important factor while selecting the oils required for heating that is use oils with higher smoke point for deep frying. Different oils have different smoke points depending on the origin and refinement of oils.

Flash point is the temperature much higher than the smoke point at which the vapors from oil can ignite when mixed with air. Dietary fat studies showed that when heated PUFA containing oils like soya, canola, sunflower, and corn oil degrade easily to toxic compounds.

WHAT ARE EDIBLE OILS?

Fatty acids triesters with glycerol which are in liquid form at room temperature are the class of lipids known as oils and are generally found in both plants and animals. TGs that are solid or semisolid at room temperature are classified as fats and occur predominantly in animals. Any material which has an oily or greasy feel and cannot be mixed with water is called "oil". Edible oils include oils used for cooking which involves heat as well as used in food preparation and flavoring not involving heat, such as salad dressings and bread dips.

WHAT IS RIGHT AND WHAT IS WRONG OIL?

Out of numerous available oils, which oil is the right oil or the wrong oil to use depends on the purpose of their use like cooking, deep frying, shelf-life of oil or other specific qualities or flavor determine the preference for use of that oil. More important is the health benefits which depend on fat composition of various oils, ratio between SFA, MUFA, and PUFA.

CHARACTERISTICS OF DIFFERENT OILS¹⁸

Mustard Oil

It is economical, vegetarian oil with characteristic pungent aroma and hot nutty taste, popularly used in East and North India containing 70% MUFA (42% erucic and 12% oleic acid), 22% PUFA (10% N-3 and 12% N-6), and 8% SFAs. Evidence suggests that mustard oil, which was previously thought to be harmful because of high erucic acid content, is now considered as one of the best as it has near ideal N-6:N-3 ratio of 6:5 and contains low SFAs and high MUFAs and PUFA along with high amount of antioxidants. "Kachi Ghani" or cold-pressed mustard oil retains the natural properties and nutritional values of mustard. Studies indicate a dose-dependent benefit of intake of vegetables or use of mustard oil on ischemic heart disease (IHD) risk. The risk was lower with the use of mustard oil for frying as compared to the use of sunflower oil and risk decreased by about 70% when cooking medium was mustard oil.^{19,20}

Rapeseed Oil (Canola Oil)

It is produced from plant belonging to *Brassica* family which is related to mustard plant and is known as "canola oil" after the term "Canadian oil". It has high MUFA and low SFA (<7%) contents with favorable N-3 levels and considered health oil by various associations and organizations.²¹

Olive Oil

As the name indicates olive oil is extracted from olives and considered to be the best oil as it has 75% MUFA and numerous useful antioxidants (hydroxytyrosol). High levels of MUFA and antioxidants (oleuropein or tyrosol) are present in extra virgin or virgin olive oil which is produced by minimum processing and intake of MUFA is known to decrease LDL and increase HDL, exerts anti-inflammatory, antithrombotic, antihypertensive and vasodilatory effect which may decrease CAD risk.^{13,22} Epidemiological evidence suggests that antioxidants (oleuropein or tyrosol) have beneficial effect against some cancers, increases arterial elasticity, and decreases risk of stroke and IHD.²³ Big disadvantage is its unfavorable N-6:N-3 ratio.

Soyabean Oil

This oil is one of the most commonly used cooking oils which is rich in SFAs (51% linoleic acid, 23% oleic acid, and 7–10% α -linolenic acid) and 10% palmitic acid and 4% stearic acid (SFAs). Soyabean oil should be used fresh because it tends to turn rancid earlier. It is suggested that to achieve the combination of high PUFA and MUFA contents by combining the oils rich in MUFA or PUFA like olive oil, mustard oil or groundnut oil to achieve optimum health benefits.

Rice Bran Oil

It is produced from rice husk and germ and contain 47% MUFA, 33% PUFA, and 20% SFA making it oil with most favorable constituents rich in phytosterols, γ -oryzanol, and vitamin E. Vitamin E and γ -oryzanol are powerful antioxidant and help in prevention of IHD.²⁴ Phytosterols helps to decrease absorption of cholesterol absorption imparting health benefits. Its mild flavor and high smoke point (254°C) makes it useful for deep frying. Only disadvantage is unfavorable N-6:N-3 ratio of 23:1.

Sunflower Oil

It is a good cooking medium with clean taste and has high PUFA, low SFAs and low TFs with high contents of waxes, carotenoids, lecithin, and tocopherols. Sunflower oil has high levels of N-6 and unfavorable N-6:N-3 ratio of 120:1. Moreover evidence of health benefits of high N-6 intake is limited.

Cottonseed Oil

It is economical, stable for frying, has long shelf-life because of natural rancid-free property and contains 18% MUFA, 52% PUFA with naturally occurring SFAs (myristic, palmitic, stearic acids) thereby called as "naturally hydrogenated" oil. Its very high SFA and very low MUFA contents make its health benefits controversial.²⁵ Moreover because of excessive use of agrichemicals, cottonseeds and so cottonseed oil tends to contain high levels of pesticides, which may cause adverse health effects. It is commonly used in various types of processed and snack foods.

Corn Oil

Germ of corn is used to extract corn oil (Maize oil) which contains 55% PUFA, 30% MUFA, and 15% SFA. It is cheap and because of high smoke point useful for frying purposes. Its increased level of N-6 as compared to N-3 may cause or predispose to some disease and depression.

Groundnut Oil

Groundnut oil has a pleasant taste, high smoke point and contains 56% MUFA (oleic acid), 26% PUFA (linoleic acid), and 8% SFA (palmitic acid) which makes it cardiac friendly oil because it rich in MUFA and a balanced oil.

Safflower Oil

Safflower oil has high smoke point favorable for frying and contains low SFAs (6%), low MUFA (13%), and high PUFA (76%). It is not considered healthy oil because its consumption may decrease TC, LDL as well as HDL cholesterol. Other disadvantage is that PUFA may turn rancid or toxic on exposure to high temperatures.

Palm Oil

Fruits of palm are used to extract palm oil which is economical and has high smoke point making it favorable for frying.

Cardiac benefits of palm oil are controversial as it contains 48% SFAs and unfavorable N-6:N-3 ratio of 20:1. Palm oil was shown to be unsafe substitute for TF in the food industry as it can lead to adverse changes in LDL cholesterol and apolipoprotein B levels like changes done by TAs.²⁶ Red palm variety of palm oil is rich in carotenes like coenzyme Q10, glycolipids tocotrienols, tocopherols, and phytosterols.

Coconut Oil

Coconut oil is a plant fat extracted from coconut fruit and contains high levels of SFAs (90%) very little PUFA, MUFA, no cholesterol, vitamin E, vitamin K, and minerals such as iron. Coconut oil is primary oil used by tropical people and its SFAs consist of lauric acid which differs from SFAs of animal origin. SFAs in coconut oil mostly consist of the medium chain TGs and may not impart same risks as other SFAs.²⁶ Lauric acid is responsible for increasing HDL levels and thereby increases TC.

Sesame Oil (“Til ka Tel”)

Sesame oil is a vegetable oil extracted from the seeds of sesame plant, one of the oldest plants used for the extraction of oil. In developing countries like India, less expensive and manual methods like hot water flotation, bridge presses, ram presses, the ghani process or small-scale expeller are used to extract oils whereas in advanced countries expeller press, larger-scale oil extraction machines, or by pressing followed by chemical solvent extraction are used. Cold pressing is popular method because it avoids chemical solvents or high temperature exposure during oil extraction and traditional methods like ghani help retain the pleasant taste, nutrients, and flavor. It is used as edible oil and for various other health benefits like skin care, hair care, anti-aging characteristics, alternative medicine, traditional massages, etc. Sesame oil is composed of almost equal amount of MUFAs (39% oleic acid) and PUFAs (41% linoleic acid) with remaining amount composed of SF (8% palmitic acid and 5% stearic acid). It is rich in vitamin K. It has high smoke points and it is least prone to turn rancid due to presence of natural antioxidants, such as sesamol. Sesame oil is most popular in states of Karnataka, Andhra Pradesh, and Tamil Nadu.

Linseed or Flaxseed Oil (Alsi ka Tel)

Linseed oil is an edible oil which is colorless to yellowish obtained by pressing or sometimes followed by solvent extraction from the dried, ripened seeds of the flax plant (*Linum usitatissimum*). Raw cold-pressed linseed oil is easily oxidized and rapidly becomes rancid generating an unpleasant odor, unless refrigerated, has a short shelf-life of only a few weeks making it less desirable for use as cooking oil. It is composed of 9–10% of SFAs (6% palmitic and 4% stearic), about 20% MUFAs (mainly 20% oleic acid), and more than 70% PUFAs (70% α -linolenic fatty acid). Several studies suggested that primary benefit of flaxseed oil is because of ALA and it exerts dose-dependent effects on inflammatory mediators and markers.²⁷

Numerous studies analyzing epidemiological investigations and experimental data have shown the ability of increased omega-3 fatty acid intake to help regulate and reduce blood pressure in hypertension and diet low in SFs and rich in monounsaturated and polyunsaturated fats from flaxseed has been demonstrated to combat CVD.²⁸ Healthy properties are related to anti-inflammatory, antioxidant, anticarcinogenic activities and to the lowering of cholesterol, the decrease of CVD and the prevention of diabetes. Linseed oil is a drying oil that is, it can polymerize into a solid form, due to which it is used with combinations of other oils, resins or solvents as an impregnator, drying oil finish or varnish in wood finishing, as a pigment binder in oil paints, as a plasticizer and hardener in putty and in the manufacture of linoleum.

Butter

Butter is from animal source with high contents of cholesterol and SFAs. Butter can increase total, LDL and HDL cholesterol and its low smoke point makes it unfavorable for deep frying.

Ghee

Ghee is made by clarifying butter which has high smoke point making it favorable for frying.

Vanaspati Ghee

Vanaspati ghee is made by hydrogenation of refined vegetable oil. Hydrogenation increases TFAs, makes it less likely to turn rancid, more stable, increases shelf-life, but it does not contain bioactive compounds, natural vitamins or antioxidants and because of low smoke point it is not favored for deep frying. It is considered to be responsible for development of IHD because of its adverse lipid profile.

CHOOSING THE RIGHT OIL

Properties of cooking oil like fatty acid contents, micro-nutrients, shelf-life, smoke point, etc. are helpful in selection of right cooking oil. Among the available cooking oils, none of it fulfills the recommended profile because if oil has high MUFA which is desirable, it may not have desired N-6:N-3 ratio or appropriate ratio of MUFA, PUFA, or SFAs. So, it is recommended to rotate or blend the oils like mustard oil, groundnut oil, canola oil, RBO, etc. to achieve the desired lipid contents.

WHY ROTATION OR BLENDING IS NEEDED?

Evidence suggests that CV health is greatly influenced by dietary fat profile and type of fat affects the lipid profile of the individual increasing or decreasing the CVD risk. TC and LDL cholesterol are increased with increased intake of SFs. Intake of PUFA greatly reduces the CVD risk as compared to MUFA.² Intake of TFAs formed during partial hydrogenation of fat,

increase LDL cholesterol, and decrease HDL cholesterol.²⁹ CVD protection is imparted by both N-6 and N-3. N-6 predominantly lowers LDL cholesterol and N-3 lowers TGs. N-3 is cardioprotective through various mechanisms like vasodilation, antiarrhythmic effect, anti-inflammatory effects, improves endothelial function, decreased platelet aggregation and reduces collagen deposition.³⁰ That is why it is important to have optimum composition of these fats to achieve health and cardioprotective effects. Numerous health and dietary bodies have issued guidelines suggesting various recommendations regarding fatty acid intake. Guidelines for prevention of CVD have suggested 8–10% SFAs of total calories, 5–8% PUFAs, and rest of the total calories are constituted by MUFA with ratio of PUFA:SFA to be about 0.8:1 and for PUFA comprising of both omega-6 and omega-3 in ratio 5:10.⁴ Favorable ratio of SFA:MUFA:PUFA comes out to be 1:1.5:1 if maximum amount of total fat intake is taken into consideration.³¹ American Heart Association (AHA) cardioprotective recommendations include intake of less than 7% of saturated fat, less than 1% TF of total calorie consumption and less than 300 mg cholesterol per day. AHA suggests an important role of oils and fats in total dietary fat intake.³² Evidence suggests that different lipid components have different favorable and adverse health effects. Even blending two cooking oils cannot fulfill the recommended ratio of different lipid components for favorable health and CVD effects, necessitating the need to blend more than two cooking oils to achieve desired lipid contents for health benefits.

CONCLUSION

In this present era of consumerism, people are exposed to different type of edible oils glorified with tall health claims and benefits, advertising various cooking oils with attractive slogans, highlighting presence or absence of different lipid contents to influence people's choice of cooking oils. This chapter discusses various lipid contents, their harms and health benefits, desired composition of different lipid contents and composition of different edible or cooking oils in an attempt to demystifying the fancy statements for all the people. Out of the discussed edible oils, none of the oils fulfill the recommended criteria of lipid contents but two oils rapeseed and mustard oil which have high PUFA and MUFA, low SFA content and highest N-3:N-6 ratio seems to be imparting most health and CVD benefits. Evidence suggests use of ghee and butter as a cooking oil should be limited and use of reheated fats and oils should be avoided. Since none of the available cooking oils fulfill the criteria of various lipid contents, it is desirable to blend or rotate different cooking oils like mustard oil, groundnut oil, canola oil, and RBO with favorable lipid contents and limit the use of visible fat content for achieving desired favorable CV and overall health benefits.

Statins and Diabetes

Rajeev Bagarhatta, Sohan K Sharma, Dinesh Gautam

INTRODUCTION

In diabetes, clinical atherosclerotic cardiovascular diseases (ASCVD) like coronary artery disease (CAD), stroke, and peripheral artery disease is common due to increased tendency of generalized atherosclerotic macrovascular disease process.¹ ASCVD is the leading cause of morbidity and most common cause of mortality in diabetes and accounts for nearly 52% of deaths in type 2 diabetes (T2D) and 44% in type 1 diabetes (T1D).²

Although diabetes itself is risk factor for CVDs, other coexisting conditions like smoking, hypertension, dyslipidemia, premature CAD in family members, presence of albuminuria and chronic kidney disease are also important risk factors that need to be systematically addressed annually in all patients of diabetes. Among above mentioned risk factors dyslipidemia is common in diabetes. It consists of low high-density lipoprotein (HDL), increased triglycerides (TGs), and postprandial lipemia. Even if lipid profile is within normal range in diabetics functionally abnormal lipids like small dense low density lipoprotein (sdLDL) and dysfunctional HDL are not uncommon.

It is well-known fact now that besides glucose control global risk factors modifications like cessation of smoking, adequate blood pressure control, and cholesterol lowering prevent or slow progression of CVDs in diabetes.² Since, dyslipidemia is a major contributor of this CV mortality and morbidity, its control is important target to be addressed.

PATOPHYSIOLOGY OF DYSLIPIDEMIA IN DIABETES

The management of dyslipidemia in diabetes essentially requires the understanding of the pathophysiology of lipid derangement in diabetes.

The lipid abnormalities in T2D consists of high TGs, decreased HDL cholesterol, and presence of sdLDL cholesterol and it leads to accelerated atherosclerosis. In T1D increased TGs are common, but HDL cholesterol is normal

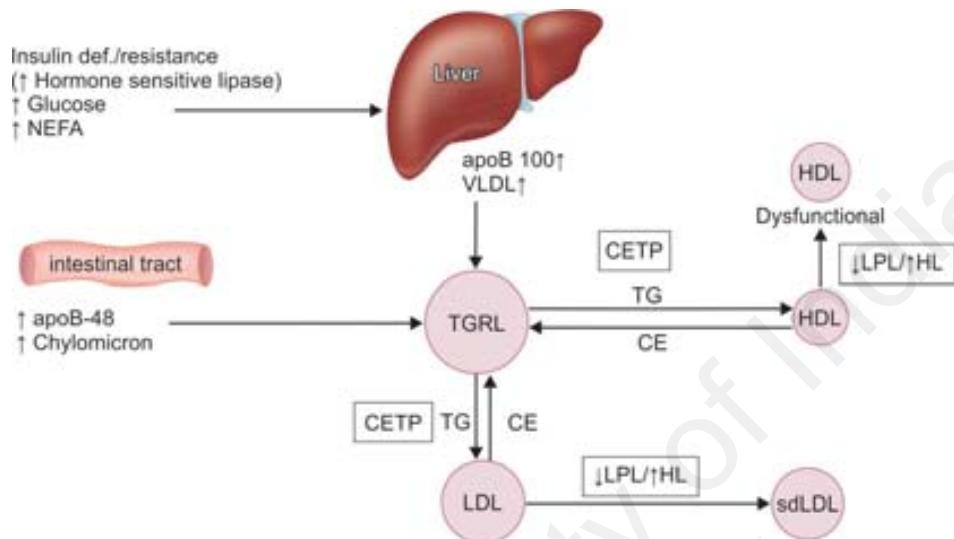

or high if hyperglycemia or albuminuria is present. In addition to above mentioned quantitative lipid abnormalities functional dysfunction of all lipoproteins is seen in diabetes. In diabetes because of insulin deficiency or resistance abnormal function of various intermediary enzymes leads to hypertriglyceridemia, low or dysfunctional HDL, and sdLDL (Fig. 1). Insulin deficiency or resistance activates hormonal sensitive lipase in centrally distributed adipose tissues which leads to increase release of nonesterified fatty acids (NEFAs) from stored TGs. High level of NEFAs in circulation results in increased uptake by liver and in turn hepatic TG overproduction and increased secretion of apolipoprotein B100. Both TG overproduction and increased apolipoprotein B100 secretion result in increased secretion of very-low-density lipoprotein (VLDL) that are rich in TGs and further catabolism of VLDL is also impaired leading to increased VLDL concentration in circulation.³

Decreased activity of lipoprotein lipase located on vascular endothelial cells in insulin deficiency or resistance contributes to postprandial lipemia. Circulating LDL can participate in cholesterol ester transfer protein (CETP)-mediated exchange of its cholesterol esters for TGs rich lipoproteins viz. chylomicrons and VLDL which generates TGs rich and cholesterol esters depleted LDL particles by lipoprotein lipase action, produces sdLDL that is more atherogenic.⁴

The process of reverse cholesterol transport from peripheral tissues is important function of HDL, but because of CETP-mediated exchange of core lipids is increased and HDL cholesterol is also TG rich. It further converts into small, dysfunctional HDL particles due to increased hepatic lipase activity in diabetes and it is no more protective.

MANAGEMENT OF DYSLIPIDEMIA IN DIABETES

In lipid management of diabetes, an important tool of treatment includes lifestyle intervention and drug

apo, apolipoprotein; CE, cholesteroyl ester; CETP, cholesteroyl ester transfer protein; HDL, high-density lipoprotein; HL, hepatic lipase; LDL, low-density lipoprotein; LPL, lipoprotein lipase; NEFA, nonesterified fatty acid; sd-LDL, small dense-low-density lipoprotein; TG, triglyceride; TGRL, triglyceride-rich lipoprotein.

FIG. 1: Effects of diabetes on triglyceride-rich lipoproteins, HDL, and LDL. Increased availability of glucose and nonesterified fatty acids in the liver leads to decreased degradation of apoB100 and increased secretion of VLDL. In the post prandial state, apoB-48 and chylomicrons contribute to overabundance of triglyceride-rich lipoproteins in blood. CETP facilitates the exchange of triglyceride and cholesteroyl esters between triglyceride rich lipoprotein and LDL as well as HDL. Subsequently triglyceride-rich LDL and HDL are hydrolyzed by hepatic lipase leads to production of small dense LDL and dysfunctional HDL.

treatment. Among drugs, statin is the only drug recommended in diabetic dyslipidemia. Fibrates and niacin are not recommended in standard guidelines.⁵⁻⁷ If the LDL cholesterol is still high (≥ 70 mg/dL) on maximally tolerated statin dose, ezetimibe and proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors can be added.

Monitoring of Lipid Profile Status

For adult with diabetes and not on lipid lowering drugs, fasting lipid profile should be estimated at the initial evaluation and repeated every 5-year or more frequently if required, in patients with age less than 40 years. The patients of more than or equal to 40 years with diabetes are usually on guideline directed statin therapy, hence the lipid profile estimation should be done before starting the patient on statin and 4–12 weeks after initiation or change of the dosing of the drug and yearly thereafter.

Lifestyle Modification

The modification of lifestyle entails motivation of the patients for increased physical activity, weight loss, and above all medical nutrition therapy. Emphasis should be laid on decreased intake of saturated fats, trans-fats, and cholesterol while encouraging the patients for increased intake of viscous fibers (e.g., legumes, citrus fruits, and oats), omega-3 fatty acids, and plant sterols. These nutritional interventions are customized keeping the associated medical conditions, lipid status, type of diabetes, and patient's age in mind. In subjects with high TGs (≥ 150 mg/dL) and low HDL cholesterol

(<40 mg/dL for males and <50 mg/dL for females), a good control of sugar has a beneficial effect on the plasma lipid status.

Initiation of Statin Therapy as per Risk Stratification

It is beyond doubt that because of increased prevalence of lipid derangements, T2D patients have higher incidence of clinical ASCVD and statin therapies in this subgroup of patients as per multiple clinical trials and meta-analysis of over 18,000 patients have shown significant reduction in CVD events and CAD-related mortality.⁸⁻¹²

In agreement with these recommendations statins form the drug of choice for cardio protection. As mentioned in Tables 1 and 2), there are two statin dosing intensities that are to be used in clinical practice.

It is known that the reduction with statin therapy in the coronary heart disease deaths and nonfatal myocardial infarction is maximum in patients with the highest number of risk factors but at the same time the statin therapy has overall benefit in patients with diabetes who are having a moderate or low-risk of CVD.¹³

The diabetic patients are risk stratified as per the presence or absence of documented clinical ASCVD and are respectively advised to receive secondary or primary prevention therapy. It is obvious that patients with clinical ASCVD are at higher risk and warrant high-intensity statin therapy as documented in multiple large randomized clinical studies.¹⁴

TABLE 1: Statins and additional drug treatment in diabetic patients*

Age	Clinical ASCVD [◊]	Recommended treatment [¶]
<40 years	No Yes	No statin required [#] High-intensity statin: Add ezetimibe or PCSK 9 inhibitors if LDL cholesterol ≥ 70 mg/dL despite maximally tolerated statin dose
≥ 40 years	• No • Yes	• Moderate-intensity statin [†] • High-intensity statin: Add ezetimibe or PCSK 9 inhibitors if LDL cholesterol ≥ 70 mg/dL despite maximally tolerated statin dose

*In addition to lifestyle modification.

[#]maximally tolerated dose of statin to be used, if patients not able to tolerate intended intensity.

[◊]Clinical ASCVD include coronary artery disease, stroke, and peripheral artery disease. Other cardiovascular risk factors include smoking, high blood pressure, LDL cholesterol ≥ 100 mg/dL, albuminuria, chronic kidney disease, and family history of premature ASCVD.

[†]Moderate-intensity statin can be started after discussing the risk-benefits and patient preference if above mentioned other cardiovascular risk factors are present.

[‡]High-intensity statin can be started after discussing the risk-benefits and patient preference if above mentioned other cardiovascular risk factors are present.

ASCVD, atherosclerotic cardiovascular disease; LDL, low-density lipoprotein; PCSK9, proprotein convertase subtilisin/kexin type 9.

TABLE 2: Intensity of various statins

<ul style="list-style-type: none"> High-intensity statin therapy (reduces LDL cholesterol by $\geq 50\%$) once daily Atorvastatin 40–80 mg Rosuvastatin 20–40 mg 	<ul style="list-style-type: none"> Moderate-intensity statin therapy (reduces LDL cholesterol by 30–50%) once daily Atorvastatin 10–20 mg Rosuvastatin 5–10 mg Simvastatin 20–40 mg Lovastatin 40 mg Pitavastatin 2–4 mg
--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

LDL, low-density lipoprotein.

In the era of more costly lipid lowering drugs it becomes all the more essential to target these therapies only to high CV risk patients and hence, there are many risk factors calculators available though none of them is perfect.¹⁵

The commonly used American College of Cardiology or American Heart Association CVD risk calculator to estimate 10-year clinical ASCVD risk is incomplete because it does not account for duration of diabetes or presence of other complications like albuminuria.¹⁵

Primary Prevention

Moderate-intensity statin is recommended for primary prevention in patients of more than or equal to 40 years of age.^{13,16} The intensity of therapy needs to be escalated, if there are

additional CV risk factors present. However, for the population more than 75 years, which has not been represented much in primary prevention trials, the recommendation is for at least moderate-intensity statin therapy after discussing the risk benefit with the patients.^{9,11,12}

For patients less than 40 years of age the statin treatment approaches remain same irrespective of type 1 or type 2 diabetes, especially in the presence of CV risk factors.¹⁶ After discussing the risk benefits with the patient's moderate-intensity statin therapy is recommended for patients under the age of 40 years and/or who have T1D with other CV risk factors.¹⁷

Secondary Prevention

As per the results of cholesterol treatment trialists' collaboration which involved 26 statin trials comparing high versus moderate-intensity statin, high-intensity statin treatment is recommended for all patients of diabetes with clinical ASCVD as this treatment strategy reduced nonfatal CV event rates significantly.⁹

The addition of nonstatin LDL lowering agents like ezetimibe¹⁸ and PCSK9 inhibitors¹⁴ is recommended for patients with ASCVD who are already on maximally tolerated doses of statin therapy and LDL cholesterol is still more than 70 mg/dL. Other combination therapies like statin/fibrates and statin/niacin have not been shown to provide additional CV benefit over statin alone^{5–7} and hence not recommended.

NEW ONSET DIABETES WITH STATIN

The role of statins is clearly established for primary and secondary prevention in reduction of further CV events in all high risk patients including diabetic ones. But there is a small increase in risk of incident diabetes in patients whose blood sugars are previously normal (over 5 years of follow-up, 1.2% of participants on placebo developed diabetes and 1.5% on rosuvastatin developed diabetes).¹⁹ The CV events rate reduction far outweighs the risk of incident diabetes with statin use. A meta-analysis of 13 randomized statins trials showed an odds ratio of 1.09 for new diagnosis of diabetes, so that treatment of 255 patients with statin for 4 years resulted in an additional one case of diabetes while at the same time, it prevented 5.4 CV events in these patients.^{19,20}

CONCLUSION

Diabetes is a strong risk factor for CVD outcome and dyslipidemia further aggravates the risk, so its management in diabetes is an important entity. Lipid profile assessment is essential in all patients of diabetes and also to assess adherence, response to therapy, and adverse effects. High-intensity statins are recommended at all ages in the presence of clinical ASCVD. As a primary prevention in patients less than 40 years and more than 75 years of age statins should be started after discussing risk benefits to the patients along with assessment of CV risk factors. Primary prevention is mandatory in patients between 40 years and 75 years of age with intensity of statin depending on CV risk factors.²¹

Statin Intolerance: Guide to Management

Mrinal K Das

INTRODUCTION

In spite of the highly established beneficial effects of reduction of low-density lipoprotein (LDL)-cholesterol in atherosclerotic coronary heart disease (CHD),^{1,2} the application of lipid-lowering therapy has become a challenging issue because of the increased internet-based awareness and concerns of the patients over probable side effects and potential toxicity of 3-hydroxy-3-methylglutaryl-coenzyme (HMG coenzyme) reductase inhibitors, otherwise known as statins. This can result in poor adherence to statin therapy and ultimately discontinuation.^{3,4} It is very important for patients with high and very high cardiovascular (CV) risk, since discontinuation of statins for 4–6 weeks may cause instability of the atheroma plaque⁵ and thereby increasing the risk of CV adverse events.⁶ Therefore, there is a clinical need to ascertain the correct interpretation of the symptoms and signs presented by the patients after the statin therapy as well as developing approaches and therapies for such events so that the benefit of lipid-lowering therapy is continued. The present article will attempt on these aspects of perceived adverse effects of statin therapy otherwise also called “Statin Intolerance” (SI) and highlight the available remedial measures in the light of present information and knowledge.

DEFINITIONS OF STATIN INTOLERANCE

The definition of statin intolerance has evoked great deal of interest amongst clinicians and thus generating debate⁷ over the years. The following are the various definitions given by different lipid organizations available till date.

National Lipid Association (NLA) defined SI in late 2014, as an inability to tolerate at least two statins—one at the lowest starting daily dose and another at any daily dose—due to either disturbing symptoms (real or perceived) or abnormal laboratory findings that are temporally associated with statin therapy. They are reversible after withholding statin.⁴

International Lipid Expert Panel (ILEP) definition added to the above text the subsidence of symptoms or changes in biomarkers or even significant improvement after either dose reduction or stopping the medicine. Symptoms or alteration in biomarkers are however not attributable to drug-drug interactions and predisposed conditions which have the propensity to increase the risk of statin intolerance.⁸

European Atherosclerosis Society (EAS) offered clinically oriented definition of SI by inserting the assessment of statin-associated muscle symptoms (SAMS) which included the characteristics of muscle symptoms, elevated creatine kinase (CK) levels and their temporal association with starting statin therapy, and suspension of the therapy and rechallenge.⁹

Canadian Consensus Working Group update, in 2016, defined SI as a clinical syndrome, not induced by drug interactions or risk factors for untreated intolerance and manifested by significant adverse symptoms and/or abnormal biomarker level that prevent the long-term treatment and adherence. These need to be documented by challenge (starting the medicine)/dechallenge (reduction of the dosage of medicine)/rechallenge (restarting the same medicine), as per the appropriateness, using at least two statins, including the commonly used atorvastatin and rosuvastatin. There should also be the documentation of the failure of maintenance of therapeutic goals, as recommended by the national guidelines.¹⁰

TYPES OF STATIN INTOLERANCE

Partial

There is inability to tolerate a suitable dose of a statin based on patient's CV risk as in acute coronary syndromes (ACS) there is intolerance of either atorvastatin at a dose of 40–80 mg or rosuvastatin at 20–40 mg dose. It can appear with temporal associations between symptoms and treatment onset or increased dose usually within 3–6 months.

Complete

Intolerance is when clinically apparent variety of side effects impairing organ function and/or quality of life after intake of any statin at any dose with or without associated laboratory findings.⁷

ANECDOTAL DATA

Statins are considered the most prescribed CV drugs,¹¹ both for dyslipidemia¹² as well as for patients with stable coronary artery disease (SCAD), ACS, cerebrovascular accident (CVA), hypertension, diabetes mellitus (DM), and chronic kidney disease (CKD) no matter whether there is dyslipidemia or not.¹³ The beneficial effects of statins in both primary and secondary prevention¹⁴⁻¹⁶ are the most talked about topic in both medical scientific forum and a topic of conjecture by the even unscientific social media. There has been 21% decrease in cardiovascular disease (CVD) mortality and morbidity achieved by lowering LDL-C by 1.0 mmol/L (38.7 mg/dL).¹⁷

The Cholesterol Treatment Trialists (CTT) collaboration showed 12% reduction in all-cause mortality per mmol/L reduction in LDL-C and significant reductions in myocardial infarction (MI) or coronary death (23%), the need for coronary revascularization (24%), and in fatal or nonfatal stroke (17%) after 5 years of statin therapy.¹⁸ However, statin discontinuation rates over 50% after 1-year is quite high, even among patients with CHD.^{3,19} The medical fraternity has enough evidence to project the ill-effects of statin nonadherence attributed to SI, increasing the risk for recurrent MI and CHD.^{6,20} Mancini et al.²¹ observed 70–80% of statin-treated patients being tolerant to treatment, and 20–30% to be statin intolerant. Definite evidence of SI was found in about 5–6% of patients.²¹ Banach et al.^{22,20} with a step-by-step approach yielded a diagnosis of complete statin intolerance in 2–3% of patients only. There have been few recent reports from Indian workers regarding the statin intolerance. Bharadwaj et al.²³ observed older women to be more vulnerable to SAMS especially those with multiple comorbidities and established polypharmacy. Myalgia was dose-dependent in those individuals and so they found that many physicians started with low dose of statin with subsequent up-titration as per tolerance.

Wander et al.²⁴ in the first-ever survey amongst 404 Indian physicians using statin mentioned that 92% respondents reported statin intolerance in the range of 2–20% in their clinical practice. Most of them (39%) reduced the dose of statin, followed by stopping statin and restarting at lower dose (34%). Use of alternate statin was done by 22.3% and using nonstatin by 10.9% respondents.

So number-wise, the incidence of statin intolerance is not very significant and hence proper caution is required before labeling the patient in order to impart the benefit of statin therapy.

CLINICAL FEATURES

Statin intolerance is not simply the occurrence of symptoms in general, but rather the symptoms that are perceived

TABLE 1: Incidence of statin-induced adverse features

Adverse effect	Percentage of patients	Markers (Present/Absent)	Reference
Myalgia	3–5%	CK	27–29
Myopathy	0.1–0.2%	CK	27–29
Myonecrosis	0.0016%/year	CK	27–29,48
Diabetes mellitus	9–27%	Blood sugar, HbA1c	27–30
Hepatotoxicity	1%	ALT	14, 27

CK, creatine kinase; ALT, alanine aminotransferase; HbA1C, hemoglobin A1c.

as unacceptable.²⁵ However, to correlate that negative symptoms causally to statins is often difficult to ascertain. Usually symptoms (more than 75%) are more likely to be due to statins if the complaints occur within the first 3 months of starting statin and disappear after stopping the medicine and reoccurring after resuming the same.^{26,27}

Statins-specific adverse effects are shown in table 1.

Statin-Associated Muscle Symptoms

Statin-associated muscle symptoms are the most common side effects of statins with resultant discontinuation. They could be myalgia, muscle stiffness and tenderness, cramps, and loss of muscle power with severity ranging from mild to severe.^{8,28} Based on the findings, classification of SAMS was done as follows²⁹: (1) Myalgia, (2) Myopathy, (3) Myositis, and (4) Myonecrosis or Rhabdomyolysis.

The percentage of patients with muscle symptoms since 1993–2010 as per the trials carried out during the index years.³⁰

The prevalence of SAMS is around 3–5% in randomized controlled trials including patients with dyslipidemia³¹ and up to 20% in observational studies.^{32,33} The European Atherosclerosis Society (EAS) consensus paper reported a SAMS prevalence as high as 29%.⁹ The USAGE(Understanding Statin Use in America and Gaps in Education) study on current and previous users of statin via an internet-based study showed that SAMS occurred in 60% of current and 25% of previous users.³⁴ STOMP (Effect of Statins on Skeletal Muscle Function and Performance) study, a randomized, double-blind, placebo-controlled trial, found overall incidence of 5% of SAMS with myalgia in 9.4% of patients receiving atorvastatin and 4.6% of subjects on placebo.³⁵ Table 2 is depicted to ascertain the likelihood of SAMS.

Myalgia is defined as muscle pain or flu-like symptoms (heaviness, tenderness, stiffness, aches, or cramps) with normal CK levels. NLA recommends that the SAMS Clinical Index (SAMSCI) score, the greatest score (3 points) for the typical large muscle symmetric (e.g., bilateral) aches, 2 points for bilateral aches of the smaller distal or proximal musculature, and 1 point for asymmetric, nonuniform symptoms.²⁹ The SAMSCI score helps to confirm statin-related myalgia and to exclude the nocebo effect—psychologically conditioned symptoms as a result of expectations due to achieved knowledge of drug-related side effects. As per EAS

TABLE 2: Likelihood of SAMS

SAMS less likely	Nature of symptoms	SAMS more likely
<ul style="list-style-type: none"> • Unilateral • No pattern in distribution • Tingling, twitching, shooting, nocturnal cramps or joint pain 		<ul style="list-style-type: none"> • Bilateral • Large muscle groups (e.g., thighs, buttocks, calves, shoulder girdle) • Muscle ache, weakness, soreness, stiffness, cramping, tenderness or general fatigue
Timing of symptoms		<ul style="list-style-type: none"> • Onset before statin initiation • Onset >12 weeks after statin initiation
Other considerations		Risk factors for SAMS including:
Nonstatin causes of muscle symptoms including: <ul style="list-style-type: none"> • Conditions, e.g., hypothyroidism, polymyalgia rheumatica, vitamin D deficiency • Unaccustomed/heavy physical activity • Medicines e.g., glucocorticoids, antipsychotics, • Immunosuppressant or antiviral agents 		<ul style="list-style-type: none"> • Medicine or food interactions • High-dose statin therapy • History of myopathy with other • Lipid-modifying medicines • Regular vigorous physical activity • Impaired hepatic or renal function • Substance abuse (e.g., alcohol, opioids, cocaine) female, low BMI
CK levels		<ul style="list-style-type: none"> • Elevated (>ULN; but may also be normal) • Elevated CK levels decrease after statin ceased

SAMS, statin-associated muscle symptoms; BMI, body mass index; CK, creatine kinase; ULN, upper limit of normal.

consensus paper on SAMS, above cut-off point value of 4, muscle symptoms seem to be more attributable to statin therapy.⁹

Myopathy is weakness of the muscle occurring with normal or elevated CK.³⁶ Predisposing conditions for myopathy are age more than 75 years, female sex, renal and hepatic dysfunction, hypothyroidism, alcohol abuse, excessive physical exertion, genetic susceptibility, perioperative period, and concurrent use of drugs inhibiting the metabolism of statins (clarithromycin, erythromycin, azole antifungals, diltiazem, verapamil, amiodarone, fibrates particularly gemfibrozil, cyclosporin, clopidogrel, sulfonamides, and red yeast rice).^{8,28,37} Low levels of vitamin D and coenzyme Q10 (CoQ10) might also increase the risk of statin intolerance.^{38,39} The term does not necessarily connote symptoms or any degree of CK elevation. Muscle biopsy also suggests some myopathic statin-induced abnormalities that may be present in the context of normal CK levels.³⁵

Myositis is muscle inflammation associated with symptoms like tenderness, CK elevation, and leukocyte infiltration into muscle tissue.

Myonecrosis is always associated with muscle damage and elevation of serum CK.³⁶ The most serious form of myonecrosis is rhabdomyolysis in which muscle breakdown is responsible for a massive release of CK and myoglobin, with dangerous complications viz., myoglobinuria and acute kidney injury (AKI).³⁶ Fortunately, it is very rare (incidence of 1.6 per 100,000 patient-years). Rhabdomyolysis usually occurs in genetically predisposed cases or where is drug-drug interaction.⁴⁰

The risk of developing new onset DM are more in prediabetics with insulin resistance, overweight, high blood pressure, high triglycerides, low high-density lipoprotein cholesterol (HDL-C), hyperglycemia, and duration and

intensity of statin therapy. However, benefits associated with statin therapy outweigh the risk of developing DM for high and very high-risk patients.^{37,41-43} In JUPITER (The Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin) trial during a follow-up period of up to 5 years, there was CV mortality benefits of statin exceeding the diabetes hazard, even in those having higher chance of developing diabetes. To circumvent the risk of new onset DM during statin therapy, it is prerogative of the treating physician to advise the patients to exercise, lose weight, stop smoking, and reduce caloric intake avoiding saturated and trans-fats.

EVALUATION OF STATIN INTOLERANCE

List of the routine biomarkers along with the novel or experimental biomarkers for ready reckoning is shown in table 3.

The most widely used serum marker is the serum CK level,⁴⁴ but it is inadequate as a diagnostic marker and nonspecific as levels are not always associated with myopathy.⁴⁵ One must remember that CK levels can also be elevated by exercise in a dose-independent manner³⁴ and by drug interactions, genetic variants, CoQ10 deficiency, and vitamin D deficiency.⁴⁶

Routine liver function analyses are no longer recommended as the diagnostic yield is low and cost prohibitive.⁴⁷ Statin induced rise in aminotransferase levels is rare, mild, dose-related, and not related to reduction in LDL-C. They are usually temporary, and may return to baseline levels after 2-4 weeks.^{48,49} Persistent elevation of alanine aminotransferase (ALT) more than three upper limit of normal (ULN) were observed in more than 1% of patients treated with statins. There was correlation with more than 0.5% rate for moderate-dose rosuvastatin and at slightly

TABLE 3: List of the routine and novel biomarkers for statin-induced myopathy

Serial No.	Name
1.	Creatinine phosphokinase (CK)
2.	Aspartate aminotransferase (AST)
3.	Fatty acid binding protein 3 (FABP3)
4.	Myosin light chain 1 (MLC1)
5.	Skeletal muscle troponin I (sTnI)
6.	Myosin light chain 3 [MYL3 (S3)]
7.	CK isoform M (CKM)
8.	Phosphorus magnetic resonance spectroscopy (31P-MRS)
9.	MicroRNAs (miRNAs;133a/b and 499-5p)
10.	Complex genomic and lipidomic analyses: increased expression of arachidonic acid 5-lipoxygenase activating protein, phospholipase C, numerous species of phosphatidylethanolamine, selective pools of long-chain triglycerides, and phosphocholine ether

higher rates (about 1%) with all doses of atorvastatin or simvastatin 80 mg.⁴⁸ Interestingly, ALT elevations often improve even when statin therapy is continued. It is worth remembering that the use of statins prevents about 33% of major CVD events vis-à-vis placebo, and may cause serious liver disease only in 1/1,000,000 [number needed to harm (NNH) is 1 million]. Still between 10% and 30% of patients do not receive statins because of fear of hepatotoxicity.^{8,22}

Lactate dehydrogenase is another early marker which might predict and diagnose statin intolerance and myopathy,⁴⁷ however, its clinical utility in cases of statin-induced myopathy warrants validation.⁵⁰

Fatty acid-binding protein 3 (FABP3) and myosin light chain 1 (MLC1) could be other futuristic biomarkers of skeletal muscle toxicity.^{50,51} Similarly, skeletal muscle troponin I (sTnI), myosin light chain 3 [MYL3 (S3)], CK isoform M (CKM), and FABP3 versus CK for drug-induced skeletal muscle injury, were found to outperform CK (Burch et al.).⁵² When used in conjunction with CK, sTnI, MYL3, CKM, and FABP3 individually and collectively improved diagnostic sensitivity and specificity and diagnostic certainty, for skeletal muscle injury and responded in a sensitive manner to low levels of novel skeletal muscle injury degeneration/necrosis in rats. CKM showed the highest correlation ($r = 0.47$, $p < 0.0001$), followed by FABP3 ($r = 0.52$, $p < 0.0001$), MYL3 ($r = 0.48$, $p < 0.0001$), sTnI ($r = 0.47$, $p < 0.0001$), aspartate transaminase (AST; $r = 0.46$, $p < 0.0001$), and CK ($r = 0.32$, $p < 0.0001$).⁵² These findings suggest that sTnI, MYL3, CKM, and FABP3 are suitable for voluntary use, in conjunction with CK, in experimental studies in rats to monitor statin-induced muscle injury and for the potential translational use in early clinical trials to ensure patient safety.⁵² Dobkin⁵³ suggested the functional assessment of hip-flexor and abductor performance.

Phosphorus magnetic resonance spectroscopy (31P-MRS) study by Wu et al.⁵⁴ for the evaluation of the kinetics of recovery exercise phosphocreatine found that patients on statin therapy for 4 weeks had prolonged metabolic recovery time in the calf despite no change in serum CK levels.⁵⁴ However, there were several shortcomings like cost, dependence of renal dysfunction, rapid clearance, heterogeneous response depending on the type of myotoxins in general.^{47,55}

Complex genomic and combined lipidomic analyses have been tried, but were found to have difficulty to perform and interpret routinely in clinical practice.

Two microRNAs (miRNAs 133a/b and 499-5p) were assessed and miR-133a/b was found to be sensitive and specific markers of cardiac and skeletal muscle toxicity⁵⁶; miR-499-5p was more applicable in statin-induced muscle injury in the marathon runners.⁵⁷ Thus, though the new biomarkers for statin-induced myopathy are on the horizon, most cannot be commonly used or recommended because of either the complex methodology or costs. Further works are highly warranted to ascertain their sensitivity and specificity.⁴⁷

MANAGEMENT

The basic principle in the management of SI is to attempt with all vigor to not allow patients to discontinue the statin. All the stake holders should be convinced about the data that there is not only increased chance of developing plaque instability after statin discontinuation, but also there may be rebound inflammation after about 4–6 weeks of stopping statin. Since prevention is always better than cure, so the approach should start with the prevention. The following steps are apt from the preventive points of view.

Pretreatment Assessment

- Assess risk [(e.g., elderly, prior muscle pains, familial hypercholesterolemia (FH) of myopathy, renal disease, DM, hypothyroidism)]
- Consider exogenous factors (e.g., statin dose, alcohol use, drug-drug interactions, excessive grapefruit juice use)
- Measure baseline CK, ALT, thyroid-stimulating hormone (TSH), and creatinine.

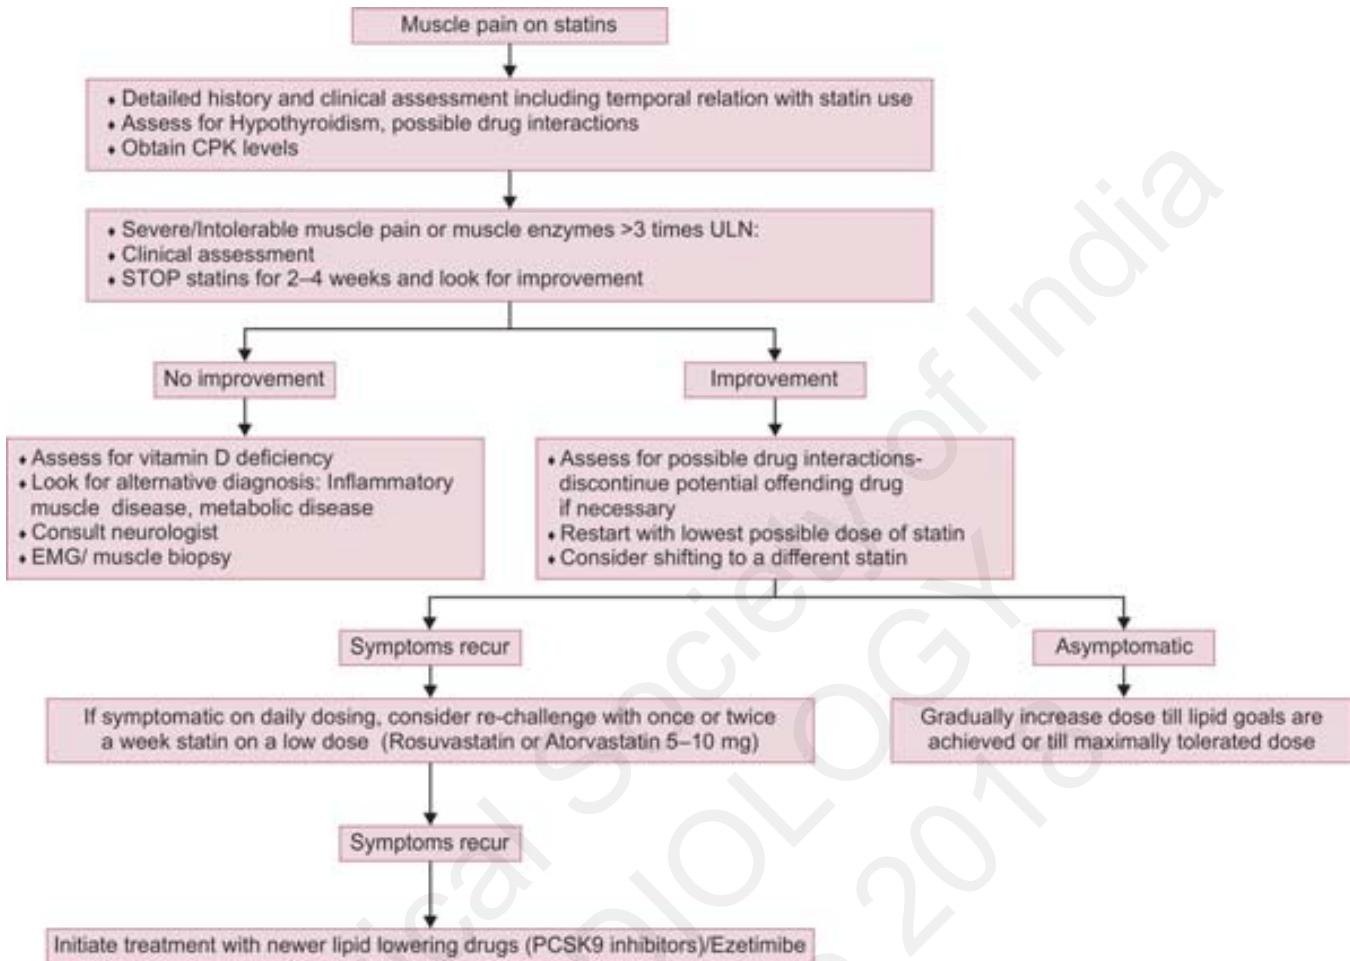

Counseling

- To inform the patients that statins are very well tolerated in most people
- To inform the patients about muscular symptoms and when to discontinue.

Monitoring

Check CK/ALT when monitoring lipid-lowering efficacy:

- At 6–8 weeks after starting or with dose increase and then every 6–12 months
- Avoid severe exercise for several days prior to testing.

CK, creatine kinase; EMG, electromyography; LDL-C, low-density lipoprotein cholesterol; ULN, upper limit of normal.

FLOWCHART 1: Algorithm for the evaluation of statin-induced muscle disease.

Flowchart 1 depicts the algorithm for the management of SAMS.⁵⁸⁻⁶⁰

ALTERNATIVE AGENTS

There is a huge list of alternative agents to take care of statin intolerance as depicted in box 1. All these drugs or agents are not having the same potency to reduce the LDL-C. However, many of them may be considered for add-on therapy, which may alter the residual risk. Ezetimibe monotherapy was used limitedly in less than 5–10% patients since there was no United States Food and Drug Administration (US FDA) recommendations and restricted reimbursement in Europe.⁶¹ Use of proprotein convertase subtilisin/kexin type 9 (PCSK9) is also used in very limited number of patients because of the cost involvement. Evolocumab and alirocumab underwent several phase II and phase III clinical trials in high-risk CV patients. Cohort included patients with statin intolerance FH. Evolocumab significantly reduced LDL-C by approximately

60–65%, having favorable effects on other lipid parameters and lipoprotein(a). It is well tolerated as a single agent or in combination with statins alone, or statins plus ezetimibe. The therapy did not demonstrate major side effects like SAMs or new onset DM, or neurocognitive disorders. The effectiveness and safety of evolocumab in a pooled analysis was comparable in patients with or without type 2 DM (T2DM) and did not differ between T2DM subgroups.⁶²⁻⁷⁴

Statin and other currently available drug combination have limited capacity to lower LDL-C in patients at high CV risk leaving a condition called residual risk. Bempedoic acid (ETC-1002) is a new star in the block acting through adenosine triphosphate-citrate lyase inhibition. The efficacy of combination of statins and bempedoic acid has been evaluated in a randomized controlled trial (NCT02072161).⁷⁵⁻⁷⁸ Monacolins such as policosanol and bergamot inhibit HMG-CoA reductase, and red yeast rice extract (*Monascus purpureus*) contains a variety of monacolins.⁷⁹ Berberine and red yeast rice combination

BOX 1 Second-line statin alternatives⁹⁰**Currently available agents:**

- Cholesterol absorption inhibitors (Ezetimibe)
- Bile acid sequestrants (colesevelam, colestipol, and cholestyramine)
- Niacin
- Fibrates
- PCSK9 (proprotein convertase subtilisin/kexin) inhibitors
- Cholesteryl ester transfer protein (CETP) inhibitors
- Bempedoic acid (ETC-1002)

Nonpharmacological approaches:

- To reduce intake of saturated and trans fats
- To choose monounsaturated and polyunsaturated fats
- Mediterranean diet
- Plant extracts: Sugar cane-derived policosanols, and artichoke leaf extracts, red rice yeast
- Nutraceutical combination berberine, astaxanthin, CoQ10, folic acid
- Acid ethyl ester (AMR101)
- Chokeberry flavonoid extract
- Spirulina
- Viscous fiber

significantly improved different lipid fraction levels [i.e., lowered total cholesterol, LDL-C, and triglyceride levels ($p <0.001$ for all) and increased HDL-C concentration ($p <0.001$)] after treatment for 16 weeks.⁸⁰ Armolipid Plus, with ingredients of natural substances like red yeast rice, policosanol, and berberine combined with folic acid, astaxanthin, and CoQ10 having complementary lipid-lowering properties, had lower risk of statin intolerance like situation because of low doses of its active ingredients—low enough not to be associated with untoward effects but high enough to exert therapeutic effects in combination with other complementary substances.⁸¹ Spirulina, a filamentous, water blue-green microalga (*Cyanobacterium*)⁸² with lipid lowering in one meta-analysis⁸³ of seven randomized controlled trials demonstrated significant reduction of total cholesterol (-46.76 mg/dL; $p <0.001$), LDL-C (-41.32 mg/dL; $p <0.001$), triglycerides (-44.23 mg/dL; $p <0.001$), and elevated levels of HDL-C (6.06 mg/dL; $p = 0.001$). Indian spice turmeric (*Curcuma longa L.*) has curcumin, a natural dietary polyphenol responsible for the yellow color of the analgesic, has antioxidant⁸⁴ and anti-inflammatory properties which may help in taking care of SAMS by preventing and reducing muscular fatigue. Curcumin is safe to consume, even at dosages of up to 8–12 g daily.⁸⁵ It blocks the inflammatory pathway of the nuclear factor, inhibits muscular atrophy, and help in rejuvenating muscle fibers after injuries.⁸⁶ It has also lipid-modifying properties and may serve as an adjunctive therapy in SAMS, with added benefit of reduction of LDL-C possibly at a lower statin dose.⁸⁷ It has the potentiality to modulate the biomarkers of HDL functionality by increasing apolipoprotein AI (apo-AI) and

lecithin-cholesterol acyltransferase (LCAT) and decreasing cholesterol ester transfer protein (CETP), paraoxonase-1 (PON1), myeloperoxidase (MPO), and lipoprotein-associated phospholipase A2 (Lp-PLA2).⁸⁸ In some human trials, berberine, polydatin, marine n-3 PUFAs, n-3 PUFA-enriched fish oil, docosahexaenoic acid (DHA)-enriched canola oil and quercetin-3-O-β-D glucoside demonstrated the capacity to lower PCSK9 levels, an important regulator of lipid metabolism and an efficient target for plasma LDL-C reduction.⁸⁹

INDIAN EXPERIENCE WITH STATIN-INDUCED MUSCLE SYMPTOM

The recent survey amongst Indian physicians as per Wander et al. found the following responses regarding the management of statin intolerance²⁴ as shown in table 4. In ACCORDANCE study where the practicing behavior of the physicians in India with statin therapy, Das et al. found that when patients complained of myalgia and had a CK less than four times upper limit of normal (4X ULN), most of the physicians (56.29%) preferred to discontinue statin for 6 weeks and then rechallenge with the same statin at low dose rather than rechallenging with the same dose or replacing the statin. Only 3.66% physicians were of the opinion of discontinuing statin completely.⁹¹ Figure 1 shows the physicians' preferred treatment choices for statin-induced myalgia or rise in CK less than four times ULN in that study.

CONCLUSION

Statins or HMG coenzyme reductase inhibitors are the most prescribed medicine in the modern times and the cornerstone in the therapy of atherosclerotic CHD. But, at times, it is associated with adverse effects in the form of statin-induced muscle symptoms or SAMS, new onset DM or hepatic disorder. This syndrome is called SI, which limits the achievement of therapeutic LDL goal. This in turn results in the instability of the atheroma plaque that might increase the morbidity and mortality associated with CAD. However, the condition can be challenged, dechallenged, and rechallenged starting with lower dose of the same drug or different drug. In extreme and definite cases, one may have to take recourse to nonstatin therapeutic measures. It is the prerogative of the

TABLE 4: Preferred options for management of statin intolerance

Preferred strategy	Percent Responders
Reducing statin dose	39%
Stopping statin and restarting at lower dose	34.5%
Using alternative statin	22.3%
Using nonstatin drugs	10.9%
Lifestyle modification	1.4%

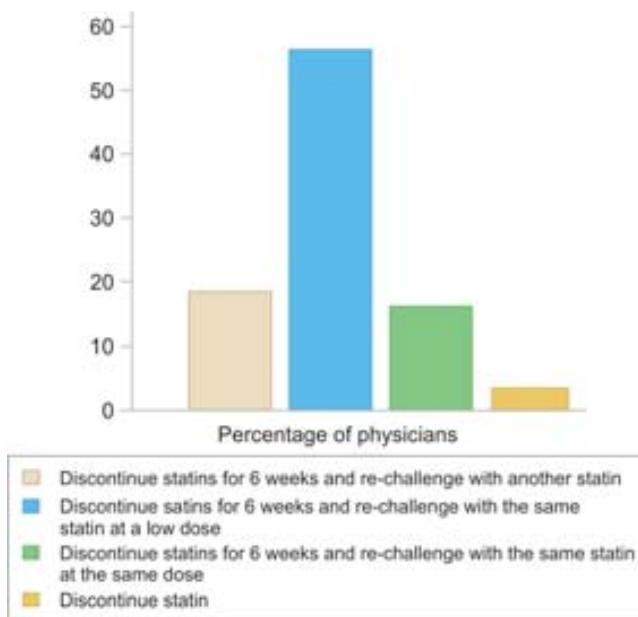

FIG. 1: Physician practice preferences for patients with statin induced muscle symptoms and creatine kinase levels <4 times normal.

treating physicians to convince the patient as well as himself or herself that this is a very rare condition that can be tackled appropriately and give the benefit of continuation of the therapy.

Nonfasting Lipid Levels: Clinical Relevance and Implications for Practice

Ajay K Sinha, Vikas Singh, Narendra Kumar

INTRODUCTION

Dyslipidemia is one of the most common risk factors for ischemic heart disease (IHD). Multiple studies focusing on conventional, nontraditional, and various novel risk factors of IHD have recognized dyslipidemia as a significant risk factor.¹ Lipid profile is the screening test for dyslipidemia where the total cholesterol (TC), triglycerides (TGs), high-density lipoprotein cholesterol (HDL-C), and low-density lipoprotein cholesterol (LDL-C) levels are tested. One of the challenges with lipid profile measurement is the need for sample collection exclusively in fasting state.^{2,3} This is inconvenient to the patient and promotes noncompliance. Rationale for utilizing nonfasting lipid profiles in clinical practice are more accurate view of 24-hour lipids, time, and cost-efficiency, as well as endorsement by many societies including the American Heart Association.

RATIONALE FOR REQUIREMENT OF A FASTING SAMPLE

Postprandial changes in lipoprotein composition are known to occur, particularly the increase in TGs concentration which directly correlates with the meal fat and carbohydrate content.

The calculation of LDL-C using the Friedewald equation is significantly affected by the increased levels of TG.

Treatment goals are often based on the use of fasting samples for lipid measurement in many clinical trials and epidemiological studies.

Since, most people tend to eat food several times during the day, the postprandial state tends to predominate over a 24-hour duration. Therefore, generally, the lipid component of blood serum or plasma is obtained after 8 hours of fasting. The values obtained might not reflect accurate levels of the lipoprotein concentrations or the plasma lipid in the sample and may not be reliable risk marker for cardiovascular disease (CVD).^{4,5} In addition, recent evidence has demonstrated

that nonfasting TG concentrations are a better predictor of future coronary events compared to fasting TG, in both men and women. Hence, there is an urgent need to review the information available on the subject considering all pros and cons.

EMERGENCE OF NONFASTING LEVELS MEASUREMENT

There is a gap in scientific evidence to support superiority of fasting lipid profile compared to nonfasting one during evaluation of the overall CV risk assessment. In the last decade, scientific guidelines around the globe have encouraged the use of routine nonfasting lipid profiles. There has been paradigm shift in understanding fasting versus nonfasting lipid profile in certain countries, notably Denmark where standard clinical practice is for nonfasting lipid testing. As per the scientific guidelines issued from the Danish Society of Clinical Biochemistry recommending the use of random nonfasting lipid profiles as the benchmark for all laboratories in Denmark, and simultaneously suggesting physicians to reevaluate the TG levels in the fasting state when the nonfasting values are over 350 mg/dL (4 mmol/L).^{6,7} In 2014, the National Institute for Health and Care Excellence (NICE) guidelines have also supported the use of nonfasting lipid measurement. The nonfasting lipid measurements simplifies the blood sampling for patients, general practitioners, laboratories, and hospital clinicians, and also improves patient compliance for testing for lipid.⁸⁻¹⁰ There are some caveats that limit the wider adoption of nonfasting lipid estimation, including the following:

- Fasting lipid profile measurement is believed to provide more standardized measurement
- Nonfasting lipid profiles make calculation of LDL-C via the Friedewald equation invalid
- As fasting has been the clinical standard, it is unclear what values should be flagged as abnormal when using nonfasting rather than fasting plasma lipid profile.

LIPID COMPONENT MEASUREMENT

Total cholesterol, HDL-C, and TGs are measured directly. However, LDL-C can either be measured directly or calculated by the Friedewald equation, e.g., if TGs are 400 mg/dL (4.5 mmol/L) [by the formula—total cholesterol minus HDL-C minus TGs/2.2 (all in mmol/L), or minus TGs/5 with values in mg/dL].¹¹ Direct measurement of LDL-C is ideally preferred at TG concentrations more than or equal to 4.5 mmol/L (400 mg/dL).

Can Nonfasting Values be a Reliable Marker of Cardiovascular Diseases?

Often, the Friedewald equation is applied for fasting lipid profile and when the LDL-C is calculated using this formula with TG level of 400 mg/dL (4.5 mmol/L) is similar to LDL-C measured using either nonfasting and fasting lipid values. Therefore, there is no strong reason for a fasting sample for LDL measurement if TGs are not significantly raised.

Remnant cholesterol is another marker which is a significant causal risk factor for CVD and has been studied in detail. It is calculated as total cholesterol minus LDL-C minus HDL-C, using nonfasting or fasting lipid profiles.¹²⁻¹⁴

Non-HDL-C is calculated as total cholesterol minus HDL-C and is equivalent to LDL-C, remnant cholesterol, and lipoprotein(a) [Lp(a)] cholesterol combined. Several consensus papers and guidelines have supported the use of non-HDL-C for CVD risk prediction and does not require a fasting sample. Guidelines from ATP III and the Canadian Cardiovascular Society (CCS) have endorsed non-HDL-C as a secondary target for treatment of hyperlipidemia as it does not get altered by nonfasting condition.

For an accurate CVD risk prediction, additional measurement of Lp(a) is desirable. Whenever a patient is being screened for CV risk, Lp(a) should be ideally measured once for sure.¹⁵ Due to the variation of Lp(a) levels up to 10% in any individual, its determination should be preferably included in all lipid profile estimations.

Triglyceride concentration increase during a fat tolerance test.¹⁶ However, the increase in plasma TGs observed after usual food ingestion is not usually observed during a fat tolerance test.^{17,18} As the Friedewald equation is used for calculation of LDL levels, which includes the TG concentration, thus estimated LDL is thought to be affected significantly by diet consumption. Although, the calculated LDL and directly measured cholesterol values are equivalent using both fasting and nonfasting samples. A modification of this formula may be used¹⁹ when chylomicrons are high, which may be fairly accurate.

Several randomized cholesterol-lowering trials have used fasting level measurements, and for aliasing with evidence-based medicine, fasting blood sampling has often been the standard in day-to-day CV risk assessment. However, three major statin trials and plenty of population-based studies used random, nonfasting blood sampling, providing acceptable evidence to challenge the traditional practice of usage of fasting samples. Several large-scale registries and population-based studies including diabetic population from

pediatric population to adult, both in female and male have now confirmed that plasma lipids and lipoproteins change only little with one's habitual food intake.²⁰ It applies to the most of individuals, but rarely some exhibit out of the box response.

How Much is the Difference Between Fasting and Nonfasting Samples?

During comparison of fasting with nonfasting lipid profile clinical studies, only little raised plasma TGs and insignificantly lesser total and LDL lipid levels were observed, with no change in HDL-C values. Such nonsignificant and transient changes in cholesterol levels seem to be clinically insignificant. Although, Langsted et al. observed a transient decrease in LDL lipid estimates of 23 mg/dL (0.6 mmol/L) after 1-3 hours of a meal consumption by a diabetic. It assumes clinical significance²¹ especially when it is used as an argument to withhold statins for a patient. The maximal mean changes after 1-6 hours after a meal is considered to be clinically insignificant at +26 mg/dL (0.3 mmol/L) for TGs, 8 mg/dL (20.2 mmol/L) for total cholesterol, 8 mg/dL (20.2 mmol/L) for LDL-C, +8 mg/dL (0.2 mmol/L) for calculated remnant cholesterol, and 8 mg/dL (20.2 mmol/L) for calculated non-HDL-C, while concentrations for HDL-C, apolipoprotein A1, apolipoprotein B, and Lp(a) remained unchanged.^{20,22} Interestingly, the reduction in LDL and total cholesterol levels at 1-3 hours after the last meal intake measured with and without diabetes became statistically nonsignificant after adjusting for plasma albumin concentration as a marker of fluid intake.

Is There Anything Against the Nonfasting Samples?

Several clinical studies have attributed marginal decrease in plasma LDL lipid level liberal fluids ingestion for nonfasting samples. This leads to changes although insignificant misclassification of CV risk, which, therefore, will lead to error in initiation of lipid therapy. Although this is associated with small risk, associated mostly with diabetics and is not a universal finding across the clinical studies.²¹

Nonfasting sample can possibly sometimes confuse the differentiation between familial hypercholesterolemia and congenital variants of high TGs. Pediatric population have highly variable plasma cholesterol levels and thus, necessitating for a fasting second sample for an accurate diagnosis of a lipid disorder needing drug therapy. Fasting is less critical for first-stage screening but may be more important when trying to establish a phenotypic diagnosis of genetically determined dyslipidemias.

Switching Your Practice Pattern from Fasting to Nonfasting Samples? Certain Facts to Keep in Mind

The lower LDL lipid levels observed especially in diabetics 1-6 hours after typical food intake needs to be kept in mind when using nonfasting cholesterol estimates to decide either

TABLE 1: When to use fasting and nonfasting blood samples for evaluating the plasma cholesterol profile

Patients for lipid profile testing	
Nonfasting	Fasting
<ul style="list-style-type: none"> Initial lipid profile testing in any patient In children and elderly For cardiovascular risk assessment Patients admitted with acute coronary syndrome^a In diabetic patients^b (due to hypoglycemic risk) Patients on stable drug therapy If preferred by the patient 	<ul style="list-style-type: none"> Nonfasting triglycerides 5 mmol/L (440 mg/dL) Known hypertriglyceridemia followed in lipid clinic Recovering from hypertriglyceridemic pancreatitis Starting medications that cause severe hypertriglyceridemia Additional laboratory tests are requested that require fasting^c or morning samples (e.g., fasting glucose^c, therapeutic drug monitoring)

^aRepeated lipid profile testing is needed later as acute coronary syndrome lowers lipid concentrations.

^bDiabetic hypertriglyceridemia may be masked by fasting.

^cIn many countries, fasting blood sampling is restricted to very few analytes besides lipid profiles: one example is fasting glucose; however, in many countries, even fasting glucose measurement is being replaced by measurement of hemoglobin A1c without the need to fast.

to start a statin or even modify its dosage. Interestingly, since the observed reduction in LDL lipid level is due to hemodilution and liberal water intake rather than to diet intake, a similar LDL reduction is likely to occur when using fasting lipid profiles with no restrictions on fluid intake.

Since statin therapy is decided not just on numerical value of plasma cholesterol in both European and US guidelines but rather on a person's comprehensive CV risk that includes the presence of CVD, familial hypercholesterolemia, and diabetes. Therefore, minor changes in the cholesterol level estimation to nonfasting conditions from fasting will affect only a few individuals regarding the decision to start a statin or not.

CONCLUSION

We mostly remain in the nonfasting state, reflecting "our habitual physiological status". Blood samples typically measured after 8-12 hours of fasting have been the standard for assessing the plasma lipid profile. Postprandial effects do not appear to diminish, and rather may in fact enhance the strength of the associations between plasma lipid, lipoprotein, and apolipoprotein concentrations and risk of CVD. A meta-analysis from the Emerging Risk Factors Collaboration suggested that nonfasting non-HDL-C and nonfasting calculated LDL-C were superior to fasting measurements for predicting CV risk.²³ Several prospective clinical studies have observed significant associations for nonfasting lipids, apolipoproteins, and lipoproteins with future risk of CVD. Therefore, numerous landmark statin therapy clinical trials have used nonfasting lipids for inclusion criteria and simultaneously for observing the therapeutic efficacy of lipid-lowering therapy. Such observations suggest that nonfasting blood level estimations is not only highly practical and effective but also advantageous in estimating cholesterol driven CVD risk and treatment responses.

A simple and practical approach recommendation to improve compliance of patients are to advice nonfasting cholesterol estimation for most individuals, while fasting sample may be considered for individuals with nonfasting plasma TG 440 mg/dL (5 mmol/L). Fasting can be a barrier

to population screening, is unpopular with children, is often unsuitable for patients with diabetes, and counters the use of point-of-care testing, and fasting requirements can add to the overall costs of lipid testing. Nonfasting tests are also used to assess other metabolic disorders, such as hemoglobin A1c in diabetes.

Nonfasting and fasting measurements of the lipid profile must be viewed as complementary and not mutually exclusive.

A joint consensus statement from the European Atherosclerosis Society and European Federation of Clinical Chemistry and Laboratory Medicine summarized the practical utility of the fasting and nonfasting samples (Table 1).

Therefore, it appears that the main reason for measuring lipid levels in the fasting rather than the nonfasting state is simply a custom worldwide; and due to this, the fasting requirement has been applied in almost all randomized lipid-lowering trials.

Diabetes and Cardiovascular Disease: Implications of Recent Cardiovascular Outcome trials with Newer Anti-diabetic Drugs for Cardiovascular Protection

Prakash Deedwania

INTRODUCTION

Diabetes mellitus (DM) and coronary heart disorders (CHDs) are two of the most common noncommunicable diseases that are leading cause of death and disability in India. Diabetes increases the risk of most cardiovascular disorders (CVDs) by 2- to 4-fold and its presence in those with preexisting CVD is one of the most powerful predictors of adverse clinical outcome. It is important to note that although DM is considered as predominantly a metabolic condition primarily due to glycemic control perturbations it is now well recognized that most diabetic patients develop CVD and CV events are the leading cause of death and disability in DM. It is therefore essential that cardiologist be familiar with the implications of diabetes in their patients with DM and provide comprehensive therapeutic strategies to reduce the risk of CV events in their diabetic patients. Comprehensive CV risk reduction in DM should be focused on aggressive management of glycemic status, blood pressure (BP), lipids, as well as use of antithrombotic agents, and therapeutic lifestyle modification including recommendations for regular physical activities and prudent dietary modifications. In this chapter the primary focus will be centered on the clinical implications of the recent CV outcome trials (CVOTs) with a large number of newer antidiabetic drugs that have provided very encouraging and exciting data regarding their safety and in several cases cardioprotective efficacy in diabetic with preexisting CVD as well as those at high risk of future CV events.

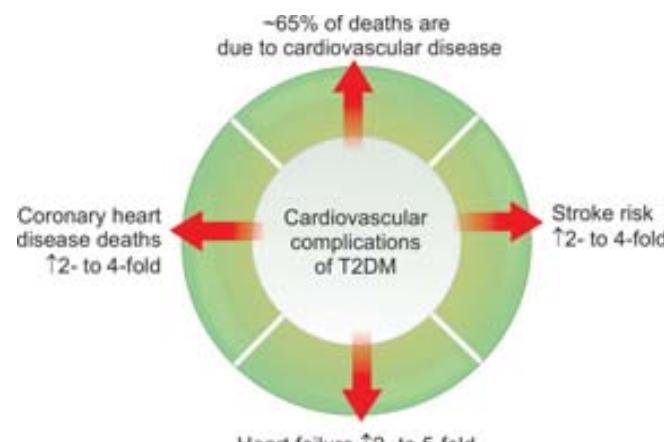

BACKGROUND

Diabetes has reached epidemic proportions throughout the world. It is estimated that the number of cases of diabetes worldwide among adults 20 years or older is about 410 million and the prevalence is increasing with the number of cases projected to increase to over 640 million by the year 2040.¹

The top three countries with the highest numbers of people with diabetes in are India, China, and the US. The greatest relative increases will occur in India, sub-Saharan

Africa and the Middle East while the greatest absolute increase in the number of people with diabetes will be in India. India has the dubious distinction of being called as the “diabetes capital” of the world and is home to nearly 75 million cases of diabetes with a prevalence of 8.7% among the adult population.^{1,2} The recent data from the Global Burden of Disease (GBD) the overall prevalence of DM increased by 66% between 1990–2016 from 3 to 5%, whereas age-standardized prevalence increased by 30% from 4.6 to 6%.² Also, the GBD data reveal that the number of deaths and DALYs due to DM have nearly tripled during the period from 1990–2016. These data also pointed out that DM significantly contributed to the causation of CHD, strokes, CKD, and peripheral artery disease (PAD). The factors responsible for these dramatic increases are increasing body mass index (obesity), dietary factors, and lack of regular physical activity.

It is now well recognized that CV frequently coexist with DM and CV events are the leading cause of death and disability in patients with DM. Individuals with diabetes have a 2- to 4- increase in the risk of cardiovascular disease (CVD) as compared to normal individuals (Fig. 1); there is also a higher case fatality rate in individuals with diabetes. CVD accounts

T2DM, type 2 diabetes mellitus.

FIG. 1: Showing the risk of cardiovascular events in diabetes mellitus.

for 60–75% of deaths in persons with DM. Much of the morbidity and mortality is from atherosclerotic coronary artery disease, cerebrovascular disease leading to stroke, congestive heart failure (CHF), PAD, and sudden cardiac death.

THERAPEUTIC STRATEGIES FOR CONTROL OF CARDIOVASCULAR DISEASE IN DIABETES

As mentioned earlier treatment strategies focused on the reduction of CVD and CV events in DM should consist of comprehensive risk reduction strategy which should be comprised of aggressive management of glycemic status, BP, lipids, as well as use of antithrombotic agents, and therapeutic lifestyle modification including recommendations for

regular physical activities and prudent dietary modifications (Table 1).³ Although, a number of studies in last two decades have demonstrated significant CV protection with the use of BP control, as well as lipid lowering therapy with statins in patients with DM the results of glucose lowering therapies with the traditional hypoglycemic agents have been rather disappointing.⁴ Although, several trials conducted during the past decade evaluated the benefit of intensive glucose control with the available antidiabetic drugs these trials have generally failed to show significant benefit in reducing the risk of macrovascular events [such as myocardial infarction (MI) or stroke] despite demonstrating significant reductions in microvascular events such as diabetic nephropathy, retinopathy, and neuropathy (Table 2). The precise reason for the failure to achieve significant reduction in CV events

TABLE 1: Describing the multifactorial approaches for cardiovascular risk reduction in diabetes

Goals for risk-factor management in diabetes		
Risk factor	Goal of therapy	Reference
Cigarette smoking	Complete cessation	ADA
Blood pressure (with proteinuria)	<130/80 mm Hg <125/75 mm Hg	ACC/AHA 2017, ADA JNC 7, ADA
LDL-C	<100 mg/dL <70 mg/dL in high risk	2014 ACC/AHA guidelines, ADA 2018
Triglycerides 200–499 mg/dL	Non-HDL-C <130 mg/dL Triglyceride <150 mg/dL	2014 ACC/AHA guidelines, ADA 2018
Prothrombotic state	Low-dose aspirin therapy (patients with CHD and other high-risk patients)	ADA
Glucose	HbA1c <7%	ADA
Overweight and obesity (BMI $\geq 25 \text{ kg/m}^2$)	Lose 10% of body weight in a year	OEI
Physical inactivity	Excercise prescription dependent on patient status	ADA

remains to be established, it has been suggested that the lack of favorable effect on CV events might be related to adverse effects of resultant hypoglycemia with the use of multiple hypoglycemic agents to achieve intensive glycemic control.

However, the scenario has changed dramatically with the recent introduction of several newer classes of hypoglycemic agents which have been tested in large prospective randomized clinical trials in patients with either preexisting CVD or those at high risk of CVD. These CVOTs have been conducted based on the 2008 Food and Drug Administration (FDA) mandate to demonstrate safety of all newer hypoglycemic agents prior to seeking approval. The following review is a concise synthesis of these new trial data from CVOTs for the clinical cardiologist as the clinicians must familiarize themselves with these drugs as they will become important part of therapeutic armamentarium for diabetic patients with pre-existing CVD or at future risk of CVD as evidenced by recent approval by the FDA of several of these agents for CV protection.

ROLE OF ANTIDIABETIC (HYPOGLYCEMIC) MEDICATIONS IN CARDIOVASCULAR PROTECTION

Hypoglycemic drugs, through various mechanisms of action lower blood glucose and effectively reduce microvascular target end-organ damage like retinopathy, nephropathy, and neuropathy.⁴ However, there did not appear to be a strong and convincing relationship between the lowering of blood sugar [as evidenced by glycated hemoglobin (HbA1c) reduction] and reduction in CV events with the traditional drugs.⁵⁻⁸ Additionally, some of the beneficial effects are mitigated by episodes of hypoglycemia that were associated increased risk of CV events and cardiac as well as all-cause mortality.⁹⁻¹²

The increased risk of heart failure (HF) and concerns about MI with the use of thiazolidinediones (rosiglitazone and pioglitazone) led to heightened awareness of potentially harmful CV effects of these otherwise effective hypoglycemic drugs and has resulted in drastic reduction in their clinical use. In response to the concerns of increased CV risk, the FDA and other regulatory agencies mandated all new diabetes drugs to demonstrate CV safety.¹³⁻¹⁵ Since, the primary use of a hypoglycemic drug is to control blood glucose (as demonstrated by lowering HbA1c), it was required that all new drugs would be approved for marketing only after adequately powered RCTs could demonstrate that such treatment would not be associated with unacceptably high rates of CV events in the phase-3 clinical trials (upper bound of the 95% confidence interval for major adverse CV event not to exceed 1.8). Postapproval, a phase-4 CV safety outcome trial in high-risk patients (with pre-existing CVD) would need to further demonstrate a CV event rate not exceeding the upper bound of the 95% confidence interval of 1.3. A minimum of 2-year follow-up data would be required with independent adjudication of CV outcomes.

As a result of this mandate, the last half-decade has seen a steady stream of CV safety trials in patients with pre-existing CVD or those at risk of CVD (Fig. 2). And, although, these CVOTs were designed to demonstrate safety, some of the trials have shown unprecedented CV benefit in secondary prevention of CV events and related outcomes (Fig. 2). It is therefore critical for the cardiologist to familiarize with these newer therapies and results of these CVOTs so that they can prescribe the appropriate drugs for their diabetic patients with CVD or at risk of CVD to provide maximum CV protection and reduce the risk of future CV events. The following is a review of the newer hypoglycemic agents tested in the recent CVOTs.

FIG. 3: Showing comparison of the EMPA-REG and CANVAS trials on major cardiovascular and renal outcomes.

Dipeptidyl Peptidase-4 Inhibitors

Dipeptidyl peptidase 4 (DPP-4) inhibitors prolong the activity of glucagon-like-peptide 1 (GLP-1) the gastric-inhibitory-peptide, and other incretins by preventing their breakdown.¹⁶ The agents in this class have modest HbA1c reductions, but their appeal lies in that they do not cause hypoglycemia or weight gain.¹⁶ Three DPP-4 inhibitors namely saxagliptin, alogliptin, and sitagliptin have been tested in CVOTs (SAVOR-TIMI 53, EXAMINE, and TECOS, respectively).¹⁷⁻¹⁹ None were found to increase adverse CV events, CV mortality, or all-cause mortality (Tables 1 and 2). Neither was there a signal of CV benefit.

Heart failure hospitalizations were, however, a concern with this class of drugs. SAVOR-TIMI 53 showed an unexpected 27% increased risk of HF hospitalizations (3.5% vs. 2.8%) with saxagliptin. This adverse effect was not initially apparent with alogliptin in the main report of the EXAMINE study. But a subsequent *post-hoc* analysis suggested increased HF hospitalizations (2.2% vs. 1.3%) in patients without a history of HF [hazard ratio (HR) 1.76 (1.07–2.90)] but no increase in those with pre-existing HF [1.00 (0.71–1.42)].²⁰ In 2015, the FDA issued a safety warning for the risk of HF risk with saxagliptin and alogliptin.²¹ No signal of increased HF hospitalizations was seen with sitagliptin in TECOS.

Sodium-glucose Co-transporter 2 Inhibitors

Sodium-glucose co-transporter 2 (SGLT2) is a low affinity, high capacity sodium-glucose co-transporter in the proximal renal tubules and is responsible for glucose reabsorption. SGLT2 inhibitors are orally administered drugs that block this receptor, thereby, preventing glucose reabsorption into

the blood stream and facilitating elimination of glucose in the urine (glycosuria). As a result, these agents also have a diuretic effect and promote weight and BP reduction by sodium and water loss.²²

EMPA-REG OUTCOME trial evaluated the CV effects of 10 mg or 25 mg of empagliflozin added to standard therapy in diabetic patients with known CVD and demonstrated impressive results.²³ The primary composite outcome of CV death, MI, and stroke occurred less frequently with empagliflozin (10.5% compared to 12.1% in the placebo group; $p = 0.04$ for superiority) (Fig. 3). This difference was largely driven by significantly lower CV death in the treatment group (3.7% vs. 5.9%; $p < 0.001$) without significant differences in MI or stroke rates. All-cause death was also reduced with empagliflozin (5.7% vs 8.3%; $p < 0.001$). Most interestingly, empagliflozin reduced HF admissions by 35% (2.7% vs. 4.1%; $p = 0.002$). This was a major paradigm shift from the previous hypoglycemic medications that either had no effect or increased HF hospitalizations (rosiglitazone, saxagliptin). Also, the beneficial CV effects of empagliflozin appeared much earlier than GLP-1 analogs like liraglutide suggesting a prominent hemodynamic rather than anti-atherosclerotic mechanism of action. The robustness of HF outcomes in the EMPA-REG OUTCOME trial have been debated due to the lack of cardiac function and biomarker assessment (such as brain natriuretic peptide) which are otherwise a norm in most HF trials. Additionally, in subgroup analysis, HF hospitalizations were statistically significantly reduced in patients without HF at baseline but not in those with HF.²⁴ Trials specifically evaluating HF outcomes are now underway.²⁵ Regardless, prior to these findings, no glucose-lowering drug had shown an improvement in HF outcomes in patients with diabetes.

Canagliflozin was the second SGLT2 inhibitor to undergo a CV safety trial (CANVAS)²⁶ and consistent with results of EMPA-REG OUTCOME, showed reduction in HF hospitalization (5.5% vs. 8.7%) (Fig. 3). Canagliflozin was shown to be superior to placebo in reducing the primary combined outcome of CV death, MI, and stroke (26.9% vs. 31.5%; $p = 0.02$), but did not improve any of these outcomes individually. However, the reduction in the HF related outcome was identical to that observed with empagliflozin in the EMPA-REG OUTCOME trial.

Apart from CV benefits modulated through osmotic diuresis, reduction in weight, arterial stiffness, and left ventricular afterload, and overall modulation of the cardio-renal axis, SGLT2 inhibitors also reduce the progression of renal disease and delay the need for dialysis.^{25,27} This is a major advantage in diabetic patients where renal disease is an important cause of progressive morbidity and mortality.

Prescribing physicians must be cognizant of some known adverse effects of SGLT2 inhibits. Since SGLT2 inhibitors act by inducing glycosuria, superficial genital mycotic infections (especially in women and uncircumcised men) are more common with their use. Their use can also be associated with increased risk of UTIs and diabetic ketoacidosis (rare). Increased amputation and bone fractures with canagliflozin in the CANVAS trial are also concerning. The FDA has issued a warning to avoid canagliflozin in patients that may be at a higher risk for amputations.²⁸

Glucagon-like Peptide 1 Analogs

Glucagon-like peptide 1 analogs are a class of injectable hypoglycemic drugs that activate the endogenous GLP-1 receptor. They promote glucose-dependent insulin release, inhibit glucagon secretion, and delay gastric emptying.²⁹

Lixisenatide, liraglutide, semaglutide, and most recently exenatide have been tested in CVOTs (ELIXA³⁰, LEADER³¹, SUSTAIN-6³², and EXSCEL³³ respectively) while dulaglutide is currently being tested (REWIND).³⁴ It is apparent from the results of the published trials that the benefits of GLP1 analogs may not be a class effect. While LEADER and SUSTAIN-6 were able to demonstrate CV event reduction, the results of ELIXA not as encouraging, and EXCEL showed no benefit.

ELIXA showed a neutral CV effect of shorter-acting lixisenatide (daily injection) added to standard therapy in diabetic patients who had an MI or unstable angina episode in the preceding 6 months. The positive results of the subsequent LEADER trial came as a surprise. Not only was liraglutide (daily injection) noninferior to placebo, it was superior in reducing the primary composite outcome of CV death, MI, and stroke (13% vs. 14.9% in placebo; $p = 0.01$). The reduction in the primary endpoint was driven by significantly lower CV mortality (4.7% vs. 6%; $p = 0.007$). Moreover, liraglutide reduced all-cause mortality as well (8.2% vs. 9.6%; $p = 0.02$). While there was numerical reduction in MI and stroke rates, this did not reach statistical significance. SUSTAIN-6, which had similar inclusion criteria as LEADER (Table 1), also showed composite CV event reduction (6.6% vs. 8.9%; $p = 0.02$) with semaglutide (weekly injection), which

was driven by a significant reduction in strokes (1.6% vs 2.7%; $p = 0.04$) rather than CV mortality or MI.

Neither liraglutide nor semaglutide had a significant effect on HF admissions, suggesting a different mechanism of action than SGLT2 inhibitors. Though not completely understood, it has been postulated that these drugs may have more of an antiatherothrombotic effect. Other positive effects like BP lowering, weight reduction, and avoidance of hypoglycemia may contribute to improved CV outcomes.³⁵

As mentioned, the CV benefits of GLP-1 agonists are not consistent across this class of medications. The recently published EXSCEL trial comparing exenatide weekly injection to placebo in diabetic patients, majority (73%) of whom had preexisting did not show a signal for benefit in any of the CV outcomes.³³ Results of the REWIND trial evaluating CV outcomes with dulaglutide (weekly injection) are expected in 2018.³⁴

Gastrointestinal side effects, driven by delayed gastric emptying, are an important consideration while prescribing GLP1 agonists and may be a reason for nonadherence or discontinuation of the medication.

CONCLUSION AND FUTURE DIRECTION

The current global epidemic of DM with the attendant CVD poses a big challenge to health and quality of life of large populations. India is in the midst of the epidemic of DM and CHD with an increasing number of individuals being affected by these disorders in the prime of their careers. With this perspective, the current understanding of DM as a vascular as well as metabolic disorder is very important. Although, in the past glucose control with the traditional hypoglycemic agents including insulin failed to result in any significant CV benefit the recent CVOTs have provided clinicians with a new set of antidiabetic drugs with proven CV benefit in patients with diabetes and CVD. New medications like empagliflozin and liraglutide improve not only CV mortality but also all-cause mortality in diabetic patients with CVD. The FDA has approved both empagliflozin and liraglutide to reduce the risk of CV death in adults with diabetes and CVD. It is important to keep in mind that these drugs in all of the CVOTs were used in addition to metformin as the baseline therapy in all patients so the clinician must still consider metformin as the first-line antidiabetic medication in most patients, if it is well tolerated. Additionally, SGLT2 inhibitors like empagliflozin and canagliflozin reduce HF hospitalizations. If the results of the ongoing trials with empagliflozin in HF patients prove their utility these drugs can be considered as additional choice for the treatment of CHF patients.

As many cardiac patients will present with coexisting DM it is critical for the clinician to understand the therapeutic strategies to reduce the risk of future CV events in such patients. As stated earlier, this can only be achieved with a comprehensive risk factor management (ABCDE approach) consisting of glycemic control ($\text{HbA1c} < 7\%$), BP control ($< 130/85 \text{ mm Hg}$), cholesterol lowering therapy with statins ($\text{LDL-C} < 70$), dietary modification (low glycemic index foods with low saturated fat and caloric restriction, exercise on a regular basis ($> 30 \text{ minutes} \times 5 \text{ times/week}$)).

There is an immediate need for clinicians to embrace the evidence and switch from traditional diabetes medications to newer therapies with proven CV benefit. Physician education and increasing awareness of these persuasive clinical trial results will increase their comfort level in making this transition to provide cardioprotective therapy in their patients with diabetes and CVD and those at high risk of future CV events.³⁵

Diabetes Classification New Dimensions

Jugal Kishor Sharma, Amit Gupta

INTRODUCTION: DIABETES A JOURNEY FROM ANTIQUITY TO 21ST CENTURY

Diabetes mellitus is known to mankind since antiquity with the first mention of the disease dated as early as 1500 BC. However the first clinical description was given by Sushruta 1000 years later.¹ Over the centuries diabetes has seen many changes with respect to its origin, pathophysiology, diagnosis, classification, management, and complications and a plethora of literature is available on diabetes. Some of the milestones in history of diabetes are worth remembering. These milestones may be as trivial as someone noticing that ants were attracted to urine of patients with diabetes (Ancient Indian Literature) to the more complex ones like identification of islets of Langerhans by Paul Langerhans in 1869² in pancreas and path breaking discovery of insulin in November 1921 by Banting and Best.³ In 21st century diabetes has become a global challenge and can truly be called as a disease without borders.

DIABETES CLASSIFICATION: HISTORY

First attempt to standardize the nomenclature and definition of diabetes was made in 1979 by a consensus statement given by National Diabetes Data Group⁴ which was also endorsed 1 year later by World Health Organization (WHO). Based on the consensus diabetes was divided into two major types viz. insulin-dependent diabetes mellitus (IDDM) and noninsulin-dependent diabetes mellitus (NIDDM). This classification because of its inherent limitations added to the confusion. The classification and diagnostic criteria were again revised in 1997 and diabetes was classified into four types.⁵ The American Diabetes Association (ADA) classifies diabetes as described in ADA standards of care 2017⁶ into four types (Table 1).

A systematic review "Incorrect and Incomplete Coding and Classification of Diabetes: a Systematic Review" published in 2010 in Diabetic Medicine⁷ drew attention to the

TABLE 1: American Diabetes Association classification of diabetes (2017)

Type of diabetes	Pathophysiology
Type 1 diabetes	<ul style="list-style-type: none"> Autoimmune β-cell destruction-absolute insulin deficiency
Type 2 diabetes	<ul style="list-style-type: none"> Progressive loss of β-cell function along with insulin resistance
Gestational diabetes mellitus	<ul style="list-style-type: none"> Associated with pregnancy
Miscellaneous	<ul style="list-style-type: none"> MODY (maturity onset diabetes of young/monogenic diabetes) LADA (latent autoimmune diabetes of adults) Neonatal diabetes Diseases of exocrine pancreas/fibrocalcific pancreatic diabetes (FCPD) Drug or chemical induced diabetes

implications for the incorrect and incomplete classification of diabetes. Stone MA et al. highlighted the often seen dilemma of differentiating between type 1 and type 2 diabetes mellitus especially in young patients. It also brought to the notice that there were consistent failures in recognizing other clinical subtype like maturity onset diabetes of young (MODY) and latent autoimmune diabetes of adults (LADA).⁸

DIABETES CLASSIFICATION: WHY DO WE NEED A NEW CLASSIFICATION SYSTEM?

Traditionally diabetes is classified into two types: type 1 and type 2. Type 1 and type 2 diabetes most likely only represent two extremes of hyperglycemia with multiple possibilities in between ranging from MODY, LADA, ketosis-prone diabetes (KPD), Fibrocalcific pancreatic diabetes (FCPD), gestational diabetes mellitus (GDM), Neonatal diabetes, and various secondary forms of diabetes.⁹ There is enough evidence

SECTION 3

Diabetes and Heart

to consider Alzheimer's disease (AD) as type 3 diabetes characterized by insulin deficiency and insulin resistance leading to Alzheimer's type neurodegeneration with selective involvement of brain.¹⁰ Glaucoma, an irreversible cause of blindness is also called as diabetes of brain and researchers say its type 4 diabetes.¹¹

Diabetes results from interplay between genetic and environmental factors, while genetics determines susceptibility to the disease, the environment (lifestyle factors, physical activity, infections, obesity, and nutrition) plays a vital role in shaping the clinical phenotype of the patient with diabetes. Most of us have seen and experienced in our clinical settings that all diabetic patients are not alike. Some of the patients respond well to even low doses of medications and remain stable for decades while others do not respond even to multiple drugs including insulin and in such patient's disease progresses rapidly with development of multiple complications, earlier than that predicted by natural history of diabetes.

There is no perfect classification system for diabetes and current classification systems are not adequate. Diabetes is one of the diseases which has grown at a tremendous pace over the last few decades and poses a significant threat to human health. Diabetes is a chronic progressive disease and is associated with systemic complications. There have been several recent advances in the management of diabetes and its complications but yet there are challenges and unmet needs as we are not yet able to slow the progression of the disease or accurately predict the complications. There are challenges with the diagnosis as well as its management. Diabetes is a heterogeneous disease and current classification schemes do not seem to fulfill the requirement of an ideal classification system. An ideal classification system may be the one which serves as a guiding tool to both the researchers as well as clinicians. It must also address the patient centric issues like therapeutic education, evaluation of outcome with focus on prevention of the complications. It shall also help the clinicians to design the best management plan for the patient while incorporating current guidelines-based best practices. Nonetheless diagnostic criteria for diabetes are also based on single entity, i.e., glucose. This

heterogeneity of diabetes warrants a new approach to classify diabetes which can be more meaningful to the patients, researchers, and clinicians.

NEW PROPOSED CLASSIFICATION OF DIABETES

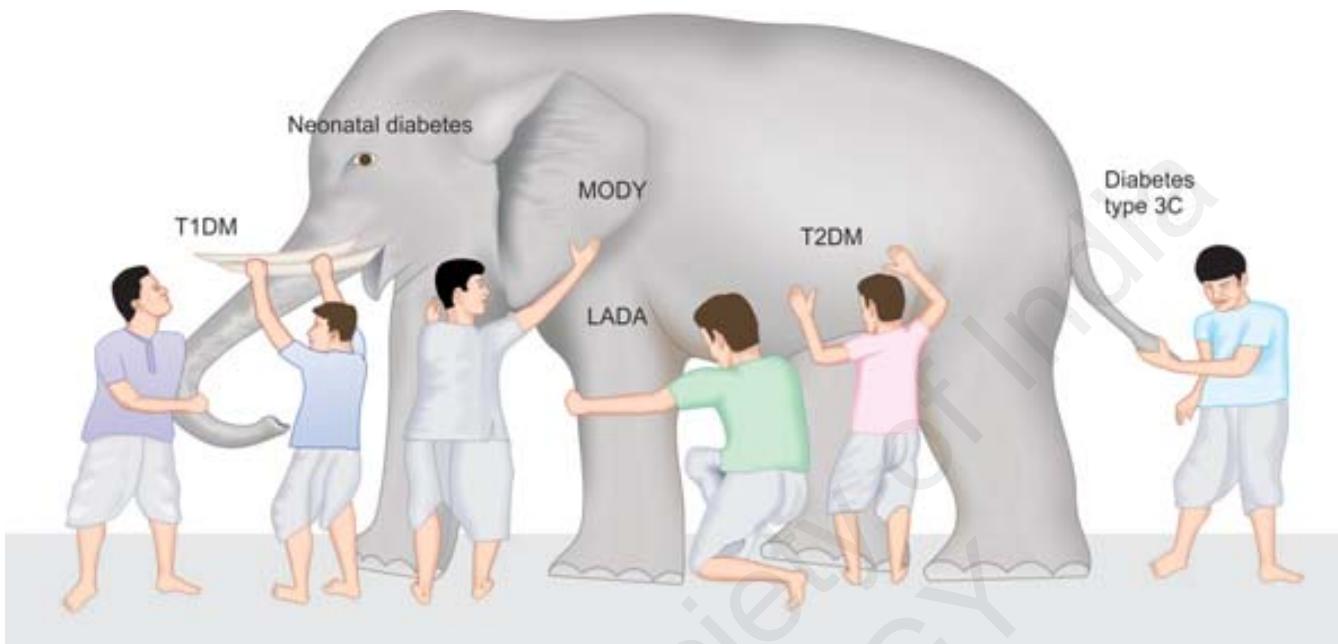

In 2016, an article titled "The Time Is Right for a New Classification System for Diabetes: Rationale and Implications of the β -Cell-Centric Classification Schema" published in Diabetes Care, Stanley et al. emphasized on β -cell centric classification.¹² They proposed that all types of diabetes originate in abnormal β -cells which are further influenced by environmental, genetic, and immune components. The β -cell stress, abnormal β -cell function or losses of β -cells by more than dozen factors are central to development of diabetes. Though Stanley et al. could rationally explain the need for revision and reclassification they only urgently called for the review of the current diabetes mellitus classification system toward the consensus on a new and hopefully more useful and meaningful system.

Recently a paper published in Lancet by Ahlqvist Emma, et al. suggested novel subgroups of adult onset diabetes and their association with outcomes which can serve as a powerful tool for deciding treatment and identifying individuals who are at greater risk of developing complications.¹³ The new classification of diabetes suggested by the authors was based on unsupervised data driven cluster analysis of six commonly measured variables in four separate population groups from Finland and Sweden. The variables consisted of glutamate decarboxylase antibodies (GADA), age at onset, body mass index (BMI), glycated hemoglobin (HbA1c), homeostatic model assessment 2 estimates of β -cell function, and insulin resistance were compared metabolically, genetically, and clinically. The study identified five clusters of patients with diabetes which were replicable. Based on the study adult onset diabetes can be classified into five types. These types are severe autoimmune diabetes (SAID), severe insulin deficiency diabetes (SIDD), severe insulin resistance diabetes (SIRD), mild obesity-related diabetes (MORD), and mild age-related diabetes (MARD) (Table 2).

TABLE 2: New proposed classification of diabetes

Type of diabetes	Autoantibody GAD	BMI	Metabolic control	Insulin deficiency or resistance (HOMA- β and HOMA-IR)
SAID	Positive	Low BMI	Poor	Insulin deficiency
SIDD	Negative	Low BMI	Poor	Insulin deficiency
SIRD	Negative	High BMI	Poor	Severe insulin resistance
MORD	Negative	High BMI	Modest metabolic derangements	Mild or no insulin resistance
MARD	Negative	Variable BMI	Modest metabolic derangements	Mild or no insulin resistance

BMI, body mass index; GAD, glutamic acid decarboxylase; HOMA- β , homeostatic model assessment for beta-cell function; HOMA-IR, homeostatic model assessment for insulin resistance; MARD, mild age-related diabetes; MORD, mild obesity-related diabetes; SAID, severe autoimmune diabetes; SIDD, severe insulin deficiency diabetes; SIRD, severe insulin resistant diabetes.

T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus; MODY, maturity onset diabetes of young; LADA, latent autoimmune diabetes of adults.

FIG. 1: Figure draws an analogy for diabetes classification to errors made in identification of an elephant by a group of blind men: A story from Hindu Upnishads.

The above proposed classification appears more realistic and is based on commonly measured variables in a patient with diabetes. The study also highlighted the fact that clustering of patients in above-mentioned groups can help predict risk of complications. The authors pointed that patients classified as severe autoimmune diabetes and severe insulin deficiency diabetes were younger at onset, were more prone to ketoacidosis as well as carried higher risk of future diabetic retinopathy. Patients with severe insulin resistance diabetes were at higher risk of developing diabetic nephropathy¹⁴ and end stage renal disease (a known fact with insulin resistance). Risk of cardiovascular (CV) complications like stroke and myocardial infarction was similar in all age groups after adjusting for age and sex. What is apparent from this classification is that a reorganization of patients with diabetes into such groups can be more useful for the clinicians and it will also aid researchers because of its replicability. A patient can be selected for more aggressive treatment in SIRD while a patient with only MARD or MORD can benefit more with a less intensive regimen. Also there is a possibility that low-risk groups may require less frequent hospital visits and more flexibility in care plan, leading to decreased cost of treatment.

The limitations of the above study are that it was limited only to Scandinavian population. Whether it will hold true or not for other ethnic populations remains to be seen. Other notable limitations are that study cannot confirm causes of five different type of diabetes and remains silent about overlap or changeover from one form to the other form of diabetes as well as there is lack of data on established risk factor like blood pressure and lipid profile. Nevertheless, it reestablishes

the fact that time has really arrived to look at diabetes from several other perspectives.

CONCLUSION

The future trends in diabetes will undoubtedly be dominated by genetics, biomarkers, precision medicine, and use of technology in management of diabetes. Development of drugs targeting new sites for management of diabetes to improve the existing standard of care for our diabetic patients will also be at forefront. A newer classification scheme for diabetes is need of the hour. We also call upon the researchers to look at the Indian data for a more practical classification system.

Prevention of Coronary Artery Disease in Diabetes Mellitus

Ranjan Modi, Sunil Modi

INTRODUCTION

Diabetes mellitus (DM) is a principal risk factor for cardiovascular disease (CVD). Diabetes induced macrovascular disorders are retinopathy, nephropathy, peripheral vascular disease (PWD), stroke, and coronary artery disease (CAD). Evidence suggest that although hyperglycemia, contribute to myocardial damage after ischemic events, it is clearly not the only factor. Both prediabetes and presence of metabolic syndrome, in normoglycemic patients can increase the risk of CVD.¹⁻⁴

Targeting individual risk factors reduces atherosclerotic cardiovascular disease (ASCVD) or CAD risk in DM, but simultaneously treating multiple risk factors may reduce cardiovascular (CV) event risk more than when treated individually. The Steno-2 study which showed a statistically and clinically significant 53% reduction in the primary composite CV event end point.

Cardiovascular risk differences between intensive and conventional therapy were studied after 1 year.⁵ The number needed-to-treat was 5 over 7.8 years to achieve this magnitude of ASCVD risk reduction. The Steno-2 trial was not designed to identify which interventions were most effective, but use of statin and antihypertensive drugs may have accounted for much of the CV benefit.

The BARI-2D trial (Bypass Angioplasty Revascularization Investigation in Type 2 Diabetes) evaluated multiple interventions and their secondary analysis which all supported the fact that concurrent risk factor control lowers total mortality and the composite of death, myocardial infarction (MI), and stroke in patients with type 2 DM and established coronary heart disease (CHD).⁶

The BARI-2D trial demonstrated that control of multiple risk factors improved CV outcomes. Though achievement of treatment goals in DM care have improved over time, currently only a small percentage of world population with type 2 DM reach the recommended goals for glycated hemoglobin (HbA1c), blood pressure (BP), and low-density lipoprotein (LDL) cholesterol.⁷

Prevention of CAD in DM by addressing risk factors individually from clinical trials of lifestyle modification, lipid lowering, BP-lowering, aspirin therapy, and glucose-lowering therapies is presented here.

LIFESTYLE MODIFICATION

Appropriate lifestyle modifications have been shown to stabilize glycemic control and prevent and decrease CVD risk factors.

In a 4-year study, the Look AHEAD (Action for Health in Diabetes) research group examined the effects of lifestyle modifications on CVD risk factors.⁸ Participants were divided into a “diabetes support and education group” (DSE, the control group) and an “intensive lifestyle intervention group” (ILI).⁸ The ILI group was told to adhere to a 1,200–1,800-calorie diet and 175 minutes of physical activity each week. Risk factors evaluated at the end of the study were weight, fitness, HbA1c, BP, LDL-C, high-density lipoprotein (HDL)-C, and triglyceride (TG) levels. All CVD risk factors measured in Look AHEAD study were decreased in members of ILI except LDL-C levels which were greater in ILI than DSE.⁸ The study evaluated the need for diabetes treatment in ILI versus DSE group and demonstrated the decrease in number of patients in ILI group over 4 years.

The specific American Diabetes Association (ADA) lifestyle recommendations and goals required for decreasing the risk of CVD include moderate weight loss, (i.e., 7–10% of body weight per year) and dietary modification.⁹ The dietary guidelines recommend that only 25–35% of total daily calories should come from fat which should consist mainly of monounsaturated and polyunsaturated fats, proportion of saturated fats should be <7% of the total calorie intake with cholesterol intake reduced to <200 mg/day and a fiber intake of at least 14 g per 1,000 calories. Physical activity as well is an important lifestyle intervention for decreasing CVD risk with addition to diet restriction. Patients should be encouraged to achieve at least 150 minutes of moderate-intensity aerobic activity, or at least 90 minutes of vigorous aerobic activity in a week.

Smoking is another modifiable risk factor of CVD. Patients who smoke should be counseled and advised to quit as soon as possible to reduce the incidence of CV events.

LIPID-LOWERING THERAPY

Clinically, dyslipidemia is highly correlated with atherosclerosis, and up to 97% of diabetics are dyslipidemic.¹⁰ In addition to the characteristic pattern of increased TG and decreased HDL found in diabetics, abnormalities are also seen in the structure of the lipoprotein particles. The predominant form of LDL is the small, dense form. Small dense LDL particles are more atherogenic than large LDL particles because they can more easily penetrate and form stronger attachments to the arterial wall, and they are more susceptible to oxidation. Because less cholesterol is carried in the core of small LDL particles than in the core of large particles, subjects with predominantly small LDL particles have higher numbers of particles at comparable LDL cholesterol levels.¹¹

There is convincing evidence that the use of lipid lowering therapy and statins reduce ASCVD event rates in DM; part of this benefit is attributed to the pleomorphic anti-inflammatory effects of statins.¹²⁻¹⁴ Patients with DM between the ages of 40 and 75 years have been identified as one of the four principal groups to benefit from statins therapy in the recent American College of Cardiology or American Heart Association (ACC/AHA) guidelines. The guidelines recommend treatment with a moderate or a high intensity statin for individuals with $\geq 7.5\%$ 10-year risk of CVD.¹⁵ In those <40 or >75 years of age, guidelines recommend individualizing statin therapy based on the benefits of ASCVD risk reduction versus the potential for adverse effects, interactions with other drugs, and patient preference.¹⁵

Cholesterol Treatment Trialist (CTT) collaboration meta-analysis showed that 39 mg/dL (1 mmol/L) lowering of LDL in high-risk individuals by statins reduces coronary mortality by 19%¹⁶ and major vascular events by 21%, irrespective of prior history of vascular disease, gender, age, body mass index (BMI), baseline BP, smoking status, glomerular filtration rate (GFR), cholesterol, or predicted annual risk of major vascular events.¹⁷

The CARDS trial (Collaborative Atorvastatin Diabetes Study), assessed patients of type 2 DM, with mean baseline LDL cholesterol of 117 mg/dL (3.0 mmol/L) randomized to atorvastatin 10 mg daily or placebo. The primary CV composite outcome (time to first occurrence of acute CHD event, coronary revascularization, or stroke) showed a 37% reduction for atorvastatin compared to placebo group.

The TNT (Treating to New Targets) study which included patients with DM and CHD who were randomized to atorvastatin 10 mg versus 80 mg daily examined whether lowering LDL cholesterol below the threshold recommended at the time (100 mg/dL, 2.59 mmol/L) would result in greater CV risk reduction.¹⁸ There was a 25% reduction in major CV events (composite of CHD death, nonfatal non-procedure-related MI, resuscitated cardiac arrest and fatal or nonfatal stroke) after a median of 4.9 years of treatment. This study

provides further evidence for more aggressive LDL-lowering to reduce ASCVD in DM.

Statins and Development of Diabetes Mellitus

Statins may interfere with β -cell insulin secretion either by decreasing Ca^{2+} -dependent insulin secretion or by interfering with isoprenylation of guanosine triphosphate-binding proteins.¹⁹ Statin inhibition of isoprenoid biosynthesis may lead to lower expression of insulin signaling proteins in adipocytes and to reduced glucose transporter expression or translocation.

Although, various trials and meta-analysis have shown clear benefits of statins to reduce CV events and mortality in patients with or at risk for ASCVD^{16,17} statins can also modestly accelerate the development of DM in individuals with pre-existing risk factors.²⁰

Meta-regression analysis of large trials showed that one additional case of DM resulted from treating 225 patients with statins for 4 years, whereas 5.4 vascular events were prevented over same period of time.

The risk of statin associated diabetes appears to be related to potency²¹ and dose²² of statin and may be slightly higher in women.²³

Majority of professional bodies advise that considering the many treatments available for diabetes and the important magnitude of CV risk reduction by statins, provider should not avoid using statins when indicated solely because of concern for risk of developing diabetes.

Non-statin Lipid Lowering

Although, statins are effective in reducing ASCVD risk in DM, residual CV risk remains^{18,24} and further lowering of lipids may be of value. Although many studies in past did not demonstrate, other pharmacological class agents provide additional benefit, the IMPROVE-IT trial (Improved Reduction of Outcomes: Vytorin Efficacy International Trial) supports use of a non-statin LDL-lowering strategy to further lower CV risk.²⁵ Ezetimibe lowered LDL cholesterol further by 24% despite the relatively low baseline concentrations, which was an unexpectedly potent effect. In the trial 27% of the study population had DM, and there was heterogeneity in response with a greater 14% CV benefit among those with DM. Thus the trial supported the hypothesis that further lower LDL targets may be beneficial to reduce residual ASCVD risk in patients with DM.

The unanswered question is whether targeting high TG and or low HDL and small LDL particle size will result in further benefits.

Lipid arm of ACCORD trial (Action to Control Cardiovascular Risk in Diabetes)²⁶ examined fenofibrate versus placebo on a background of simvastatin therapy, and the FIELD (Fenofibrate Intervention and Event Lowering in Diabetes) trial,²⁷ involved fenofibrate monotherapy versus placebo. Inclusion in the ACCORD-lipid substudy as well as in the FIELD study did not require high TG and low HDL cholesterol levels, a group which might benefit most from

fibrate therapy.²⁶ Results of both ACCORD and FIELD trials were similar.

In ACCORD trial, although there was no difference in annual rate of primary composite outcome of major adverse cardiac events (MACE) for the fenofibrate as compared to placebo, prespecified subgroup analysis revealed 29% fewer events in those with baseline TG more than 204 mg/dL and HDL less than 34 mg/dL (14% fewer events in FIELD study in similar subgroup).

Although total of four such studies consistently demonstrate favorable effects of fibrates in the subgroup of patients with the specific lipid phenotype of high TG and low HDL,²⁴⁻²⁸ further studies are needed to prove this benefit.

The addition of niacin on top of statin in (Atherosclerosis Intervention in Metabolic Syndrome with low HDL/High Triglycerides: Impact on Global Health Outcome) AIM-HIGH trial²⁹ and in (Heart Protection Study 2-Treatment of HDL to Reduce the Incidence of Vascular Events) HPS2-THRIVE trial³⁰ has not shown any further benefit and raising HDL with the use of cholesteryl ester transfer protein (CETP) inhibitors has also not shown any benefit in CV risk reduction.

LDL-lowering with Proprotein Convertase Subtilisin or Kexin Type 9 Inhibition

The latest class of LDL lowering medications consists of monoclonal antibodies to proprotein convertase subtilisin/kexin type 9 (PCSK9) present in hepatocytes. PCSK9 binds to and targets the LDL receptor for degradation.³¹ PCSK9 inhibitors prevent the degradation of the LDL receptors, thereby leading to increased removal of LDL cholesterol from the circulation. Individuals with loss of function of PCSK9 mutations have lower LDL cholesterol levels and lower CHD incidence.³² On the other hand gain of function mutations lead to most cases of familial hypercholesterolemia with elevated LDL cholesterol concentrations and resulting early ASCVD. Statins upregulate PCSK9, a potential reason that LDL cholesterol lowering with statins reaches a plateau.³³

Although PCSK9 inhibition has a potent and durable effect to lower LDL, the currently available trials are exploratory and preliminary as far as beneficial effects on CV outcomes are concerned. Furthermore such effects in diabetic population remain uncertain and will need more research and data.

Blood Pressure Control

The age-adjusted prevalence of hypertension is higher in adults with DM as compared to those without DM, with higher rates seen in older persons.³⁴

Elevated BP has shown to increase the risk of both micro- and macrovascular disease in DM,³⁵ and BP control reduces the risk of death and both micro- and macrovascular complications.³⁶

In diabetics, every 10 mm of systolic BP lowering reduces all—cause mortality by 13%, CV events by 11% and stroke events by 27%.

In general, antihypertensive drug class does not affect the overall results and rather it is BP lowering per se which confers clinical benefit. However, there are differences between particular drugs and individual CV endpoints. For example, diuretics were associated with 17% lower relative risk of heart failure [mainly driven by (Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial) ALLAHAT trial], and angiotensin receptor blockers (ARB's) are associated with a lower risk of heart failure and mortality [mainly driven by (Losartan Intervention for Endpoint reduction in hypertension study) LIFE trial]. In contrast calcium channel blockers are associated with a higher relative risk of heart failure but a lower risk of stroke.

The benefits of renin-angiotensin-aldosterone system (RAAS) inhibitors to control BP in diabetics over other antihypertensive has been observed in (Appropriate Blood Pressure Control in Diabetes) ABCD trial³⁷ (Heart Outcomes Prevention Evaluation) HOPE trial³⁸ and in LIFE trial³⁹ and on the basis of these data, current guidelines from AHA or American Diabetes Association (ADA)⁴⁰ propose that RAAS blockade with an angiotensin-converting enzyme (ACE) inhibitor or ARB should be used first in the treatment of hypertension in DM.⁴¹

As far as the effect of standard versus more intensive BP lowering in individuals with DM is concerned,⁴² a recent meta-analysis including three trials with a total of 7,312 adults with type 2 DM and hypertension were followed up for 2 to 5 years.⁴³ Intensive reduction of systolic BP to 130 mm Hg or lower or diastolic BP to 80 mm Hg or lower was associated with a 35% decrease in risk for stroke and a trend for reduced mortality as compared with a standard systolic BP target of 140–160 mm Hg and diastolic BP target of 85–100 mm Hg.

The recent AHA guidelines for CV risk reduction¹⁵ recommend a BP goal of <140 mm Hg and <90 mm Hg for systolic and diastolic BP, respectively. The guidelines also recommend that initial therapy should include an ACE inhibitor or ARB for renal protection. The next choice could be to include a thiazide diuretic or calcium channel blocker. In the recently published (Systolic Blood Pressure Intervention Trial) SPRINT trial patients without DM, it would be reasonable to consider targeting BP <120/80 in individuals with DM, especially in the presence of renal disease or increased risk for stroke.

Glycemic Control

Although there are multiple mechanisms contributing to hyperglycemia in diabetes, progressive β-cell failure is a key aspect in the natural history of type 2 DM⁴⁴⁻⁴⁶ leading to gradual worsening hyperglycemia and rising HbA1c.^{47,48}

Considering the fact that 85% of patients with established DM take glucose-lowering medications and ASCVD in the form of MI and stroke accounts for up to 80% mortality in type 2 DM⁴⁹ it is desirable that medications to manage hyperglycemia must not adversely impact CV risk factors or increase ASCVD, and ideally should reverse atherosclerosis and lower CV risk. However, many antidiabetic medications

SECTION 3

Diabetes and Heart

have no beneficial effects on CV risk or actually may exacerbate CV disease or deteriorate CV risk factors.⁵⁰⁻⁵⁷

Intensive glycemic control reduces relative risk of nonfatal MI and CHD events by about 15%, although it has no effect of intensive glycemic control on all-cause mortality in meta-analysis of the multiple randomized trials targeting different intensity of glycemic control.⁵⁸

In recent decades, several clinical trials have investigated the effect of intensive treatment of hyperglycemia on CV risk reduction. When intensive treatment of hyperglycemia is initiated early in patients with short duration of diabetes and low CV risk, with target glycosylated hemoglobin levels below 7%, significant CV benefits can be achieved. However the same does not hold true when tight glycemic control is targeted in older patients with history of long duration of DM and higher CV risk profile.

This early protection is postulated to result from a mechanism known as “metabolic memory,” which means that the effect of the early glycemic exposure is remembered later in target organs resulting in long-term deleterious or protective effects. Epigenetic changes and intracellular metabolic changes resulting in oxidative stress, lowgrade inflammation, and endothelial dysfunction are the mechanisms considered to be involved in this process.

ANTITHROMBOTIC MEDICATIONS

The ADA and AHA, in the year 2007, jointly recommended that in patients with DM who are at increased CV risk, low-dose aspirin (acetylsalicylic acid, 75–162 mg/day) should be used as a primary prevention strategy.⁵⁹

After this recommendation, the Japanese Primary Prevention of Atherosclerosis With Aspirin for Diabetes, JPAD)⁶⁰ and the (Prevention of Progression of Arterial Disease and Diabetes) POPADAD⁶¹ trials raised doubts about the efficacy of low-dose aspirin in patients with DM. In the light of those results, the ADA, AHA, and American College of Cardiology Foundation (ACCF) convened to review and synthesize available evidence and updated recommendation in 2009.⁵⁹

During the evaluation to determine the updated recommendations, the joint committee considered not only the benefits of aspirin for preventing CAD, but also the known problem of gastrointestinal bleeding with daily administration of aspirin.

The joint committee concluded that low-dose aspirin (75–162 mg/day) for CVD prevention is “reasonable” for adults with DM who have no history of vascular disease but who are at increased risk of CVD (10-year risk >10%) and are not at increased risk of bleeding.⁶²

The committee added that aspirin should not be recommended for CVD prevention if patients are at low-risk of CVD (10-year risk <5%), noting that the potential adverse effects of bleeding are higher than the potential benefits. Low-dose aspirin “might be considered” for CVD prevention in patients with diabetes who are at intermediate risk of CVD (10-year >5–10%).⁶²

The joint committee also stated that all modifiable CVD risk factors should be addressed and optimally managed for patients using aspirin. Helping patients reach their individual CV goals through such management will decrease their 10-year CVD risk, meaning that fewer patients with DM may need to continue taking aspirin in the long-term.

BARIATRIC SURGERY

Bariatric surgery induces substantial and sustained weight loss⁶³ and remission or improvement in type 2 DM in 40–85% of patients, hypertension in 28–75% of patients, and dyslipidemia in 70–90% of patients.⁶⁴

The rates of improvement in obesity comorbidities vary based on both the specific procedure performed and underlying patient characteristics. Together, these metabolic improvements may lead to reduced ASCVD risk and event rates. Various observational cohort studies suggest that bariatric surgery versus usual care may be associated with reduced number of CV deaths and lower incidence of CV events in obese adults,⁶⁵ as well as reduced incidence of MI in obese individuals with type 2 DM.⁶⁶ In patients who have had bariatric surgery for obesity management, total mortality rates appear 30–40% lower⁶³ and may be more prominent in those with DM at the time of surgery,⁶⁷ although survival benefit effects may take years to manifest.

Thus, for patients with DM and BMI more than 35 kg/m² who have undergone appropriate medical and psychological evaluation, who understand the risks, lifestyle changes, and monitoring involved with bariatric surgery, have medical, social, and psychological support, bariatric surgery may be recommended when performed by an experienced bariatric surgeon at a bariatric center of excellence.

FUTURE OR WHAT IS IN HORIZON

A number of new approaches to treat DM are under development which may provide molecules with dual benefit of glycemic control as well as of CV risk reduction. In the meanwhile, CV outcome trials will provide useful information on CV safety of use of antidiabetic drugs in patients with established heart disease or in those at high-risk for CV events. The recent trials showing convincing CV benefits of using sodium-glucose co-transporter-2 (SGLT-2) inhibitors is significant and requires more trials to show their consistent benefits.

CONCLUSION

Cardiovascular disease remains the principal cause of death and disability among patients with DM, in whom CAD typically occurs 14.6 years earlier with greater severity, and with more diffuse distribution than in individuals without DM.

Reducing the ASCVD burden and preventing CAD in diabetes is a major clinical condition that should be given priority to reduce premature deaths, to improve quality of life and lessen economic burdens of associated morbidities.

The long-term treatment of DM is difficult and challenging because of diverse goals to control metabolic derangements and to simultaneously reduce CV risks. DM clearly exacerbates mechanism of atherosclerosis and heart failure which are not adequately modulated by focusing solely on glycemic control. Fortunately, aggressive management of other CV risk factors particularly lowering LDL and controlling BP provides substantial CV risk reduction.

Further investigations are required on potential benefits and risks of new glucose lowering therapies and optimal timings of (early/prolonged) glucose targeting interventions. Evidence for a more effective antiplatelet regimen than aspirin in moderate-to-high risk diabetic patients without ischemic heart disease (IHD) is necessary. Recommended BP goals are not fully evidence based, and the role of new potent PCSK9 inhibitors and of those drugs addressing TG and HDL need further studies. Another unaddressed issue is the risk benefit ratio of polypharmacy required in optimizing control of multiple CV risk factors resulting into reduced drugs compliance and risk of drug-drug interactions.

Diabetes and Coronary Artery Disease: Prevalence and Mechanisms

Satyanarayan Routray, Dipak R Das

INTRODUCTION

The association between diabetes mellitus (DM) and coronary artery disease (CAD) is very strong despite the fact that there are wide ethnic and geographical variations in their prevalence. The protective female gender effect is lost in diabetic subjects and indeed women with DM are possibly more prone to develop CAD than men with DM.¹ It was established in the "Organisation to Assess Strategies for Ischemic Syndromes study" (OASIS) that diabetic subjects without prior CAD had a similar risk as nondiabetic subjects with prior CAD, with poorer prognosis seen in diabetic subjects after a clinical event.² DM was described as a cardiovascular disease (CVD) equivalent according to National Cholesterol Education Program (NCEP) guidelines. Metabolic abnormalities due to DM have been found to predispose to vascular changes, leading to atherosclerotic endpoints.³ In addition to CV risk factors seen in nondiabetic subjects, diabetic specific risk factors also contribute to CAD.⁴ Furthermore, DM and CAD develop at an earlier age in Indians and associated complications are more as compared to Caucasians.⁵⁻⁸ The reasons for this heightened CAD risk in Indians is not entirely clear, but is thought to be mainly due to high prevalence of insulin resistance and related atherogenic risk factor in this population.^{5,6} It is also likely that factors associated with urban lifestyle or migration such as high calorie diet and lack of physical activity further enhance the underlying insulin resistance and consequently CAD. Not surprisingly, there seems to be a lack of relative decline in CAD rates in diabetics in India as compared to the West.^{9,10}

PREVALENCE OF DIABETES AND CORONARY ARTERY DISEASE

The first systematic nationwide study on prevalence of DM in India was performed by the Indian Council of Medical Research (ICMR) task force on DM. The prevalence was reported to be 2.1% in urban and 1.5% in rural populations.¹¹ From these modest rates in early nineties, the prevalence

has sky rocketed to the current alarmingly high rates of approximately 20% in urban and 10% in rural populations suggested by some authors.¹² The methods to acquire data for assessing the prevalence of CAD in diabetics has not been uniform across the world. The parameters to substantiate CAD have been nonhomogenous, thereby creating a lot of confusion. There is no prevailing consensus among researchers as to whether electrocardiography (ECG) or echocardiogram (ECHO) or radionuclide studies or angiographic evidence should be mandatory for substantiating CAD in DM. The specific data regarding prevalence of CAD in DM in Indians have been sparse. Evidence indicates that the prevalence of CAD is rapidly increasing in India, particularly in the urban areas. In the 1970s, prevalence of CAD was 1% in urban India.¹³ By 1990, the prevalence of CAD reported by Chadha et al. in Delhi was 9.7%.¹⁴ The increase in prevalence of CAD in urban and rural population suggested from a meta-analysis based on meta-analysis of the CAD prevalence based on the surveys conducted since 1990 was 9-fold and 2-fold, respectively.¹⁵ CVD is the most common cause of death in diabetics and atherosclerosis accounts for almost 80% of all diabetic mortality.¹⁶ Presence of DM increases the risk of CVD 2-4 folds. Type 2 DM represents more than 90% of the diabetic population in India. However, type 1 DM also has an independently higher risk of CVD and their disease develops at younger age. A striking increase in the risk of a first or recurrent myocardial infarction (MI) is reported in diabetics as compared with nondiabetics.

Haffner et al. in a population based study in Finland with follow-up period of 7 years showed that a diabetic patient without a history of MI has almost same risk for a first MI as a nondiabetic subjects who has already sustained MI.¹⁷ Considering these, American Diabetic Association made recommendations to treat diabetic subjects as though they already have established CAD. All the manifestations of CAD are at least 2-fold more common in patients with DM than in nondiabetic individuals. Conversely, the prevalence of DM in CAD is approximately 20%.^{16,17} There is evidence from Indian data that CAD is more common in diabetic subjects.

TABLE 1: Prevalence of coronary artery disease in different types of clinic or population-based studies

Author	Year	Clinic/ popula- tion (pop)	State/city	Percentage
Chaddha	1990	Pop	Delhi	9.7
Raman Kutty	1993	Pop	Kerala	7.4
Mohan	1995	Clinic	Chennai	17.8
Gupta	1995	Pop	UP	7.9
Ramachandran	1998	Pop	Chennai	14.3
Ramachandran	1999	Clinic	Chennai	11.4
Mohan	2001	Pop	Chennai	21.4
Gupta	2002	Pop	Rajasthan	8.2
ICMR	1984–87	Pop	Multicentric	8.1, 4.7 (F)
Pathak	2002	Pop	Ahmedabad	20.2
Agrawal	2004	Pop	Bikaner	19.3
Gupta	2001	Pop	Surat	19

South Indian studies by Mohan et al. and Ramachandran et al. in Chennai showed a prevalence of DM varying from 12% to 16%. MV Diabetes Center, Madras conducted a study to assess the prevalence of CAD was assessed in a large cohort of 6,597 noninsulin-dependent diabetes mellitus (NIDDM) patients.¹⁰ Overall 17.8% of patients had CAD. Its prevalence was not significantly different in males and females. The Chennai Urban Population Study (CUPS) reported that overall CAD prevalence to be 11%, of which 12% was diabetic. Among these 21.4% had CAD, more than the double that of nondiabetics. All these data suggest that the epidemic of type 2 DM and CAD has already assumed alarming proportions and urgent measures are needed to stem it. The prevalence of CAD in different types of clinic or population-based studies conducted in India among diabetics is presented in table 1.

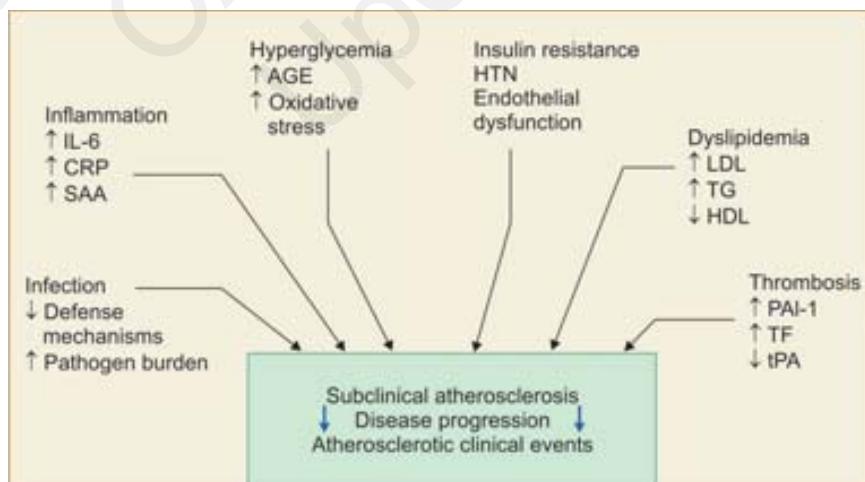

The registry data has created a new era and modality of information regarding prevalence of DM and CAD. OASIS registry 1 and 2 data have found out the age-adjusted prevalence of DM to be 39.1% in non-ST-elevation acute coronary syndrome (NSTE-ACS) patients in India.¹⁸ The multicentric CREATE registry which included 20,468 patients of ACS recruited from 89 centers spanning 50 cities in India had documented the overall prevalence of DM to be 30.4% [ST-elevation myocardial infarction (STEMI)—26.9%, NSTEMI—35.8%].¹⁹ As all recent statistics point out to a marked increase in DM worldwide, one can anticipate rising trends in prevalence of CAD associated with DM in India as well.

DIABETES AND CORONARY ARTERY DISEASE: MECHANISMS

Type 1 and type 2 DM are both independent and significant causative factor for CAD, stroke and peripheral arterial disease. Out of all hospitalizations due to complications of DM, more than 75% are attributable to CVD. Exposure of tissues to hyperglycemia in long-term is currently considered as the principal mechanism for pathogenesis of complications of DM.^{20,21} Hyperglycemia leads to a lot of alterations in vascular tissues, which ultimately induce accelerated atherosclerosis. Presently, three principal mechanisms are suggested to explain most of the pathological changes found in vasculature of diabetic patients:

1. Nonenzymatic glycation of proteins and lipids
2. Protein kinase C (PKC) activation
3. Oxidative stress.

Importantly, these mechanisms are not independent (Fig. 1). For example, hyperglycemia-induced oxidative stress promotes the formation of advanced glycation end products (AGEs) and PKC activation.^{22,23}

AGEs, advanced glycation end products; CRP, C-reactive protein; CHD, coronary heart disease; HDL, high-density lipoprotein; HTN, hypertension; IL-6, interleukin-6; LDL, low-density lipoprotein; PAI-1, plasminogen activator inhibitor-1; SAA, serum amyloid A; TF, tissue factor; TG, triglycerides; tPA, tissue plasminogen activator.

FIG. 1: Mechanism by which diabetes mellitus leads to coronary artery disease.

Source: Biondi-Zoccali GG, Abbate A, Liuzzi G, et al. Atherothrombosis, inflammation, and diabetes. J Am Coll Cardiol. 2003;41(7):1071-7.

Advanced Glycation End Products

Hyperglycemia often leads to progressive and irreversible cell dysfunction. Exact mechanism is not clear for these findings, but it has been found that cellular alterations may continue, even after return of normoglycemia (memory effect). Hence, long-term rather than short-term metabolic changes are crucial to the pathogenesis of CAD in DM. The proteins or lipoproteins present in the arterial wall react nonenzymatically with glucose, which is a key mechanism for enhanced atherosclerosis in DM. This is called as browning or Maillard reaction. Chemically reversible early glycosylation of glucose with reactive amino groups of circulating or vessel wall proteins produces Schiff bases, which later on gets modified to form more stable Amadori products. Schiff bases reach equilibrium levels in hours, whereas Amadori products reach in weeks. After a complex series of chemical rearrangements, early glycosylation products are changed over to AGE. AGE-protein adducts, once formed are virtually irreversible. With aging, AGEs continuously accumulate on long-lived vessel wall proteins at an accelerated rate in DM. Glucose concentration and time of exposure mainly determine the degree of nonenzymatic glycation. The tissue microenvironment redox potential is another critical factor to the formation of AGEs is situations in which the local redox potential has been shifted to favor oxidant stress, AGEs formation increases substantially.²⁴ The atherosclerotic process is accelerated by AGEs leading to different manifestations of CAD by diverse mechanism, which can be classified as nonreceptor dependent (Box 1) and receptor-mediated (Box 2).

Nonreceptor-mediated Mechanisms

Changes in molecular conformation of proteins are induced by AGEs which decrease their degradative capacity, alter enzymatic activity and interfere with receptor recognition (Box 1). Thus, changes in the normal physiology of proteins that are relevant to atherogenesis, may enhance CAD in DM.

BOX 1 Atherosclerosis promoting effects of advanced glycation end products: nonreceptor mediated mechanisms

- Extracellular matrix:
 - Collagen cross linking
 - Enhanced synthesis of extracellular matrix components
 - Trapping of LDL in the subendothelium
 - Glycosylated subendothelial matrix quenches nitric-oxide
- Functional alterations of regulatory proteins:
 - Basic fibroblast growth factor glycosylation reduces its heparin binding capacity and its mitogenic activity on endothelial cells
 - Inactivation of the complement regulatory protein CD59
- Lipoprotein modifications:
 - Glycosylated LDL
 - Reduced LDL recognition by cellular LDL receptors
 - Increased susceptibility of LDL to oxidative modification

BOX 2 Atherosclerosis promoting effects of advanced glycation end products: receptor mediated mechanisms

- Promoting inflammation:
 - Secretion of cytokines such as TNF- α , IL-1
 - Chemotactic stimulus for monocyte-macrophages
- Induction of cellular proliferation:
 - Stimulation of PDGF and IGF-1 secretion from monocytes and possibly SmC
- Endothelial dysfunction:
 - Increased permeability of EC monolayers
 - Increased procoagulant activity
 - Increased expression of adhesion molecules
 - Increased intracellular oxidative stress

TNF- α , tumor necrosis factor alpha; IGF-1, insulin-like growth factor 1; IL-1, interleukin-1; PDGF, platelet-derived growth factor; SmC, somatomedin-C.

The most well-known example is interference of the normal physiology of the low-density lipoprotein (LDL) particle. Elevated level of AGEs have been found in clinical studies on LDL obtained from patients of DM compared with normal individuals.^{25,26} The process of glycosylation affects both the phospholipid and apolipoprotein B (ApoB) components of LDL, which functionally alters the LDL clearance and make them more vulnerable to oxidative modifications. LDL glycosylation is increased in correlation with glucose levels, and AGE-ApoB levels are up to 4-fold higher in diabetic patients. Significant impairment of LDL-receptor-mediated uptake is produced by glycosylation of ApoB, thereby reducing the *in vivo* clearance of LDL compared to native LDL. Several studies have demonstrated that degradation of glycated LDL is impaired in cultured human fibroblasts (which possess LDL receptor) compared with normal LDL. This impairment is proportional to the extent of glycation. Human monocyte-derived macrophages in contrast to fibroblasts, recognize glycated LDL preferentially to native LDL. The uptake of glycated LDL by these cells, however, is not mediated by the LDL receptor pathway, but by a high-capacity, low-affinity receptor pathway. A nonspecific (scavenger) receptor presents on human macrophages also preferentially recognizes these glycated LDL. The recognition of glycated LDL by the scavenger receptor pathway is thought to be instrumental in accumulation of cholesteryl esters intracellularly. This process promotes atherosclerotic plaque progression and various manifestations of CAD.^{26,27}

Increased susceptibility of LDL to oxidative modification induces atherogenesis. Glycation makes the LDL more vulnerable to oxidative modification, which is considered a critical initiating step. AGE-LDL formation and oxidation is found to be directly proportional to glucose concentration, which has been found to be inhibited by the AGE formation inhibitor aminoguanidine. Change in normal function of the complement regulatory protein is another mechanism. When the membrane attack complex (MAC) of complement gets deposited in blood vessels, it stimulates proliferation of fibroblasts and smooth muscle cells. This leads to release

of growth factors such as fibroblast growth factor and platelet derived-growth factor (PDGF) from MAC-targeted endothelium. Cells express the regulatory membrane protein complement defense 59 (CD59), which limits complement activation and MAC formation. There is increased sensitivity of the endothelium in patients of DM to MAC-induced release of growth factors and cytokines. This is also attributed to glycation of the complement regulatory protein CD59 producing its inactivation.^{27,28}

Receptor-mediated Mechanisms

The AGE receptor (RAGE), a member of the immunoglobulin superfamily of receptors, has been demonstrated in various types of cells involved with the process of atherosclerosis including endothelial cells, monocyte-derived macrophages, and smooth muscle cells (Box 2). The macrophage RAGE system is closely linked to AGE turnover. It represents a mechanism that responds to raising AGE levels with aging and degrades senescent proteins. In diabetic vasculature, cells expressing increased levels of RAGE are often proximal to areas in which AGEs are abundant. AGE interaction with RAGE on endothelial cells results in the induction of oxidative stress and consequently of the transcription factor nuclear factor kappa-light-chain-enhancer of activated B cells (NF- κ B) and vascular cell adhesion molecule 1 (VCAM-1). In addition, engagement of AGEs with their specific receptors results in reduced endothelial barrier function leading to increased permeability of endothelial cell monolayers. The interaction of AGEs with RAGE-bearing endothelial cells can thus mediate initiating events in atherogenesis, which leads to catastrophic features of CAD. Increased endothelial permeability can cause enhanced lipid entry into the subendothelium. Enhancement of adhesive interactions of monocytes with the endothelial surface can subsequently result in transendothelial migration. Binding of soluble AGEs to RAGE-bearing monocytes induces chemotaxis, followed by mononuclear infiltration through an intact endothelial monolayer. Pathological studies of human atherosclerotic plaques showed infiltration of RAGE-expressing cells in the expanded intima. Monocyte-macrophage system interact with AGEs resulting in the production of mediators such as tumour necrosis factor- α , interleukin-1, PDGF, and insulin growth factor-I, which play a pivotal role in the pathogenesis of atherosclerosis. Binding of AGE-modified proteins to RAGE is associated with increased cellular proliferation in smooth muscle cells. This growth-promoting effects mediated by the RAGE are likely to be cytokine or growth-factor mediated. Under conditions of enhanced tissue AGE deposition, receptor-mediated interaction of AGE-proteins with vascular wall cells promotes the migration of inflammatory cells into the plaque with the subsequent release of growth-promoting cytokines.

Park and associates demonstrated the potential role of RAGE in the atherogenic process in DM. The induction of DM using streptozotocin resulted in atherosclerosis of increased severity compared to euglycemic ApoE controls in mice

models. The atherosclerotic process extended distally in the aorta and major arteries. Vascular lesions developed more rapidly with the formation of more complex lesions (extensive monocyte infiltration, fibrous caps, etc.). Especially at sites of vascular lesions it was evident that increased expression of RAGE and the presence of AGEs in the vessel wall. Blocking the AGE-RAGE interaction by a modified domain of RAGE produced a striking suppression of lesions in diabetic mice. The lesions got arrested at the fatty streak stage and there was a large reduction in complex lesions. These effects were not dependent on glucose and lipid levels.²⁵⁻²⁸

Protein Kinase C

Cells in which glucose transport is mostly independent of insulin bear the brunt of metabolic effects of hyperglycemia. The resulting intracellular hyperglycemia has been linked to the activation of the PKC system and subsequent development of complications of DM. Elevated ambient glucose concentrations activate PKC by augmenting the production of diacylglycerol (DAG). This crucial endogenous cellular cofactor for PKC activation is generated from products of glycolysis such as dihydroxyacetone phosphate and glyceraldehyde-3-phosphate. Such elevated concentration of DAG leading to activation of PKC in the vasculature can be maintained long term.

Protein kinase C constitutes a family of approximately 12 isoforms of serine and threonine kinases. Despite several PKC isoforms getting expressed in vascular tissue, there is a preferential activation of PKC β 2 in the aorta, heart, and retina, and PKC β 1 in the glomeruli in the rat model of DM. The PKC system is widely distributed in cells and is instrumental in the transcription of several growth factors, and their signal transduction. PKC activation in several studies has been attributed to modulate growth rate, DNA synthesis, and growth factor receptor turnover in vascular smooth muscle cells (SMC). PKC activation is induced by hyperglycemia, thereby increasing PDGF- β receptor expression on smooth muscle cells and other vascular cells (e.g., endothelial cells, monocyte-macrophages). Activation of PKC stimulates the formation of transforming growth factor- β (TGF- β), which is the key growth factor for regulation of extracellular matrix formation by activating gene expression of proteoglycans and collagen and reducing the synthesis of proteolytic enzymes that break down matrix proteins, which has a key pathogenetic role in ACS. Enhanced expression of TGF- β is incriminated in capillary basement membrane thickening, which is one of the early structural abnormalities detected in almost all tissues in DM.^{28,29}

Oxidative Stress

Oxidative stress has been incriminated as a powerful mechanism for accelerated atherosclerosis in diabetics. Hyperglycemia can induce oxidative stress through various pathways. Hyperglycemia induced intracellular reactive oxygen species (ROS), generated by the mitochondrial elec-

tron transport chain is one important mechanism leading to increased superoxide production.

Besides that, two other mechanisms have been postulated to explain how hyperglycemia induces increased ROS formation. Transition metal-catalyzed autoxidation of free glucose is one of those. Glucose itself starts the autoxidation process and free radical production producing superoxide anion (O_2^-) and hydrogen peroxide (H_2O_2) through this reaction. Another mechanism is autoxidation of protein-bound Amadori products catalyzed by transition metals, which produces superoxide and hydroxyl radicals and highly reactive dicarbonyl compounds (see glycoxidation).

Hyperglycemia may weaken natural antioxidant mechanisms. In healthy individuals, free radicals are rapidly eliminated by antioxidants such as vitamin C, vitamin E, and reduced glutathione. Decrease in glutathione content, as well as reduced vitamin E have been reported in patients of DM. Tissue and plasma levels of vitamin C are 40–50% lower in diabetics compared with nondiabetic subjects. Hyperglycemia-induced oxidant stress has close pathogenic link with two dominant mechanisms of vascular damage, namely AGEs formation and PKC activation as suggested by researchers.^{28,30}

Glycoxidation

Some AGEs are generated by combined processes of oxidation and glycation and hence, known as glycoxidation products. The amount of oxidative stress and mechanism of formation is unique for each AGE. Protein-based AGEs are irreversible, so it has been postulated that they might serve as a biomarker for the long-term oxidative stress of DM on various tissues. AGE epitopes interact with the RAGE present on cell surface to release oxygen radicals by upregulating oxidative stress response genes. Thus, hyperglycemia not only enhances both AGEs formation and oxidative stress, it also facilitates interactions between glycation and oxidation mechanisms. On the long run, this contributes synergistically to the formation of AGEs, oxidative stress, and diabetic complications like CAD. Strong correlations have been found between levels of glycoxidation products in skin collagen and the severity of renal, retinal, and vascular disease in DM.^{23,30}

Oxidative Stress and Protein Kinase C Activation

Activation of DAG-PKC can be produced by oxidants produced in the setting of hyperglycemia in vascular tissues in patients of DM. Indirect evidence to substantiate such concept has been gathered from several studies demonstrating antioxidants such as vitamin E can inhibit PKC activation probably by decreasing DAG levels.²⁸

CONCLUSION

To conclude, DM and CAD are variously termed as “deadly duo” and “partners in crime”. A study of their prevalence

and mechanisms will definitely provide critical insights into these 21st century’s alarming global pandemics. This may provide impetus to young and vibrant minds to explore new field of research in future, which can provide path-breaking strategies for countering this double menace.

Management of Diabetes in Heart Failure

Shashank R Joshi

THE PROBLEM

The coexistence of heart failure (HF) and type 2 diabetes mellitus (T2DM) represents a multidimensional challenge, in the epidemiological, pathological, as well as clinical aspects. Hyperglycemia and insulin resistance in T2DM are well-recognized pathological mechanisms for the development of diabetic cardiomyopathy and resultant clinical HF.¹ Each 1% rise in the hemoglobin A1c (HbA1c) level is known to impose a 15% increased risk of developing HF.²

As observed in the Framingham Heart Study, diabetes mellitus (DM) is associated with 1.8-fold increased risk of HF in men, and 3.8-fold increased risk in women.³ HF is also known to be among the most common early clinical manifestations of cardiovascular disease (CVD) in T2DM. One out of every seven patients of T2DM, without known CVD, develops HF over the ensuing 5–6 years.⁴

Heart failure and T2DM share a bidirectional clinico-pathological relationship. Patients with HF demonstrate a more than twofold greater odds of new-onset T2DM. Further, the development of DM also increases the mortality risk in HF by 2.5-fold.⁵ Coexistence of DM and HF incrementally worsens the quality of life.⁶ Further, chronic kidney disease (CKD) may complicate the clinical picture of DM as well as HF. These pathologically interrelated comorbidities frequently coexist, and significantly increase the risk of cardiovascular (CV) mortality.⁷ The modifiable risk-factors for HF including obesity, hypertension, coronary artery disease, and anemia, commonly coexist in T2DM and need to be addressed for optimum holistic management of HF in T2DM.⁸

The Trivandrum Heart Failure Registry of patients hospitalized for HF, suggested DM to be present in over half of the hospitalized patients. Importantly, less than a quarter of these patients received guideline-based medical treatment. As expected, the registry did suggest significantly greater 90-day mortality in these patients not receiving optimum HF therapy, as compared to the optimally managed patients.⁹ The PINNACLE India Quality Improvement Program (PIQIP)

registry also reflected a similar lack of optimum guideline-directed medical therapy in Indian patients of HF.¹⁰

SCREENING FOR HEART FAILURE IN TYPE 2 DIABETES MELLITUS

The diagnosis of HF in T2DM depends on assessments of clinical signs and symptoms, electrocardiography (ECG), N-terminal pro-brain natriuretic peptide (NT-proBNP) level, as well as confirmatory echocardiography. While the assessments of signs and symptoms as well as ECG are recommended for every patient of T2DM, the optimum diagnosis of HF may be missed in the absence of echocardiography. Boonman de-Winter et al. suggested a simple screening tool based on a validated risk-score derived from the patient history and physical examination, as summarized in table 1.¹¹ As validated in a T2DM population in the Netherlands, this clinical screening approach demonstrated optimum sensitivity (70.8%), specificity (79.0%), negative

TABLE 1: Clinical screening tool for heart failure in type 2 diabetes mellitus

Clinical criterion	Score
Age >75 years	1
History of ischemic heart disease*	1
History of transient ischemic attack or stroke	1
Dyspnea or fatigue	2
Reported ankle edema or nocturia	1
Claudication-related complaints	1
Pulmonary crepitations, elevated JVP, peripheral edema, and/or hepatomegaly	1

If the total score is more than 3 points, the patient should be referred for echocardiography.

*Prior myocardial infarction/angina pectoris/coronary artery bypass graft and/or PCI

JVP, jugular venous pressure; PCI, percutaneous coronary intervention.

predictive value (87.6%), and positive predictive value (56.4%). If the overall score is more than 3, the patient should be referred for echocardiography to confirm the diagnosis of HF. The association between this clinical screening tool and confirmatory echocardiography was strong. Further, the incremental improvement of screening was marginal, when ECG and NT-proBNP were considered in addition to this clinical screening tool. Thus, in resource-limited settings, this clinical screening tool may be of relevance in timely screening for HF in T2DM.

Further, a systematic meta-analysis of Matsushita et al. has suggested an incremental value in predicting HF risk, based on albuminuria, as well as estimated glomerular filtration rate (eGFR).¹² Both these assessments independently improve the screening efficiency of HF in T2DM, and should be considered in all patients.

GLYCEMIA CONTROL AND HEART FAILURE: CHOICE OF ANTIDIABETIC THERAPIES

While the optimum management of T2DM, from an HF perspective, remains an area of immense scientific scope and interest, our understanding has evolved mainly with the serendipitous experiences, as well as some focused research in this area. Certain antidiabetic agents like thiazolidinediones (TZDs) and saxagliptin have demonstrated clear worsening of HF-related outcomes, whereas agents like sodium-glucose cotransporter 2 inhibitors (SGLT2i) agents have suggested promising leads. The evidence with other agents remains either insufficient or equivocal. While the jury is out regarding the choice of most glucose-lowering therapies and HF outcomes in T2DM, priority must be given to an individualized patient-centric approach for optimum holistic management of T2DM.

METFORMIN

As per the legally approved prescribing information, metformin is associated with the risk of lactic acidosis, in patients with HF. However, the clinical experience of metformin over the decades, suggests a possibly favorable risk-benefit balance, for glycemia control in T2DM with HF. Robust evidence from well-conducted randomized controlled trials is not currently available for metformin; however, the ongoing research will evolve our understanding in this regard, which is presently based on evidence from observational studies.

A recently published meta-analysis of 17 observational studies evaluated the use of metformin in patients of T2DM with CKD, HF, or chronic liver disease. In all these comorbidities, metformin use was associated with a significant and meaningful reduction in the risk of all-cause mortality. Further, the risk of readmissions for congestive heart failure (CHF) was also meaningfully reduced in patients with prior HF or CKD.¹³ Another review of nine observational studies, performed in patients of T2DM and HF, suggested a significant 20% reduction in mortality with metformin, as compared to controls; the studies included in this review

mostly compared metformin with sulfonylureas. Further, the use of metformin in patients with HF did not suggest an increase in the risk of lactic acidosis.¹⁴ Mechanism-based studies on metformin have demonstrated inconsistent findings for plausible cardiovascular effects, in relation to cardiac function.¹⁵⁻¹⁸ The European Society of Cardiology (ESC) guidelines suggest metformin as a safe option for glycemia control in patients of T2DM with HF.¹⁹

SODIUM-GLUCOSE COTRANSPORTER 2 INHIBITORS

The SGLT2i agents have demonstrated promising HF outcomes in patients of T2DM. These agents have a mild glucose-mediated diuretic effect; however, they are different from classical diuretic agents, in multiple ways. The SGLT2i agents demonstrate a more predominant effect on the interstitial fluid volume as compared to blood volume, unlike the classical diuretics. This may be associated with less profound implications on rebound mechanisms, like activation of the renin-angiotensin-aldosterone system (RAAS), as well as more meaningful implications on clinical outcomes related to HF.²⁰ Some of the SGLT2i agents have demonstrated robust cardiovascular protection in well-conducted studies. EMPA-REG OUTCOME study of empagliflozin, evaluated the CV outcomes in patients of T2DM with CVD (including significant coronary artery disease, peripheral arterial disease, myocardial infarction, or stroke). Empagliflozin demonstrated significant improvements in CV outcomes on top of standard of care, including 14% reduction in the risk of major adverse CV events (composite of CV death, myocardial infarction, and stroke), 38% risk reduction in CV death, and 32% relative reduction in all-cause death. Particularly, 35% reduction in the risk of hospitalizations for HF was also observed with empagliflozin, as assessed in the secondary analysis.²¹ Further, the CV protective effects of empagliflozin were evident consistently, irrespective of the baseline HbA1c level, irrespective of the control of major CV risk-factors, and early and sustainably over the course of therapy.^{21,22} Furthermore, empagliflozin reduced the risk of hospitalizations for HF consistently, across the spectrum of 5-year risk of HF at baseline, in this study.²³ A small study involving patients of T2DM with CVD and heart failure with preserved ejection fraction (HFpEF), demonstrated improvement in cardiac structure (left ventricular mass index) and function (early lateral annular tissue Doppler velocity), with the use of empagliflozin over 16 weeks.²⁴ At present, empagliflozin is the only oral antidiabetic agent, which is approved for reduction in the risk of CV death in patients of T2DM with CVD, and is also recommended by the ESC guidelines for preventing or delaying the onset of HF and prolonging life.¹⁹

The Canagliflozin Cardiovascular Assessment Study (CANVAS) program of canagliflozin, involving patients of T2DM with high CV risk, also demonstrated a 14% reduction in the risk of major adverse CV events with canagliflozin. In the secondary analysis, hospitalizations for HF were reduced by 33% in patients receiving canagliflozin.²⁵ However,

significant reductions in CV mortality and all-cause mortality were not observed with canagliflozin, in either the patients with known history of atherosclerotic CVD, or in those with multiple CV risk-factors.²⁵ Till date, the data from prospective CV outcomes trials for the SGLT2i class are available only for empagliflozin and canagliflozin. The real-world observational studies have suggested possible benefit of SGLT2i agents on the HF outcomes in T2DM, as compared to other glucose-lowering drugs.²⁶ The limitations of observational studies must be considered during clinical decision making, as certain observations in these observational studies have been discordant with those in the randomized controlled trials of the CANVAS program.²⁷

The DECLARE-TIMI 58, VERTIS CV, CREDENCE, EMPEROR, EMPEROR-Plus, EMPA-VISION, EMPA-Kidney, DAPA-HF, DAPACARD, and DAPA-CKD are few of the ongoing trials that may provide further elaborate insights into CV and renal outcomes with the SGLT2i agents, in patients with or without T2DM. The currently available evidence suggests that the SGLT2i agents hold promise in terms of improving the HF outcomes, in patients with T2DM. The evidence for SGLT2i agents, in patients with advanced HF, is currently limited. Clinical discretion is essential when these agents are combined with loop diuretic agents; as appropriate, the dose of loop diuretic agent may be reduced. Dehydration should be avoided in patients receiving SGLT2i agents. These agents are not recommended for glycemia control, in patients with moderate-to-severe CKD (eGFR level of <45 mL/min/1.73 m²).

DIPEPTIDYL PEPTIDASE-4 INHIBITORS

The evidence regarding possible HF risk associated with the use of dipeptidyl peptidase-4 inhibitor (DPP4i) agents, has been evolving. The SAVOR-TIMI 53 study demonstrated significant 27% increased risk of hospitalizations for HF, associated with saxagliptin; this risk was more prominent in patients with increased levels of natriuretic peptide levels at baseline, prior history of HF, and background CKD.²⁸ The EXAMINE trial of alogliptin demonstrated a 19% nonsignificant increase in the risk of hospitalizations for HF, associated with alogliptin use.²⁹ In the TECOS trial of sitagliptin, no increase in the risk of HF-related hospitalizations or deaths was observed, in patients receiving sitagliptin.³⁰ A meta-analysis of these three studies suggested a nonsignificant, 14% numerically increased risk of HF-related hospitalizations with moderate heterogeneity, with DPP4i agents in comparison to placebo.³¹

The CV safety meta-analysis of linagliptin did not suggest increased risk of HF events.³² The VIVIDD trial assessed vildagliptin in patients with heart failure with reduced ejection fraction (HFREF). Vildagliptin was not associated with significant increase in left ventricular ejection fraction. However, the left ventricular end-diastolic volume was significantly increased in patients receiving vildagliptin.³³ The evidence on hard clinical CV outcomes with teneligliptin is presently under evaluation. Teneligliptin may cause QT interval prolongation in patients with arrhythmia, severe

bradycardia or its history, patients with CHF, low-serum potassium, congenital prolonged QT syndrome, history of torsades de pointes, or patients using antiarrhythmic drugs.

A meta-analysis of good quality studies of DPP4i agents, demonstrated significant 13% increased risk of hospitalizations for HF with these agents. The evidence does not address whether this increased risk is a class effect for the DPP4i agents.³⁴

In March 2018, a warning note was added to the prescribing information of all the DPP4i agents, for considering the risks and benefits of DPP4i agent prior to initiating treatment in patients at risk for HF, such as those with a prior history of HF and a history of renal impairment, and to observe these patients for signs and symptoms of HF during therapy. Patients must be advised of the characteristic symptoms of HF and to immediately report such symptoms. If HF develops, the DPP4i agent should be discontinued. If the available evidence is considered on face value, a conclusive evidence of increased risk of HF is presently available only for saxagliptin, among the DPP4i agents.

GLUCAGON-LIKE PEPTIDE-1 RECEPTOR AGONISTS

The glucagon-like peptide-1 receptor agonists (GLP-1RAs) are known to increase the heart rate. In patients of T2DM with CVD, liraglutide has demonstrated significant reduction in major adverse CV events, as well as CV mortality, in the LEADER trial.³⁵ Liraglutide is also indicated for reduction in CV events, beyond glycemia control, in patients of T2DM with CVD. However, the CV benefits evident with liraglutide are more likely to be based on antiatherosclerotic mechanisms. In terms of the HF-related outcomes, the GLP-1RA agents have not demonstrated a clinical benefit.³⁶ More importantly, liraglutide use had been associated with a nonsignificant trend of increase in death or hospitalization for HF, in patients of HFREF, in the FIGHT study.³⁷ In another study involving patients of HFrEF, liraglutide therapy had been associated with increased heart rate by 6 beats/min, and significantly increased risk of serious cardiac events.³⁸

The evidence suggests clinical consideration of possible increase in the heart rate with the use of GLP-1RA agents, in the management of T2DM with HF. Further, there is no evidence to suggest clinical benefit of these agents on HF-related outcomes.

SULFONYLUREAS

The available evidence based on observational studies, suggests a possibly increased risk of CV events and mortality, associated with the use of sulfonylureas.³⁹ The risk of HF with metformin and sulfonylureas was compared in an observational study of propensity matched groups. The use of sulfonylureas was associated with significant 30% increased risk for hospitalizations for HF, as compared to metformin. These findings were consistently observed in patients with or without prior HF.⁴⁰ In another propensity matched analysis

of an observational registry database, DPP4i agents as well as TZDs were associated with lower risk of hospitalizations for HF, as compared to sulfonylureas.⁴¹ The Bypass Angioplasty Revascularization Investigation 2 Diabetes (BARI 2D) was a randomized controlled trial, involving patients of T2DM and significant coronary artery disease. In this study, the insulin-provision therapy group (sulfonylureas and/or insulin) was associated with a similar incidence of HF events, as compared to insulin-sensitization therapy group (metformin and/or TZD).⁴² The ongoing CAROLINA trial, for assessing the CV outcomes with linagliptin or glimepiride, as second-line therapies in T2DM, will provide further insights on CV outcomes with sulfonylureas.

Overall, the evidence, on possibly increased risk of HF events with the use of sulfonylureas, has been inconclusive. Limited evidence from observational studies suggests possibly increased risk for HF events associated with sulfonylurea use, in comparison to metformin, DPP4i agents, and TZDs. However, the subanalysis of a randomized controlled trial might suggest a possible benefit of doubt, in favor of a safe HF profile of these agents.

THIAZOLIDINEDIONES

The prescribing information of pioglitazone includes a warning statement related to the occurrence or exacerbation of congestive HF. Patients receiving TZDs should be closely monitored for the signs and symptoms of HF. If the development of HF is suspected, TZDs should be discontinued and HF should be managed as per the standards of care. TZDs are not recommended in patients with symptomatic HF, and are absolutely contraindicated in patients with established the New York Heart Association (NYHA) class III or IV HF.

The PROactive study assessed the CV outcomes with pioglitazone, in patients of T2DM with macrovascular complications.⁴³ In this trial, pioglitazone was associated with significantly increased risk of hospitalizations due to HF, but not in the rate of mortality due to HF. Further, the RECORD trial also demonstrated a 2.1-fold increased risk of death or hospitalization due to HF, in patients receiving rosiglitazone. An increased risk of fatal HF outcomes was observed with the use of rosiglitazone in this trial.⁴⁴

INSULIN

Insulin hormone has a strong propensity for sodium and fluid retention, which may facilitate the pathological development of HF. The clinical evidence of possibly increased risk of HF outcomes with the use of insulin is presently limited, and inconclusive. In patients of T2DM with HF, evidence from randomized controlled trials and observational studies suggests an increased risk for HF-related hospitalizations, and mortality outcomes, associated with insulin use.⁴⁵ The effects of intensive glycemia control with insulin were assessed in patients of myocardial infarction and hyperglycemia, in the two DIGAMI studies; both these studies suggested contradictory outcomes for insulin, in terms of improvement in survival.^{46,47} The ORIGIN trial

of insulin glargine suggested a neutral effect on the risk of hospitalizations for HF. The effect of higher doses of insulin glargine was not evaluated in the ORIGIN study.⁴⁸ Among the short-acting insulin, the observational evidence is presently limited to make any conclusive inference.⁴⁹ In patients with advanced diabetes or comorbid diseases, the use of insulin may be unavoidable, regardless of the limited evidence on the possible increased risk of HF.

CONCLUSION

The importance of comprehensive management of T2DM, from a HF perspective, cannot be understated. HF is one of the most common manifestations of T2DM, and occurs early in the course of disease. Following guideline-directed medical therapy for HF is essential to improve outcomes. Our evidence-based understanding, on the possible influences of antidiabetic therapies on HF outcomes, has been evolving over time. At present, the evidence suggests a clearly increased risk of HF-related outcomes, with agents like saxagliptin and TZDs. SGLT2i agents have demonstrated a clinical promise in improving HF-related outcomes. The evidence regarding most of the other classes of agents on HF outcomes has been limited, inconsistent, or inconclusive. In the individualized patient-centric approach for the management of T2DM, the available evidence (with apposite strengths and limitations) on the HF outcomes with different agents should be considered to support clinical decision making.

Epidemiology of Hypertension in India: The Real Scenario

Rajeev Gupta, Kiran Gaur

INTRODUCTION

High blood pressure (BP) is the most important risk factor for global morbidity and mortality. The latest iteration of global burden of disease (GBD) study has reported that high systolic BP, poor diet, and tobacco use are the most important risk factors for mortality and morbidity.¹ GBD has estimated that more than 11% of global deaths are due to hypertension.¹ In India also, it has emerged as the most important risk factor for deaths and disability.² According to reports from World Health Organization (WHO),³ GBD study,⁴ and non-communicable disease risk factor collaboration (NCDRiSC)⁵ the prevalence of hypertension is increasing globally and currently more than one billion people have hypertension (defined as systolic BP ≥ 140 mm Hg and/or diastolic BP ≥ 90 mm Hg). NCDRiSC study reported that number of adults with raised blood pressure increased from 594 million in 1975 to 1.3 billion in 2015, with the increase largely in low-income and middle-income countries.⁵ This article reviews status of hypertension prevalence in India using systematic reviews of previous epidemiological studies, two recent large nationwide surveys and GBD study estimates for determining absolute burden of hypertension in India.

SYSTEMATIC REVIEWS OF EPIDEMIOLOGICAL STUDIES

In India, multiple reviews of previous studies have been conducted. All have reported a significant and increasing burden of hypertension.⁶⁻⁹ This increase has been reported in both urban and rural areas in India. In the mid-1950s, Indian urban population-based epidemiological studies used older WHO criteria for diagnosis (known hypertension or BP > 160 mm Hg systolic and/or 95 mm Hg diastolic) and reported hypertension prevalence of 1.2–4.0%.⁶ Since, then prevalence of hypertension in Indian cities has been steadily increasing from 3.0–4.5% in early 1960's to 11.0–15.5% in mid-1990's.⁶ Although rural populations in India generally have

lower prevalence of hypertension there has been a significant increase in these populations from less than 1% in early 1960's to 5–7% in late 1990's.^{6,7}

Systolic BP ≥ 140 mm Hg and/or diastolic BP ≥ 90 mm Hg is the currently accepted diagnostic threshold for hypertension worldwide, although the 2017 American College of Cardiology (ACC) and American Heart Association (AHA) hypertension guidelines have proposed a lower threshold.¹⁰ Many prevalence studies of hypertension defined by current criteria have been performed in the present century in India. These studies have been performed in urban (Table 1) as well as rural (Table 2) populations.⁹ Most of the studies are regional. There are only a few multi-centric studies in the country. All these studies reveal a greater prevalence of hypertension in urban populations.⁹ However, recent studies report that hypertension is increasing more rapidly in the rural populations and there is an urban rural convergence in its prevalence.⁹ These studies also show that almost a third of adult Indian population has high BP. This is similar to other parts of the developing world and only slightly lower than the developed countries.³

Reviews have reported that there are large regional differences in hypertension prevalence in India as shown in tables 1 and 2. Anchala et al. performed a meta-analysis of recent hypertension prevalence studies in India and reported significant differences in hypertension in various zones of the country with greater prevalence in northern, eastern, and north-eastern regions of the country.⁸

Some years ago, we recommended that periodic surveys in India such as national family health surveys (NFHS), national statistical survey organization surveys (NSSOS), and district level household surveys (DLHS) should focus on hypertension screening.⁹ Government of India, under the national program for control of cardiovascular diseases, stroke, diabetes, and cancer initiated a large project of opportunistic screening in India.¹¹ More than 50 million adults were screened and it was reported that 6.2% participants were suffering from diabetes while hypertension was

in 5.5%. These numbers are clearly an underestimate and much lower than the government sponsored (Indian Council of Medical Research) studies¹² as well as recent national studies^{13,14} reviewed later.

Recent reviews of various local and regional hypertension epidemiological studies in India have reported that hypertension is present in 25–30% urban and 10–20% rural subjects in India.^{7–9} However, there are large regional variations in its prevalence and these rates may be not truly representative. Multisite studies that evaluated hypertension prevalence using similar tools in various regions of the country are few. These studies are limited to male industrial workers,¹⁵ lower socioeconomic status women,¹⁶ middle class urban men and women,¹⁷ urban and rural men and women at a few locations in the country,^{18–21} and rural men and women.²² Hypertension prevalence in these studies varies from 15 to 20% in rural and 20 to 35% in adult participants in these studies (Fig. 1). However, all these studies lack national representativeness.

Anchala et al⁸ performed a meta-analysis of all hypertension epidemiology studies in India using studies from Medline, Web of Science, and Scopus databases from 1950 to 30 April 2013. These sites were searched for 'prevalence, burden, awareness, and control of BP or hypertension (≥ 140 mm Hg systolic BP and/or ≥ 90 mm Hg diastolic BP) among Indian adults of more than or equal to 18 years of age. Of the total 3,047 articles, 142 were included. Overall prevalence for hypertension in India was calculated as

29.8% (95% confidence interval (CI): 26.7–33.0). Significant differences in hypertension prevalence were noted between rural and urban regions [rural: 27.6% (23.2–32.0) and urban: 33.8% (29.7–37.8); $p = 0.05$]. Regional estimates for the prevalence of hypertension were, in rural populations: north 14.5% (13.3–15.7), east 31.7% (30.2–33.3), west 18.1% (16.9–19.2), and south 21.1% (20.1–22.0); and for urban: north 28.8% (26.9–30.8), east 34.5% (32.6–36.5), west 35.8% (35.2–36.5), and south 31.8% (30.4–33.1), respectively. Greater hypertension prevalence was observed in eastern regions of the country. It was concluded that we need more studies to detect true prevalence of hypertension in the country.

National Family Health Survey-4

Fourth NFHS was focused on obtaining multiple adult socioeconomic, demographic, and lifestyle factors using a nationally representative sample.¹³ For the first time, this survey also determined hypertension prevalence among young men and women in India using a representative sampling across the country.² This survey was implemented in both urban and rural areas.^{23,24} A uniform sample design was adopted in all the districts. The primary sampling units for rural areas were villages and for urban locations the census enumeration blocks. The field agencies were given a list of selected sampling units for each state or union territories that were selected for the fieldwork. NFHS-4 was designed to provide information on various demographic

SECTION 4

Hypertension

parameters and other family welfare and health indicators by background characteristics at the national and state level and, for the first time, at the district level also. Because of need to report health indicators at the district level, the NFHS-4 sample size was increased to 571,660 households, as compared with 109,041 households in NFHS-3. NFHS-4 adopted a two-stage sampling design in rural and urban areas of each district of India.²² This survey ultimately interviewed 601,509 households, 699,686 women, and 103,525 men from 28,583 primary sampling units composed of villages in rural areas and census enumeration blocks in urban areas in 640 districts of the country. The domain of clinical, anthropometric, and biochemical testing in NFHS-4 included random blood glucose and BP measurements with estimates to be reported at the district level for women aged 15–49 years and men aged 15–54 years. All these components in the field were evaluated using portable equipment. An automatic and battery-operated BP instrument was used. Only medical or other personnel with specific training on the procedures were

involved. NFHS-4 was conducted in two phases, and each phase covered almost an equal number of states or groups of states and union territories. Detailed methodology of BP measurement are available at NFHS-4 website¹³ and has been reported earlier.²⁴

We have obtained the hypertension prevalence data from the NFHS-4 website and prevalence in various states among men and women is reported in table 3. The sample sizes are population proportionate and data shows that there are significant differences in prevalence of hypertension in different states of the country. Accordingly, the prevalence is much greater in the southern, north eastern and north western states of the country and is significantly greater in men as compared to women (Table 3). Of the 33 states that are represented in table 3, hypertension prevalence of more than 15% is observed in 8/33 (24.2%) states and low prevalence (<5%) is observed in 6/33 (18.2%) states. Other states have a medium prevalence 5–15%.

BP, blood pressure.

NFHS, national family health surveys.

FIG. 2: Heat map showing hypertension prevalence in various states of India in NFHS-4 study.

Country-level prevalence of hypertension in NFHS-4 among the younger age individuals is 13.6% in men, 8.8% in women and 11.3% overall.¹³ The prevalence is significantly greater in urban as compared to rural locations: men 15.1% versus 12.6%, women 9.6% versus 8.5% ($p < 0.01$). The urban-rural differences are not as large as reported in the regional studies (Fig. 1).

Heat map showing prevalence of hypertension in various states of India is shown in figure 2. This shows that the highest prevalence of hypertension is in northern and north-eastern Indian states of the country that include Punjab, Himachal Pradesh, Assam, and north-eastern states. The prevalence is moderate in western and southern Indian states while the lowest prevalence is observed in central Indian states extending from Rajasthan in the west to Bihar in the east.

Limitations of the NFHS-4 study have been reported earlier.²⁴ A major shortcoming of the NFHS program is the

exclusion of middle and older age adults. It is well-known that hypertension prevalence increases with age.¹⁰ Exclusion of this high prevalence group has led to lower prevalence in this study as compared to previous regional and national studies in India. On the other hand, prospective studies collaboration has reported that intervention at younger age is associated with greater benefit in terms of vascular protection and reduction of cardiovascular mortality and morbidity.²⁵ Therefore, these data are important and convey an important message to healthcare policy-makers and providers.

District Level Household Survey-4 and Annual Health Surveys

Government of India along with the Registrar General of India have recently developed a robust method to estimate various cardiovascular risk factors in all states of the country.²⁶ Measurement of BP and data on hypertension prevalence is

being obtained since the year 2012. Geldsetzer et al., pooled data from two large household surveys in India—DLHS-4 and annual health survey (AHS) which were undertaken between 2012 and 2014.¹⁴ The data obtained are representative at the district level and jointly cover 29 states of India. Data from two states, Gujarat and Jammu & Kashmir – are not available.

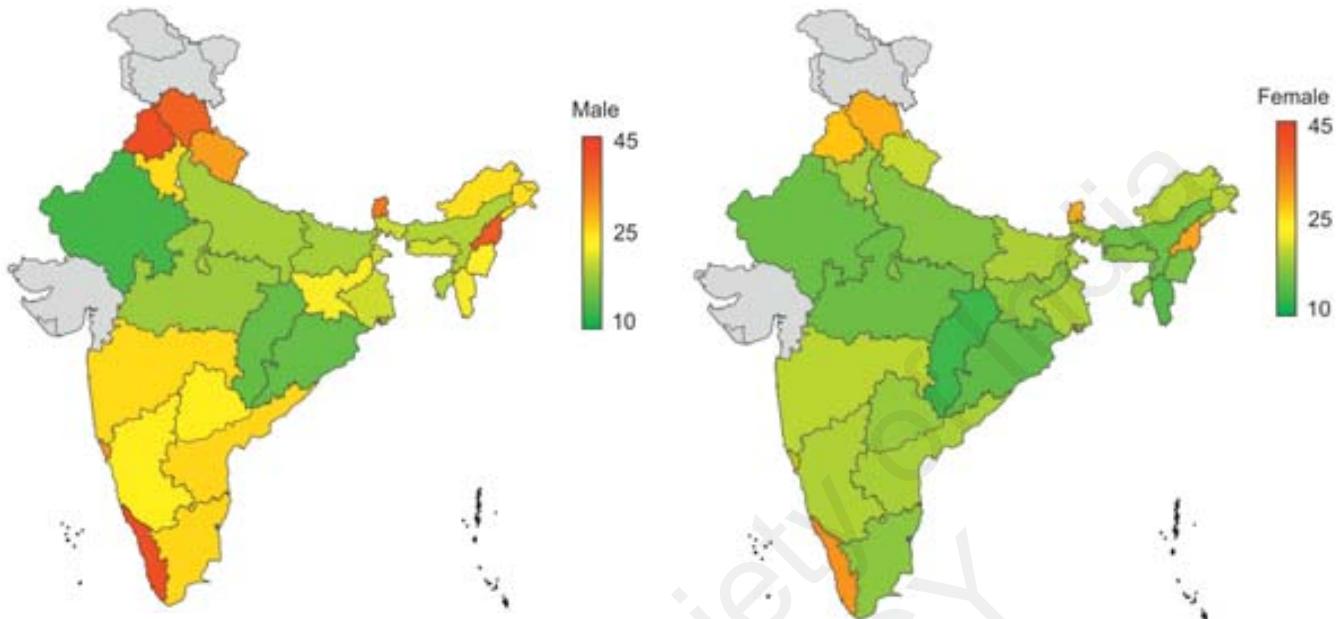

Results of this study have been published recently.¹⁴ In this study, of the 1,320,555 adults, 53.1% were women. The crude prevalence of hypertension reported in the study is 25.3% (95% CI 25.0–25.6%) with greater prevalence in men (27.4%, CI 27.0–27.7%) compared to women (23.6%, CI 23.3–23.8%). Age-standardized prevalence is significantly greater in men (24.5%, CI 24.2–24.9%) as compared to women (20.0%, CI 19.7–20.3%). The prevalence is greater in urban than rural participants. The age-standardized prevalence ranged from

13.5% (CI 12.2–14.9%) among women in Chhattisgarh to 43.5% (CI 38.3–48.9%) among men in Daman and Diu.

The study also reported that hypertension is common even among the younger age groups participants (18–25 years) with prevalence of 12.1% (CI 11.8–12.5%). There was positive association of socioeconomic status with hypertension prevalence although being in the richest versus poorest household income was associated with only a small difference (rural 4.15% and urban 3.47%). This suggests convergence of urban-rural and a rich-poor difference in hypertension prevalence in India as has been reported earlier.⁹ This study also reported significant differences in prevalence of hypertension across the Indian states with age-adjusted prevalence varying from 18.0 to 41.6% as shown in table 4 and figure 3. This study concluded that there is a

TABLE 4: Hypertension prevalence in adult men and women in district level household survey (DLHS-4)

Absolute numbers (millions)	20.9	23.4	26.2	29.3	34.4	39.4
DALY Rate/100,000	2415	2451	2497	2576	2807	3000
% of total DALYs	3.9	4.4	5.0	5.7	7.0	8.5

high prevalence of hypertension across all socioeconomic groups in India. The prevalence of hypertension is high even among the young age individuals. This is similar to previous studies from sub-national and regional studies in India.⁸ This study concludes that this epidemiological evidence of high hypertension prevalence in India should prompt central and state governments in India towards increased efforts on hypertension detection, treatment, and control.²⁷

There is a significant correlation of state-level hypertension prevalence among NFHS-4 and DLHS studies in both men ($r = 0.55$, $p = 0.004$) and women ($r = 0.35$, $p = 0.077$). This suggests that high BP at younger age, as observed in NFHS-4, has tracked into older age participants in DLHS, especially in men. This has important implications for primordial prevention of hypertension¹⁰ in India and suggests that policies for reducing salt and fat consumption and promoting fruit and vegetable intake in India should begin at younger age groups in all regions of the country.

Global Burden of Diseases Study

The GBD study group has been estimating mortality and morbidity from various diseases of multiple risk factors for the last two decades.¹ Since the year 2010, the investigators have estimated various risk factors from 1990 onwards and calculated their impact on health.²⁸ High BP is the most important of disease burden and the current estimate from GBD 2016 suggest that more than 12% of global deaths are attributable to this risk factor.¹ Estimated data on deaths and disability adjusted life years (DALYs) or India are available at the GBD website.²⁹

Table 5 shows trends in deaths and DALYs attributed to high systolic BP for India. High systolic BP led to 784,700 deaths in 1990 which more than doubled to 16,347,000 deaths in 2016, an increase of 108.3%. The death rate increased from 90.8 per 100,000 in 1990 to 124.2 per 100,000 in 2016, an increase by 36.8%. Similarly, absolute number of DALYs lost increased from 20.86 million in 1990

to 39.41 million in 2016 (increase by 88.9%) and DALYs per 100,000 increased from 2,415 in 1990 to 3,000 in 2016, an increase by 24.2%. These increases in deaths and DALYs in India are in contrast to high-income countries, where these rates are declining.²⁹ Absolute number of patients with hypertension is not available for India but increasing trends in DALYs and other parameters confirms that hypertension is increasing in the country and is one of the most important cause of deaths and disability.²

In 2016, GBD study for the first time estimated sub-national (state-level) causes of deaths and risk factors in India.³⁰ However, details of hypertension and related morbidity and mortality are not yet available. It is expected that future iterations of GBD study shall have these data. However, as GBD study estimates are based on synthesis of real-time data from various national and sub-national studies, it is expected that the study shall report similar state-level differences as highlighted in the present review.

ASSOCIATION OF HYPERTENSION WITH MACROLEVEL RISK FACTORS

Reasons for increasing hypertension in India are multiple. These include individual factors such as unhealthy lifestyle factors including sedentary habits, unhealthy diet (high-calorie, high-unrefined carbohydrate, high-fat, high-salt, and high-alcohol intake, etc.), stress, overweight, obesity, abdominal obesity and insulin resistance, and various genetic factors. Complex interplay of these is involved in pathogenesis of hypertension.³¹ All these factors are well-known and are not highlighted in the present review. Factors specific to South Asian and Indians have been highlighted earlier and include overweight and obesity especially abdominal adiposity, diabetes, smoking and alcohol consumption, nutrition transition, and sedentary lifestyles.³²

Data on association of hypertension with various social, economic, developmental, and other social determinants of health are sparse in India. A previous review has highlighted important of epidemiological transition in India in increasing prevalence of hypertension.³³ There is evidence that urban-rural differences in hypertension are decreasing and there is an urban-rural convergence.⁹ Similar data are reported in the DLHS study also.¹⁴ To determine association of prevalence of hypertension in different states in India with various social factors we performed a macrolevel analysis.

We used data on hypertension prevalence available from the DLHS (Table 4) and correlated it with various social factors. These factors include state-level human development index (HDI, derived from income, education, and fertility statistics),³⁴ social development index (SDI, derived from multiple socioeconomic factors),³⁵ urbanization index (UI, ratio of urban to rural population in a state),³⁶ epidemiological transition index (ETI, ratio of communicable to non-communicable disease mortality),³⁰ and healthcare quality index (HQI, availability of healthcare facilities at primary care).³⁷ We calculated Pearson's correlation coefficient (*r*) for each of these variables using state-level data of these socioeconomic

TABLE 6: Correlation of hypertension prevalence in Indian states with various socioeconomic and lifestyle indicators (Pearson's *r*)

	State level hypertension prevalence (DLHS)	
	Men	Women
Socioeconomic factors		
Human Development Index	0.620 (0.001)	0.558 (0.003)
Social Development Index	0.739 (0.001)	0.603 (0.010)
Urbanization Index	0.432 (0.014)	0.338 (0.058)
Epidemiological Transition Index	-0.646 (0.00)	-0.621 (0.001)
Healthcare Quality Index	0.262 (0.148)	0.127 (0.488)
Lifestyle factors		
Smoking/Tobacco use	-0.511 (0.008)	-0.399 (0.043)
Alcohol intake	0.061 (0.767)	0.120 (0.559)
Overweight/Obesity (BMI >25 kg/m ²)	0.629 (0.001)	0.570 (0.002)

Numbers in parentheses are p value

factors and hypertension prevalence (DLHS). The results are shown in table 6.

In both men and women, there is a positive association of HDI and SDI with hypertension prevalence at a macrolevel suggesting that these factors are important. These findings are also similar to results from 11-city India Heart Watch study where we reported that hypertension prevalence was greater in states with greater HDI and SDI.³⁸ There is a weak positive association (insignificant) with urbanization suggesting that urban-rural differences in hypertension prevalence in India are disappearing and it is likely that hypertension would be more common in rural areas of India in the near future. This would be, then, similar to hypertension epidemiology in high- and middle-income countries where it is more common in rural areas.^{3,4} Significant association of hypertension with state-level prevalence of obesity (body mass index >25 kg/m²) (Table 6) confirms internal consistency of the data.

We also performed correlation of hypertension prevalence (DLHS) with health quality index as published by the National Institution for Transforming India (NITI Aayog), Government of India (Fig. 4). No significant correlation is observed of hypertension prevalence with availability of primary healthcare in men ($R^2 = 0.06$) or in women ($R^2 = 0.01$). It is expected that states with greater hypertension prevalence would have better primary care. However, the data (Fig. 4) show that states with high prevalence of hypertension have similar quality of primary healthcare as those with low prevalence. Moreover, the health index has been developed with focus on mother and child healthcare and a better index needs to be developed that also focuses on chronic healthcare delivery, important for hypertension control. Better hypertension control in India needs focus on strengthening primary care in the country^{3,39} and clearly more effort is required in India to upgrade primary care services for better hypertension control.^{39,40}

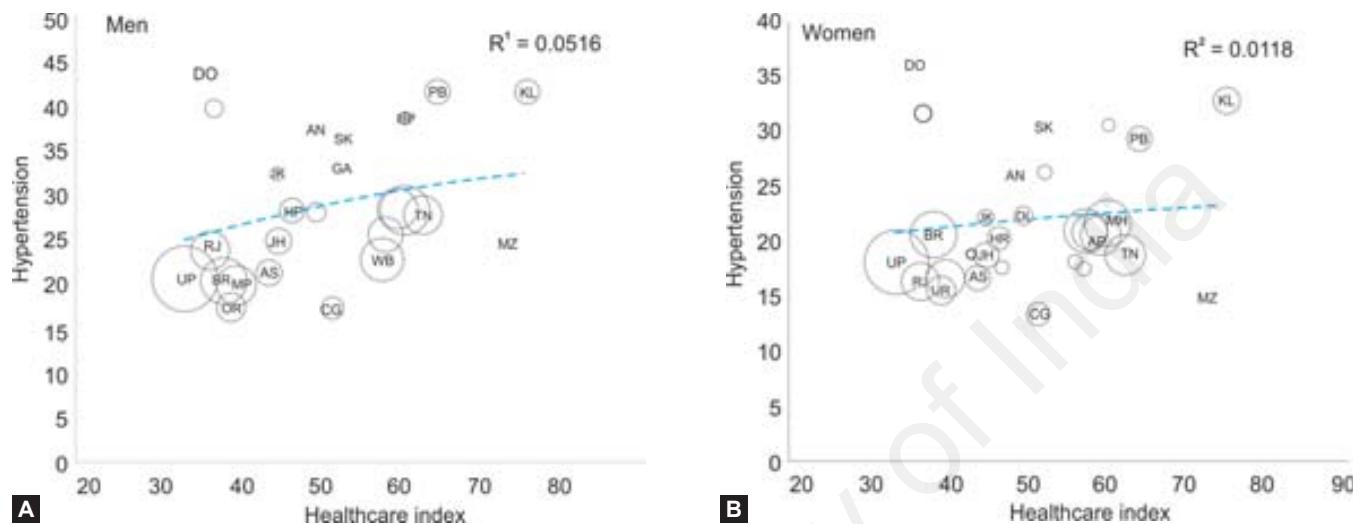

FIG. 4: Correlation of hypertension prevalence with healthcare quality index in men and women in various Indian states.

CONCLUSION

In conclusion, this review highlights that hypertension is the most important risk factor for disease burden in India.² Previous meta-analysis have reported increasing trends in hypertension in India.^{6,7} High prevalence of hypertension has been reported in both urban and rural locations in the country.⁸ However, these epidemiological studies have been mostly single or multi-site studies which have failed to provide national data. Two recent studies have used proper nationwide sampling and uniform tools to determine the true prevalence of hypertension in India. Fourth NFHS evaluated hypertension prevalence in younger men and women and reported hypertension in 13.8% men (15–54 years) and 8.8% women (15–49 years) with an overall prevalence of 11.3%. More representative data from DLHS and AHS reported hypertension in 25.3% with a greater prevalence in men (27.4%) as compared to women (20.0%). Hypertension is more in urban areas. The GBD study reports that hypertension associated mortality and morbidity in India is high and increasing. Our review shows that social determinants of hypertension are important and states with greater human and social development and urbanization (HDI, SDI, UI) have more hypertension. This is in contrast to developed countries, such as USA, where hypertension is more in less developed states.⁴¹ This review also shows poor association of hypertension with healthcare availability. This suggests that primary healthcare system in the country needs to be ramped-up for better hypertension control in the country.

Primary Prevention of Hypertension

Panniyammakal Jeemon, Dorairaj Prabhakaran

INTRODUCTION

Hypertension is one of the leading risk factor for cardiovascular disease (CVD) and a major contributor to global mortality and disability.¹ Annually, approximately over ten million deaths are attributable to hypertension.² The low- and middle-income countries (LMIC) bear disproportionately higher burden of hypertension in absolute numbers³ due to a rapid increase in prevalence and the sheer size of its population. For example, LMICs contribute to nearly two-thirds of the mortality attributable to hypertension, globally.³ The rising burden of hypertension in LMIC is also reflected in the rising population level mean blood pressure (BP) especially in the South Asian and sub-Saharan population.⁴

Despite progress in recent decades in prevention, detection, and treatment of high BP, hypertension remains an important global public health challenge. Hypertension is said to be a disease paradoxes. It is easy to detect but diagnosis rates are dismal, easy to treat but treatment rates are disappointing and several potent drugs are available but control rates are abysmal. For example, numerous meta-analyses have unequivocally demonstrated that treating and effectively lowering BP is associated with reductions in cardiovascular events and mortality.⁵ However, treatment and control rates of hypertension are abysmally poor at the population level in LMIC.⁶ Additionally, various studies conducted in LMIC suggest that hypertension onset occurs relatively early in life,⁷ often associated with clustering of multiple CVDs risk factors,⁸ and lead to premature cardiovascular events such as heart attacks and stroke.

Reducing the population level BP is an effective strategy in addressing the burden of hypertension. Although, pharmacological treatment is effective in reducing BP in the hypertensive group, its impacts on population mean BP reduction is limited. Primordial and primary prevention are key strategies for population-wide reduction in average BP. For example, more than half of the reduction in CVD mortality in developed countries is attributed to improvements in

population level risk factors such as tobacco use, cholesterol, and BP control.⁹

CLASSIFICATION OF HYPERTENSION

The seventh report of the Joint National Committee on prevention, detection, evaluation, and treatment of high BP (JNC VII report) define hypertension as a confirmed elevation of systolic or diastolic BP (≥ 140 mm Hg or ≥ 90 mm Hg, respectively).¹⁰ The cut-off will be based on the mean of two or more properly measured seated BP readings on each of two or more office visits. However, based on observational data, CVD risk begins to accrue at lower systolic BP (SBP) value of 115 mm Hg.¹¹ Lifestyle modifications in the context of delaying the onset of hypertension in individuals with systolic or diastolic BP (SBP or DBP) less than 140/90 mm Hg is largely referred to as primary prevention. The JNC VII report recommends individuals with SBP in the range of 120–139 mm Hg or DBP 80–90 mm Hg engage in health-promoting lifestyle modifications to prevent the development of hypertension and CVD.¹⁰ Additionally, lifestyle modification is also recommended as concurrent treatment for patients with hypertension.

THE NEED FOR PRIMARY PREVENTION OF HYPERTENSION IN INDIA

Data on annual incidence of hypertension in Indian population are scarce. In a longitudinal follow-up study conducted in a representative sample from two cities of India (Delhi and Chennai), the average SBP increased by 2.6 mm Hg and one in six developed hypertension.¹² The estimated impact of 2.6 mm Hg rise in average BP on hypertension prevalence is large as it can double the current prevalence rate of 30% over a period of 10 years. The most susceptible group to develop hypertension is the least privileged, lesser educated, and from the lowest socioeconomic strata.¹² This will have important ramifications at the population level, due to

lesser likelihood of treatment affordability. Additionally, there is a tendency to ignore treatment options among the above mentioned group due to asymptomatic nature of hypertension and could potentially lead to devastating health consequences. The impact of a major cardiovascular event due to uncontrolled hypertension on household economy is substantial as it takes away potentially productive life years and probable bankruptcy due to huge out of pocket payments for treatment.

PRIMARY PREVENTION

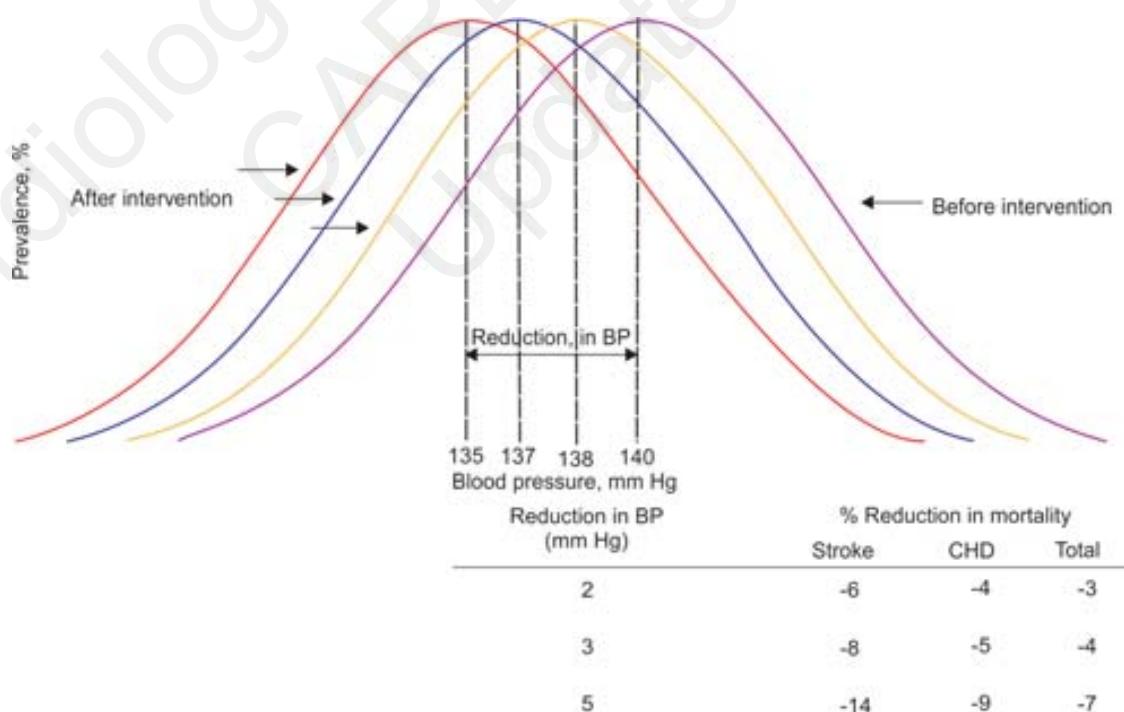

Primary prevention of hypertension provides an avenue to interrupt and prevent the continuing costly cycle of managing hypertension and its complications. In order to achieve the UN sustainable development goal (SDG) of one-third reduction in premature CVD mortality by 2030, concerted efforts must be undertaken not only in earlier detection and treatment of hypertension, but also in implementation of primary prevention strategies.¹³ Primary prevention focuses on preserving good health by removing the precipitating causes or potential determinants of poor health. The larger goal of primary prevention efforts in hypertension is to curtail the growing incidence of hypertension in India.

There are two main approaches in the primary prevention of hypertension. The first one is known as the population-based approach of involving the general population. The main objective of the population wide approach is to bring down the average BP at the population level (Fig. 1). It is based on the principal that majority of the population falls under the middle portion of the blood pressure distribution, and majority of the adverse events occur among individuals in the

middle of the BP distribution. Therefore, a minor reduction in the average BP shifts the population distribution curve toward the left and saves the population from potentially devastating adverse events. For example, Cook et al. based on their findings from the Framingham Heart Study, reported that a 2 mm Hg reduction in the population average of DBP for white United States residents aged 35–64 years would result in a 17% reduction in the prevalence of hypertension, a 14% decrease in the risk of stroke and transient ischemic attacks, and a 6% reduction in the risk of coronary heart disease.¹⁴ The second approach is a targeted approach among high-risk individuals who are prone to develop hypertension. Given the high propensity for development of hypertension in older population, individuals from the low socioeconomic group, those who are currently consuming alcohol, those who are with moderately elevated BP, overweight and dysglycemic individuals,¹² targeting these subgroups for prevention of hypertension may provide greater yield. Higher risk older adults are more likely to be successful with lifestyle interventions than young adults with lower risk. However, prevention strategies targeted earlier in life provide the greatest long-term probability for overall risk reduction and burden of BP-related complications in the community.

Interventions for Primary Prevention of Hypertension

There is no convincing evidence of a J-shaped relationship or a “threshold” below which the relationship between level of BP and high-risk of cardiovascular and renal diseases is observed.¹⁵ Therefore, the benefits of shifting the distribution

BP, blood pressure; CHD, coronary heart disease.

FIG. 1: Pictorial representation of shift of population level blood pressure distribution after primary prevention intervention.

TABLE 1: Recommendations for prevention of hypertension

Strategy	Detailed recommendation
Physical exercise	For nonhypertensive individuals to reduce the possibility of becoming hypertensive, accumulation of 30–60 min of moderate intensity dynamic exercise (e.g., walking, jogging, cycling, or swimming) 4–7 days per week in addition to the routine activities of daily living are recommended. There is no incremental benefit for higher intensities of exercise
Weight reduction	Multi-disciplinary approaches that includes dietary modification, increased physical activity and behavioral interventions are useful in reducing weight. Maintenance of health body weight with body mass index in the range of 18.5–24.9 and waist circumference <90 cm for men and <80 cm for women are recommended for nonhypertensive individuals to prevent hypertension. Lifestyle modification in combination with moderate intensity physical exercise is effective in reducing the body weight up to 6–7% of the baseline levels
Alcohol consumption	Healthy adults should avoid alcohol consumption or at least limit alcohol consumption to <2 drinks per day, and consumption should not exceed 14 standard drinks per week for men and 9 standard drinks per week for women. One standard drink is considered to be equivalent of 13.6 g or 17.2 mL of ethanol or approximately 44 mL (1.5 Oz) of 80-proof (40%) spirits, 355 mL (12 Oz) of 5% beer, or 148 mL (5 Oz) of 12% wine
Dietary recommendations	A DASH diet that is rich in fruits, vegetables, low-fat dairy products, dietary and soluble fiber, whole grains, and protein from plant sources that is reduced in saturated fat and cholesterol is recommended for prevention of hypertension. In India millets which were traditional diets are rich in fiber and should be encouraged. Even locally available, seasonal and inexpensive fruits and vegetables are helpful in reducing and maintaining optimal blood pressure
Sodium intake	No more than 2.4 g sodium (<6 g sodium chloride) is generally recommended as daily dietary intake
Potassium intake	Potassium supplementation is not recommended. However, dietary sources rich in potassium are effective in reducing blood pressure especially in a high sodium environment. These include fruits and vegetables
Calcium and magnesium supplementation	Both calcium and magnesium supplementation are not recommended for prevention of hypertension
Stress management	Relaxation techniques and Yoga-based interventions are recommended for primary prevention of hypertension based on evidence from multiple small studies carried out largely in the United Kingdom
Tobacco use	Though the influence of smoking/tobacco is limited in chronic hypertension, abstinence from tobacco is recommended as a broader primary prevention strategy
Enhancing access to appropriate facilities	Enhancing access to appropriate facilities such as green space, parks, walking trails, bike paths, etc. are effective in encouraging physical activity and reducing blood pressure
Fish oil supplementation	Evidence on fish oil supplementation on blood pressure reduction is equivocal and therefore not recommended as a strategy for primary prevention of hypertension
Herbal or botanical supplements	Available evidence is not sufficient to make recommendation on any of the herbal or botanical supplements for blood pressure reduction

DASH, Dietary Approaches to Stop Hypertension.

curve of population level BP toward the left with lower average BP far outweigh any potential risk associated with lowering average BP, even in normotensive individuals. The key strategies for primary prevention of hypertension are described in table 1.

Sodium Reduction

Sodium reduction is unequivocally the most efficient primary prevention intervention at the population level for hypertension.¹⁶ On an average, 1.7 g/day reduction of average salt intake may result in 2 and 1 mm Hg reduction in SBP and DBP, respectively. No more than 2.4 g sodium or 6 g sodium chloride (just under a teaspoon of salt) is generally recommended as daily dietary intake. It has been estimated that moderated reduction in salt intake at the population level among middle-aged Indians may be sufficient enough to avert nearly 400,000 CVD events [myocardial infarctions (MIs) and stroke] and 81,000 deaths (5% reduction) over a period of 10 years.¹⁷ Lower intake of dietary sodium reduces the risk of CVD, especially in those who are also overweight.

Potassium Supplementation

Potassium supplementation is considered as another useful strategy for BP reduction in both hypertensive and normotensive individuals.¹⁸ A daily dietary intake of more than 3.5 g/day of potassium is generally recommended.¹⁹ The benefits of potassium supplementation is observed to be larger in persons with high dietary sodium intake.²⁰ The preferred strategy to increase potassium intake is to consume foods rich in potassium (apart from fruits and vegetables sweet potato, navy bean, and yogurt are rich in potassium) rather than supplements. However, recent guidelines do not support supplementation of potassium.²¹

Weight Reduction

Several epidemiological studies suggest that weight gain is associated with increased risk of hypertension.^{22,23} Similarly, randomized controlled trials also demonstrate that weight loss is associated with reduction in BP.²⁴ A sustained weight loss of 4.4 kg or more can reduce SBP and DBP by 5.0 and 7.0 mm Hg, respectively.²⁴

Moderate Alcohol Consumption

Alcohol consumption is known as the most important modifiable risk factor for hypertension.²⁵ The relationship between high alcohol intake (typically three or more drinks per day) and elevated BP has been documented in many epidemiologic studies. A dose-dependent reduction in BP with reduction in alcohol consumption is reported in individuals who consume alcohol on a regular basis.²⁵ Available data suggest no cardiovascular protection among Indians even if they consume up to two standard drinks per day.²⁶ Additionally, isolated binge drinking (consuming more than four drinks in a row per occasion), a form of drinking associated with increased risk of heart disease,²⁷ is very common in Indians and it is extremely harmful.

Physical Activity

Inverse relationship between physical activity levels and BP has been reported from several epidemiological studies.²⁸⁻³¹ Regular aerobic physical activity for at least 30 min/day for at least 5 days of the week has been recommended for primary prevention of hypertension. Simple interventions such interruption of prolonged sitting time is also found to be effective in reducing BP.³²⁻³⁴

Dietary Pattern

The dietary approaches to stop hypertension (DASH) diet which is rich in fruits, vegetables, dietary, and soluble fiber, and low-fat dairy products but reduced in saturated and total fat is demonstrated to be effective in reducing mean BP in both hypertensive and nonhypertensive individuals.³⁵ The national high BP education program coordinating committee³⁶ for the primary prevention of hypertension recommends consumption of a diet rich in fruits, vegetables, and low-fat dairy products and reduced in saturated and total fats.

Comprehensive Lifestyle Modifications

Impact of lifestyle interventions on SBP is summarized in table 2. Clinical trials data suggest that comprehensive lifestyle modification interventions are effective in bringing down both SBP and DBP (Fig. 2)³⁷ in individuals with SBP in the range of 120–159 mm Hg and DBP in the range of 80–86 mm Hg. Similar reduction in BP has been documented in studies conducted in real life settings in India. For instance,

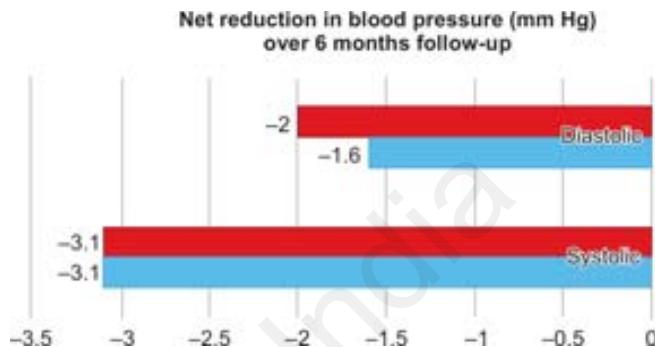

FIG. 2: Blood pressure reduction in multicomponent behavioral interventions. Blue bars indicate blood pressure reduction in individuals randomized to an established multi-component intervention (weight loss, reduced sodium intake, reduce alcohol consumption, and increased physical activity) and red bars indicate blood pressure reduction in individuals randomized to multicomponent intervention plus the Dietary Approaches to Stop Hypertension diet versus advice only.

a worksite-based intervention program implemented in India with both population-wide and high-risk approach was effective in bringing down both SBP and DBP to 5% of the baseline average BP.^{8,38} Such intensive approaches may be useful in shifting the population distribution curve of BP toward the left and effectively bringing down the number of individuals with moderately elevated BP. Since, a large proportion of adverse cardiovascular events would occur in individuals belonging to the middle of the distribution curve of BP at the population level, comprehensive interventions may have the potential to delay such events.

Innovative Models in Primary Prevention of Hypertension

Task sharing strategy of involving frontline health workers has great potential for scale up of community-based intervention activities for primary prevention of hypertension at the national level. The DISHA study³⁹ is one of the largest community-based cluster randomized trial in India designed to test the effectiveness of “task sharing” interventions in shifting the population distribution of BP toward the left side of the distribution curve. Advent of mHealth technologies also opens the door to reach out to mass population lifestyle interventions targeting primary prevention of hypertension.

GAPS IN KNOWLEDGE AND FUTURE RESEARCH NEEDS

There are several pressing research needs in the primary prevention of hypertension. They are: (A) Early life influences (first thousand days) on BP and potential strategies to minimize risk in early life; (B) Physical and behavioral factors that influence BP during childhood and adolescence; (C) Testing alternative strategies of implementing lifestyle intervention at scale in community settings and identifying barriers to implementation; (D) Identifying the impact of novel strategies of improving physical fitness and reducing

TABLE 2: Impact of lifestyle modification interventions on systolic blood pressure*

Modification	Effect on SBP reduction (range)
Weight reduction	5–20 mm Hg/10 kg weight loss
Adopt DASH eating plan	8–14 mm Hg
Dietary sodium restriction	2–8 mm Hg
Physical activity	4–9 mm Hg
Moderation of alcohol consumption	2–4 mm Hg

DASH, Dietary Approaches to Stop Hypertension; SBP, systolic blood pressure.

sedentary time such as high-intensity interval training and breaking the sitting time every 20 minutes, etc.; (E) Efficacy and effectiveness of specific dietary interventions, such as increased dietary protein or dietary fiber intake, and other modifications of whole diets in the prevention of hypertension; (F) Characterizing phenotypic, genetic, epigenetic, and metabolomic predictors of response to interventions for prevention of hypertension.

CONCLUSION

Comprehensive lifestyle interventions and policy interventions on salt restrictions have high potential of shifting the population distribution of BP toward the left of the distribution curve. Furthermore, several studies both epidemiological and randomized controlled trials suggest that the positive lifestyle changes for prevention of hypertension can be sustained over long periods. The BP-lowering effects of positive lifestyle changes observed is almost equivalent to the effect size observed in some of the drug trials in hypertension. Policy response on restricting the salt use is highly desirable and cost effective in the Indian settings. Despite several barriers to implementation, potential for health benefits makes primary prevention of hypertension an important national priority in India.

Cutoff for Hypertension: Implications of 2017 Guidelines for Indian Patients

Rajeev Narang, S Srikant

INTRODUCTION

Diagnosis of hypertension (HT) has altered considerably over recent years. Two main factors that have led to this change are publication of newer studies showing lower thresholds for diagnosis of HT and wide adoption of digital blood pressure (BP) recording instruments. The first provides scientific basis for altering the practice while second compels change due to practical considerations.

Digital BP instruments have become cheaper and widely available. They now provide more accurate, reliable, and reproducible readings. A number of studies have compared these instruments with traditional sphygmomanometer and found favorable results. Majority of these automated BP measuring devices use oscillometric technique. The British and Irish Hypertension Society lists many models which they have tested and found reliable (<https://bihsoc.org/bp-monitors/>).

A large proportion of patients in urban settings have digital BP recording instrument at home. This provides an opportunity to measure BP with several advantages. One is that, it is measured in home setting, hence avoiding the stress of hospital or clinic visit and eliminating white-coat HT phenomenon. Second is that multiple readings are possible over a period of one or more days providing information similar or even superior in some respects to ambulatory BP monitoring. The patients should hence be encouraged to invest in a good oscillometric BP monitoring instrument and record BP at home. They should also note these readings in a diary and bring it to clinic at time of visit. The frequency of BP recording will vary according to the situation. For stable patients once a week recording may be sufficient while those starting on new or altered therapies should measure it daily, so that lesser or greater than desired effect is picked-up early. Recording of BP by patients themselves also necessitates patient education in this regard. The cut-offs for diagnosis are largely based on clinic visits rather than home settings. In addition, they do not consider normal variation in BP that is very common. Considering all data and taking into account

normal variation of BP, it seems reasonable to educate patients to keep upper cutoff as 140 mm Hg. Regarding upper cutoff of diastolic BP, it is reasonable to educate patients that diastolic pressure above 90 mm Hg, if recorded on more than two occasions, indicates need for increase in dosage of medication. In recent years, emphasis has been shifting towards targeting mainly systolic BP, rather than diastolic. There are very few patients in whom diastolic BP remains elevated, when systolic pressure has come down to normal. Recent studies have also targeted systolic BP as preferred method of titrating therapy.

It is important to inform patient regarding lower cutoffs also. Patients recording their BP at home often get alarmed when lower than usual readings are obtained. Presence of symptoms should be ascertained in these patients. More severe symptoms include giddiness, dizziness, presyncope, or syncope. The symptoms are often postural as when patient get out of bed in the morning. The symptoms may be mild or subtle as fatigue, listlessness, and lack of energy.

Low systolic BP often leads to giddiness, dizziness, pre-syncope, and syncope, especially in elderly persons. Patients should be educated that they need to reduce their BP medication, if systolic BP falls to less than 110 mm Hg. Low diastolic BP is a complaint most often made by elderly persons who have isolated systolic HT as a result of stiffening and reduced compliance of major blood vessels. Asymptomatic low diastolic BP has not been documented to have any deleterious effects in studies of BP control. There is some evidence that incidence of open-angle glaucoma may be increased, if patients who have diastolic BP lower than 60 mm Hg.

Wide adoption of self-recording of BP by digital instruments also provide an opportunity of self-management of BP by patients. For this, patient should be prescribed at least one drug in small dose which they can up or down-titrate. For example, patients may be advised to take amlodipine 2.5 mg twice a day initially. If on home monitoring BP is found to be low, this can be reduced to once a day or omitted altogether.

On the other hand, if the systolic or diastolic BP continues to be high, this can be up-titrated to 5 mg twice a day. Patients should also be educated regarding maximum dose that can be taken. Similar instructions can be given with other agents, e.g., telmisartan (20 mg) or hydrochlorothiazide (12.5 mg).

In 2017, American Heart Association updated the HT guidelines.¹ The major change was that systolic BP of 130 mm Hg or more or diastolic of 80 mm Hg or more is considered HT and needs to be controlled (Tables 1 and 2). Hence, persons with systolic BP of 130–140 mm Hg and/or diastolic 80–90 mm Hg are now classified as hypertensive, while they were earlier classified as prehypertensive by Joint National Committee (JNC) 7 criteria.² This re-labels a large number of people as having elevated BP and warranting life style changes. The 2017 guideline also emphasizes individualized cardiovascular risk assessment. They use 10-year cardiovascular disease (CVD) risk calculation to decide on treatment threshold.³ This will also mean that most elderly patients would get treated with medications earlier. Use of a risk calculator for BP treatment may over-estimate risk in many individuals and perhaps lead to over-medication. Whether a CVD risk calculator can decide when to treat HT is debatable.

Basic question is whether intensive treatment of HT is better than less aggressive approach. Although systolic blood pressure intervention (SPRINT) trial showed it to be beneficial, ACCORD and secondary prevention of small subcortical strokes (SPS3) trials did not find significant

benefit.^{4–6} SPRINT trial found that in patients (N = 9,361) at high risk of CVD without history of stroke or diabetes, intensive BP control (systolic <120 mm Hg) improved cardiovascular outcomes and overall survival compared to standard therapy (target systolic BP 135–139 mm Hg). Some serious adverse events were modestly increased. In ACCORD study, 4,733 patients with diabetes at higher risk of cardiovascular events were studied. Intensive BP control (target systolic BP <120 mm Hg) did not reduce adverse events [rates of nonfatal myocardial infarction (MI), nonfatal stroke, or cardiovascular mortality] when compared with standard BP control (target systolic BP <140 mm Hg). In SPS3 study, 3,020 patients with recent lacunar stroke were studied. It was found that target systolic BP less than 30 mm Hg did not reduce incident stroke when compared to higher-target systolic BP control (140–150 mm Hg).

However, the probability (P) value (0.08) did indicate a trend towards reduction. Greater emphasis seems to have been given to the SPRINT data in 2017 guidelines.

Another aspect is that stage-1 HT becomes a very narrow range and normal variability of BP may make a person in and out of this stage (Fig. 1). It is common these days for patients to record BP at home with oscillometric devices and to bring to the clinic a chart of those readings, some of which may be in stage 1 and others in elevated BP range.

Narrowness of stages may make this classification difficult to implement.

American College of Physicians has set the threshold for treatment at 150 mm Hg for average risk older (>60 years) people.⁷ It was estimated that this new guideline would classify almost 46% of middle-aged Americans as hypertensive as compared to 32% as per the previous guidelines.⁸

Additionally, the prevalence of high BP is expected to triple among men under age of 45 years, and double among women under 45 years of age and would result in almost 20 million of them getting started on medication. Other major guideline-making associations like the American College of Physicians/National Institute for Health and Care Excellence (NICE)/ European Society of Cardiology (ESC) have not as yet accepted this guideline.

TABLE 1: Controlled reading of blood pressure for different stages

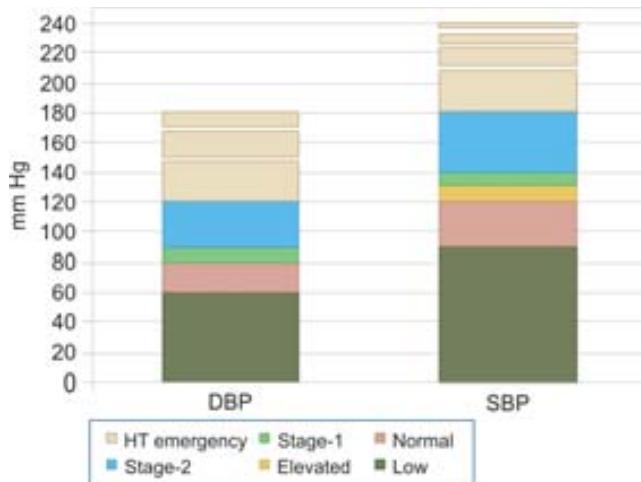

Category	Blood pressure (2 or more readings taken on 2 or more occasions)
Normal	SBP <120 and DBP <80 mm Hg
Elevated	SBP 120–129 and DBP <80 mm Hg
Hypertension	SBP >130 or DBP >80 mm Hg
Stage 1	SBP 130–139 or DBP 80–89 mm Hg
Stage 2	SBP ≥140 or DBP ≥90 mm Hg

DBP, diastolic blood pressure; SBP, systolic blood pressure.

TABLE 2: Treatment for different group of blood pressure stages

Group	Treatment (goal for everyone is <130/80 mm Hg)
"Elevated" BP (SBP 120–129 and DBP <80 mm Hg)	Lifestyle modification (non-pharmacological therapy)
Stage-1 hypertension (SBP 130–139 and DBP 80–89 mm Hg) <ul style="list-style-type: none"> Without known clinical atherosclerotic cardiovascular disease and 10-year cardiovascular risk <10% (According to the ACC/AHA calculator)	Lifestyle modification; re-assessment after 3–6 months
Stage-1 hypertension (SBP 130–139 and DBP 80–89 mm Hg) <ul style="list-style-type: none"> With known clinical atherosclerotic cardiovascular disease or 10-year cardiovascular risk ≥10% (According to the ACC/AHA calculator)	Lifestyle modification and drug therapy; reassess in one month
Stage-2 hypertension (SBP ≥140 mm Hg or (DBP ≥90 mm Hg)	Lifestyle modification and drug therapy (consider two agents from different classes); reassess in 1 month

ACC, American college of cardiology; AHA, American heart association; DBP, diastolic blood pressure; SBP, systolic blood pressure.

DBP, diastolic blood pressure; HT, hypertension; SBP, systolic blood pressure.

OTHER HIGHLIGHTS

Other highlights of these guidelines include:

Screen for Other Risk Factors

Screen for risk factors like smoking, diabetes, dyslipidemia, obesity, wrong diet, stress, and sleep-apnea.

Investigations

Basic testing for HT includes fasting blood glucose, blood cell count, lipids, metabolic panel, thyroid-stimulating hormone, urinalysis, and electrocardiogram with optional echocardiogram, uric acid, and urinary albumin-to-creatinine ratio.

Screening for Secondary Causes

The screening for secondary causes of HT is necessary for new-onset or uncontrolled HT in adults including drug-resistant (≥ 3 drugs), abrupt onset, age less than 30 years, target organ damage [cerebral vascular disease, retinopathy, left ventricular hypertrophy, heart failure, coronary artery disease (CAD), chronic kidney disease (CKD), peripheral artery disease, albuminuria].

Screening includes testing for CKD, Reno vascular disease, primary aldosteronism, obstructive sleep-apnea, drug-induced HT, and alcohol-induced HT. Others include pheochromocytoma, Cushing's syndrome, congenital adrenal hyperplasia, hypothyroidism, hyperthyroidism, and aortic coarctation.

Treatment

Non-pharmacologic Therapy

Weight loss, sodium restriction, and potassium supplementation, increased physical activity, restrict alcohol. Use of medications is recommended in patients with clinical CVD and an average systolic BP greater than or equal to 130 mm

Hg or a diastolic BP greater than or equal to 80 mm Hg. Use of medication is also recommended for a systolic BP greater than or equal to 140 mm Hg or a diastolic BP greater than or equal to 90 mm Hg.

Targets

For adults with confirmed HT and known CVD or 10-year atherosclerotic cardiovascular disease (ASCVD) event risk of 10% or higher, a BP target of less than 130/80 mm Hg is recommended. For adults with confirmed HT, but without additional markers of increased CVD risk, a BP target of less than 130/80 mm Hg is recommended as reasonable.

Principles of Drug Therapy

Initial therapy includes thiazide diuretics, calcium channel blocker (CCBs) and angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blocker (ARBs). Two first-line drugs of different classes are recommended with stage-2 HT. The primary change in recommendations regarding pharmacologic therapy is the elimination of beta-blockers from first-line therapy for patients with primary HT. For adults with confirmed HT and known stable CVD or greater than or equal to 10% 10-year ASCVD risk, a BP target of less than 130/80 mm Hg is recommended.

The strategy is to first follow standard treatment guidelines for CAD, heart failure with reduced ejection fraction (HFrEF), previous MI, and stable angina, with the addition of other drugs as needed to further control BP. In heart failure with preserved ejection fraction (HFpEF) with symptoms of volume overload, diuretics should be used to control HT, following which ACE inhibitors or ARBs and beta-blockers should be titrated to systolic BP less than 130 mm Hg. Treatment of HT with an ARB can be useful for prevention of recurrence of atrial fibrillation.

Chronic Kidney Disease

Blood pressure goal should be less than 130/80 mm Hg. In those with stage-3 or higher CKD or stage 1 or 2 CKD with albuminuria (>300 mg/day), treatment with an ACE inhibitor is reasonable to slow progression of kidney disease. An ARB is reasonable, if an ACE inhibitor is not tolerated. In adults with acute intracranial hemorrhage and systolic BP greater than 220 mm Hg, it may be reasonable to use intravenous drug infusion to lower systolic BP. In acute ischemic stroke, BP should be lowered slowly to less than 185/110 mm Hg prior to thrombolytic therapy.

Diabetes Mellitus

Antihypertensive drug treatment should be initiated at BP greater than or equal to 130/80 mm Hg with a treatment goal of less than 130/80 mm Hg. In adults with diabetes mellitus (DM) and HT, all first-line classes of antihypertensive agents (i.e., diuretics, ACE inhibitors, ARBs, and CCBs) are useful and effective. ACE inhibitors or ARBs may be considered in the presence of albuminuria.

Age-related Issues

Although the new guideline lowers the blood-pressure goal for people over 65 years of age, it suggests that 30-year-olds and 80-year-olds should have the same goal. Treatment of HT is recommended for adults (≥ 65 years of age), with an average systolic BP greater than or equal to 130 mm Hg with systolic BP treatment goal of less than 130 mm Hg. In addition, the new guideline does not consider isolated systolic HT, which is a major problem among many people over 70 years of age. For older adults (≥ 65 years of age) with HT and a high burden of comorbidity and/or limited life expectancy, clinical judgment, patient preference, is reasonable for decisions regarding intensity of BP lowering and choice of antihypertensive drugs.

CONCLUSION

The new guidelines in 2017 have mainly reset the treatment threshold to 130/80 mm Hg. Most part of the guidelines summarize the current knowledge on drug therapy and disease management along with promotion of team-based system approaches for better diagnosis and management. Rather than advocate a specific target for all adults, the focus should be on choosing BP targets that allow for “a choice based on a

patient's risk profile, susceptibility to harms, and treatment preferences”.

Initial Choice of Drugs in Uncomplicated Hypertension: Not Monotherapy Anymore but Combination

C Venkata S Ram

INTRODUCTION

Systemic hypertension is a major risk factor for premature mortality and excessive morbidity. Despite numerous advances in our understanding of the pathophysiology, disease implications, and effective drug therapy, hypertension remains uncontrolled in a majority of patients. In other words, patients with hypertension remain "hypertensive" even under medical care. Although hypertension is a precursor of chronic disease burden punctuated by acute events, effective blood pressure (BP) control prevents the complication rate. A number of studies have clearly shown that controlling hypertension saves lives. Hence, there is unmistakable evidence that elevated BP (by any definition) should be treated.

The American guidelines¹ define hypertension as a BP level more than 130/80 mm Hg (Table 1) whereas the Europeans^{2,3} have retained the old definition, i.e., a BP level more than 140/90 mm Hg (Table 2). Although the American and European definitions of hypertension differ, the therapeutic BP goal is the same, i.e., less than 130/80 mm Hg in both the reports (Table 3). Whether we apply American or European definition, hypertension is rampant in India. Studies have shown that hypertension prevalence in India is escalating in the urban and rural populations alike.⁴ Uncontrolled hypertension imposes tremendous and a formidable disease burden in India.⁵⁻⁸ It is obligatory then to detect hypertension early and restore the BP to normal

level without needless procrastination. Unless we control hypertension persuasively, our citizens (including the young) are vulnerable to develop coronary artery disease (CAD), congestive heart failure (CHF), chronic kidney disease (CKD), end-stage renal disease (ESRD), cerebrovascular disease (CeVD), dementia, peripheral vascular disease (PWD), and die prematurely.

This chapter is restricted to the management of hypertension and not on the ways and means to detect hypertension. Hence, the commentary below will focus only on treatment aspects of hypertension. Whereas, pharmacological treatment is required for most patients with hypertension, the value of lifestyle modifications is incontrovertible. The first step in the management of hypertension always should be advocate salt restriction, physical activity, normal body weight, and avoidance of tobacco and alcohol in excess. These hygienic recommendations form the foundation of hypertension treatment principles.

PHARMACOLOGICAL TREATMENT OF HYPERTENSION

The primary goal of antihypertensive therapy is to reduce cardiovascular morbidity and mortality. There are excellent outcome data and observations demonstrating the drug treatment reduces the complications in hypertension.^{9,10} The cardiovascular disease (CVD) risk reduction from

Hypertension	BP goal is the same
ESC/ESH >140/90 mm Hg	>130/80 mm Hg
ACC/AHA >130/80 mm Hg	

Definitions differ but the goal blood pressure is same
ACC, American College of Cardiology; AHA, American Heart Association; ESH, European Society of Hypertension; ESC, European Society of Cardiology.

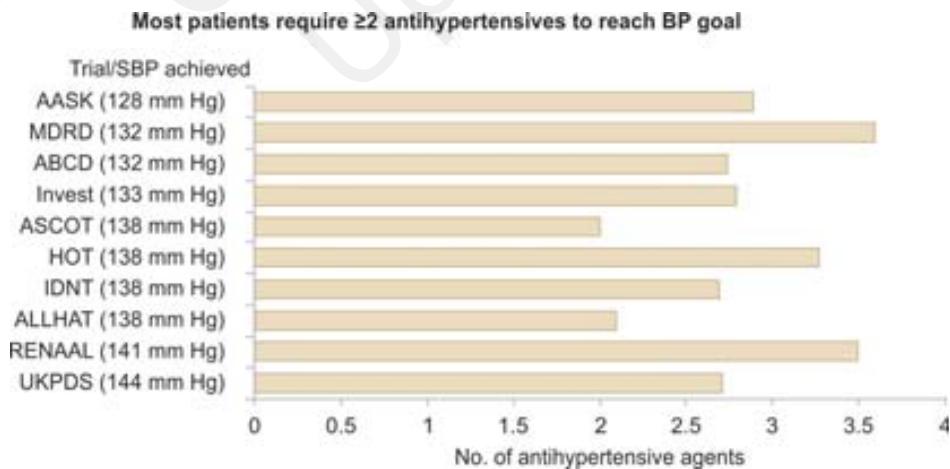

antihypertensive drug treatment is directly proportional to the level of BP reduction rather than a specific drug class.^{11,12} However, different drug classes provide unique and important benefits over and beyond BP control in patients with comorbidities.^{13,14} It is evident that lower the BP, the better is the survival and disease prevention. Hence, it is important to achieve the goal BP less than 130/80 mm Hg in most patients with hypertension.

Within the large spectrum of available antihypertensive drugs, the preferred initial choice of therapy depends on factors such as the cost, tolerability, adherence, age, and comorbidities such as diabetes, CKD, CAD, CeVD, CHF, etc. The doctors should select the drug(s) upon consideration

of these factors. American guidelines proposed diuretics, calcium channel blockers (CCBs), angiotensin-converting enzyme inhibitors (ACEIs), and angiotensin receptor blockers (ARBs) for the initial therapy of hypertension whereas the Europeans have restored β-blockers to the list as primary agents.

While a number of studies have shown the efficacy of monotherapies to control hypertension in the short term, nearly all the major outcome trials have utilized combination therapy to achieve and maintain target BP levels (Fig. 1). Until recently, various guidelines recommended initiating therapy with one drug and adding other drugs in sequence (so called stepped care approach). This sequential monotherapy has been shown to be effective in the prevention of hypertension-related complications. However, the stepped-care strategy has also demonstrated that monotherapy may be sufficient in only 30–40% of patients whereas with dual or triple drug combinations, the BP control rate is close to 90% or even higher.^{15,16} Furthermore, response to monotherapy takes time at the risk of nonadherence, and patients are exposed to long periods of elevated BP levels. It makes sense, therefore, to initiate therapy with dual drug combination to claim BP control early and to assure patient compliance. Thus, we are moving fast to implement initial combination therapy (instead of monotherapy) to control hypertension. There may be instances like doubtful hypertension, white coat hypertension, frail, elderly, and acute intercurrent illness, where monotherapy may be the right choice but for a vast majority, initiating combination therapy is strongly recommended by the latest guidelines. Thus, the consideration in 2018 is not which antihypertensive drug initially but which combination? The author strongly recommends initiating with combination therapy for the following reasons:

- Safe
- Effective and tolerated
- Required
- Timely control of BP

SBP, systolic blood pressure.

FIG. 1: Blood pressure control usually requires combination therapy.

- Patient satisfaction
- Positive clinical outcomes.

AN ABBREVIATED OVERVIEW OF DRUGS FOR INITIAL COMBINATION THERAPY

Diuretics

Diuretics are among the first generation of drugs shown to lower the BP level in patients with hypertension. All the guidelines have consistently recommended diuretics as an essential component of antihypertensive therapy. And there are excellent outcome data from clinical trials using diuretics as a part and parcel of therapy. The initial mechanism of BP reduction by diuretics is natriuresis, but the long-term BP control is via a reduction in the systemic vascular resistance (SVR). Diuretics are also less expensive than other classes of antihypertensive drugs.

For uncomplicated hypertension, a thiazide or a thiazide-type diuretic (chlorthalidone, indapamide) are preferred. In patients with CKD and CHF, loop diuretics are to be chosen. The traditional biochemical and metabolic side effects of diuretics can be minimized by using a low-dose; however, occasional monitoring of electrolytes and renal function is necessary. The American guidelines¹ have identified chlorthalidone as a “preferred” diuretic due to its long duration of action whereas the European guidelines^{2,3} suggest a thiazide or a thiazide-type diuretic like chlorthalidone and indapamide. With judicious utilization of low-dose diuretic therapy (as a part of combination therapy), one can expect a significant reduction in the BP levels.

Beta-Blockers

Beta-blockers were widely used for the treatment of hypertension for many decades. However, their popularity waned with the meta-analyses showing that atenolol-based treatments offered no target organ protection (TOP).^{17,18} Hence, recent guidelines (except European) have downgraded β-blockers as secondary, not primary drugs for hypertension (Table 4). Beta-blockers should still be considered for compelling indications such as CAD, compensated CHF, and sympathetic overdrive situations. The documented benefits of β-blockers ensure that this class of drugs will continue to be useful in selected situations.

TABLE 4: Primary drugs for hypertension

US	European
Diuretics	Diuretics
CCBs	CCBs
ARBs	ARBs
ACEIs	ACEIs
	β-blockers

CCB, calcium channel blocker; ARB, angiotensin receptor blocker; ACEIs, angiotensin-converting enzyme inhibitors.

Cardioselective β-blockers and vasodilating β-blockers are well tolerated and less likely to cause the traditional β-blocker side effects like depression, erectile dysfunction, and metabolic aberrations. Hence, it is preferable to consider metoprolol, nebivolol, bisoprolol, and carvedilol instead of atenolol and propranolol. Like any drug class, β-blockers are best applied in clinical practice taking into account the indications and contraindications. Vast clinical experience in India endorses the utility of β-blockers in the treatment of hypertension.

Calcium Channel Blockers

Calcium channel blockers are extremely reliable drugs to treat hypertension. Either as monotherapy or as a part of multidrug regimen, CCBs have become a highly useful class of drugs with proven efficacy and positive clinical outcomes. Evidence-based recommendation for CCBs is on the basis of dihydropyridine CCBs. The molecular mechanisms of various CCBs may differ slightly but the main site of their action is mediated by the inhibition of L-type voltage-dependent calcium channels. Although the first clinically useful CCB is nifedipine, bulk of new evidence is obtained from amlodipine and other newer drugs in the class.

Studies have demonstrated that CCBs (by lowering the BP level) reduce hypertension-related cardiovascular complications; they also have been shown to cause regression of left ventricular hypertrophy (LVH), prevent experimental atherosclerosis, and reduce proteinuria (in combination with ACEIs or ARBs). When given in proper doses, CCBs are effective irrespective of age, gender, ethnicity, and comorbid conditions. In combination with other antihypertensive drugs, CCBs are of considerable value in the treatment and prevention of resistant hypertension.

Outcome studies ranging from the earlier Syst-Eur to the recent FEVER and ACCOMPLISH¹⁹ have all attested to the safety, utility, and the value of CCBs in the treatment of hypertension. Guidelines consistently recommend CCBs as primary drugs to treat hypertension.

Angiotensin-converting Enzymes Inhibitors

The renin–angiotensin–aldosterone system (RAAS) plays a pivotal role in BP regulation and in the pathophysiology of hypertension, particularly in the progression of target organ damage (TOD). The blockade of the RAAS, therefore, has become a meaningful pathway to lower the BP and to offer TOP. ACEIs as the name implies reduce the formation of angiotensin-II and thus, inhibit its vasoconstrictor actions. In addition, ACEIs also promote the functions of vasodilatory kinins. ACEIs (usually) in combination with a diuretic lower the BP in patients with hypertension. With the possible exception of captopril and lisinopril, other ACEIs are prodrugs which are converted into active compounds in the body. Some ACEIs like ramipril and perindopril have a greater affinity for tissue ACE. To what extent, this tissue affinity is responsible for TOP is not known.

Angiotensin-converting enzyme inhibitors have been recommended in the recent guidelines for initial treatment of hypertension. Although they may occasionally suffice as monotherapy, the efficacy of ACEIs for BP reduction is most expressed in combination with a diuretic. The fall in BP in response to ACEI is not accompanied by reflex tachycardia as these drugs also inhibit the sympathetic nervous system (SNS) to some extent. The efficacy of ACEIs is offset in the presence of high salt intake or with the concomitant use of nonsteroidal anti-inflammatory drugs (NSAIDs). Recent outcome trials like ASCOT-BPLA²⁰ and ACCOMPLISH¹⁹ have further signified the therapeutic role of ACEIs (in combination with CCBs). A number of ACEIs ranging from benazepril to trandolapril are available for BP control but the outcome trials are limited to captopril, enalapril, perindopril, and ramipril. While one can start with a low dose of an ACEI, it is essential to apply optimal doses used in outcome trials.

Renin–angiotensin–aldosterone system blockade in general (including ACEIs) is particularly indicated in patients with atherosclerotic vascular disease, diabetes, renal dysfunction, metabolic syndrome, left ventricular dysfunction, and CHF. ACEIs may cause cough and rarely angioneurotic edema, and are contraindicated in pregnancy.

Angiotensin Receptor Blockers

Angiotensin receptor blockers have now become the central piece of the pharmacological blockade of the RAAS for the management of hypertension and comorbidities. As the name implies, the principal locus of ARB is inhibition of the angiotensin receptors (AT1R) located in the cardiovascular system and other organs such as the kidney, brain, and the adrenal gland. Angiotensin receptor blockers also attenuate the activity of SNS to some extent. It is argued that for BP reduction, ARBs are slightly superior to ACEIs. Like ACEIs, the BP lowering efficacy of ARBs is potentiated in combination with a diuretic. All the ARBs ranging from azilsartan to valsartan are effective in the treatment of hypertension and comorbidities. They differ in terms of duration action, renal or hepatic exertion, and outcome trials. The fundamental action of ARB is via the blockade of the AT1R but drugs like azilsartan have additional pathways of vasodilation, i.e., promoting the vasodilatory Ang 1-7.²¹ It remains to be seen whether these ancillary mechanisms offer an advantage for TOP.

A number of studies with ARBs have ratified their benefits in patients with CVD, CeVD, diabetes, metabolic syndrome, and CKD. Thus, both ACEIs and ARBs appear to furnish similar TOP. However, the ability of ARBs to preserve renal function is persuasive and impelling. RAAS blockade, in general, improves endothelial function and suppresses reactive oxygen species and vascular inflammation. Certain differential effects of ARBs are emerging beyond BP control. For example, losartan has a modest uricosuric effect and telmisartan has an effect on PPAR γ which may exert favorable metabolic effects. And azilsartan augments Ang 1-7 which may increase its potency and duration of action.

The efficacy of ARBs for BP control is enhanced when used in conjunction with diuretics or CCBs. The side effects

and tolerability profile of ARBs is superior to ACEIs. The combination of ACEIs and ARBs is not useful and may even be detrimental in terms of potential adverse renal consequences. Pregnancy is an absolute contraindication for the use of ARBs. Cough and angioneurotic edema are less likely to occur with ARBs in comparison to ACEIs.

INITIAL COMBINATION THERAPY NOT MONOTHERAPY IS THE ANSWER FOR BLOOD PRESSURE CONTROL

The old stepped-care approach for the pharmacological treatment of hypertension is steadily being replaced with treat to target BP goals promptly to avoid exposure to persistently elevated BP levels. The earlier concept of initial monotherapy was based on the pharmacological observations but not on the outcome data. It is abundantly clear and well accepted now that in a majority of patients with hypertension, multiple drugs are required to achieve and maintain normotension. Hypertension guidelines do not propose therapeutic strategies based on the mechanisms of BP elevation. Instead, the preeminent goal of anti-hypertensive therapy is to achieve normotension. And to accomplish this purpose, combinations of drugs interrupts the diverse pathophysiological mechanisms of hypertension. Apart from lowering the BP level, the prescribed therapy should also counter the pathophysiological mechanisms of hypertension and TOD. These parameters dictate and mandate initiating combination therapy for hypertension, not monotherapy anymore. Combining two classes of drugs produces a synergistic effect on BP reduction (Fig. 2) whereas incremental doses of monotherapy has a ceiling effect on BP while increasing the dose dependent adverse effects (Fig. 3). The era of initial and sequential monotherapy is (rightly) now replaced by initial combination therapy.²²⁻²⁴ Combination therapy can be in the form of separate drugs or fixed dose combination (FDC) or fixed pill combination (FPC). Studies have convincingly demonstrated that a FDC or FPC is to be preferred to promote and sustain patient adherence. The key to unlock the problem of hypertension control in the community is to promote adherence to prescribed therapy. Combination therapy produces a greater

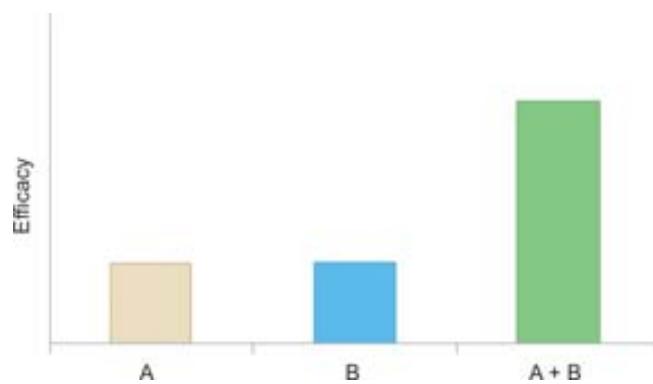

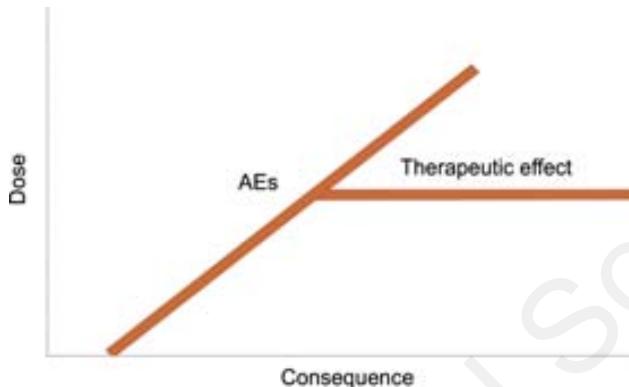

FIG. 2: Synergistic effects of combination therapy on efficacy.

effect on BP reduction while attenuating the side effects of the component drugs.

The latest American and European hypertension guidelines resolutely recommend initial combination therapy (Fig. 4). And it is the right logic. This approach is urgently germane to India which is under the wrath of uncontrolled hypertension and its devastating consequences. It is timely and appropriate for India to accept and welcome the notion of initial combination therapy for effective and prompt BP control. And as stated earlier, FDC or FPC is preferable over separate components to secure adherence to therapy. Examples of rational combinations are illustrated in boxes 1 and 2.

AEs, adverse effects.

FIG. 3: Monotherapy has a ceiling effect on blood pressure reduction.

Dual or triple combination therapy: new guideline

ARB, angiotensin receptor blocker; ACEIs, angiotensin-converting enzyme inhibitors; CCB, calcium channel blocker.

FIG. 4: Dual or triple combination therapy: new guidelines.

BOX 1 Examples of preferred combinations

- LVH: RAAS blocker + CCB
- Albuminuria: RAAS blocker plus other drugs
- Renal dysfunction: RAAS blocker plus other drugs
- CHF: RAAS blocker + diuretic ± CCB ± mineralocorticoid
- Diabetes/metabolic syndrome: RAAS blocker + CCB ± diuretic
- Systolic hypertension: CCB or diuretic or both
- Peripheral artery disease: RAAS blocker + CCB
- CAD: Beta-blocker + RAAS blocker ± CCB
- Cerebrovascular disease: CCB plus other drugs

CCB, calcium channel blocker; CHF, congestive heart failure; LVH, left ventricular hypertrophy; RAAS, renin–angiotensin–aldosterone system; CAD, coronary artery disease.

BOX 2 Acceptable dual drug combinations

- RAAS blocker + CCB
- RAAS blocker + diuretic
- Beta-blocker + diuretic
- CCBs + diuretic
- Beta-blocker + DHP CCB

Unacceptable combination

- ACEI + ARB

Acceptable triple drug combination

- Any nonduplicating combination from dual-drug choices
- Preferable → RAAS blocker + DHP CCB + Diuretic

ARB, angiotensin receptor blocker; ACEIs, angiotensin converting enzyme inhibitors; CCB, calcium channel blocker; DHP, dihydropyridine; RAAS, renin–angiotensin–aldosterone system.

The current platform for therapeutic discourse is not which monotherapy for hypertension but which combination? The elements of combination, to some extent, are governed by so-called “compelling” indications such as CAD, CHF, diabetes, CKD, etc. The combination therapy is also a foolproof concept that it eliminates factors which were previously considered such as age, racial background, salt-sensitivity volume, and comorbidities in the choice of initial monotherapy. Therefore, combination therapy is both user and patient friendly.

The time has come to treat hypertension with initial combination therapy replacing the traditional monotherapy. A large number of randomized clinical trials (RCTs) have demonstrated the value and necessity of combination therapy in achieving goal BP levels in a timely manner and in providing significant TOP. And admirable meta-analyses have cogently affirmed the clinical benefits of optimal dose combination therapies in the treatment of hypertension and in the prevention of its complications. The evidence to implement initial combination therapy is well grounded and relevant particularly to the Indian scenario in order to improve BP control rates in an enduring fashion.

Are ACE inhibitor and ARB Equal in Hypertension?

SS Chatterjee, Arka Chatterjee

INTRODUCTION

The era of renin-angiotensin system (RAS) blockade began with the introduction of the first angiotensin-converting enzyme (ACE) inhibitor captopril in 1971.¹ Since then the class of drug has rapidly become a staple for a host of cardiovascular disease (CVD) states. Losartan, the first angiotensin receptor blocker (ARB), became available in 1995.² Both these classes of drugs are used for similar indications; however, ARBs are generally considered alternatives for ACE inhibitors in case of drug intolerance. We examine the relevant data supporting the use of these agents for hypertension and in hypertension with compelling indications.

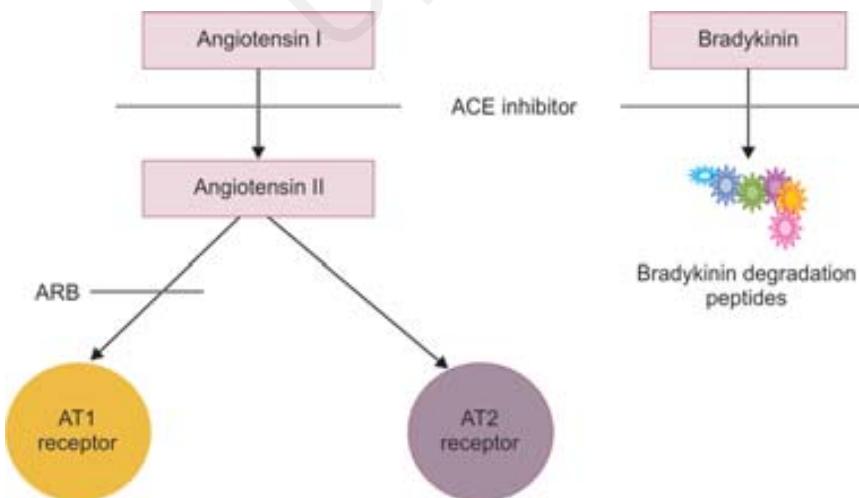

MECHANISM OF ACTION

Both ACE inhibitors and ARBs have a similar mechanism of action, albeit affecting the RAS at different levels (Fig. 1). ACE inhibitors stop the conversion of angiotensin I to angiotensin II, thus reducing the effects of activated

angiotensin II type 1 receptors. These varied effects include vasoconstriction, sodium or water retention, sympathetic activation, etc. Also, ACE inhibition retards the breakdown of bradykinin, thus increasing vasodilation. However, the adverse effects of ACE inhibitors are also secondary to increased bradykinin, i.e., cough, angioedema, etc. ACE inhibition also reduces the angiotensin II type 2 receptor activation which has also been postulated to increase vasodilatory effects. On the other hand, ARB agents specifically block activation of type 1 receptors which thus precludes the additional effects of ACE inhibitors on type 2 receptors and bradykinin.

EFFICACY IN REDUCING BLOOD PRESSURE

Multiple aggregated studies have tried to answer the question of variability in different agents for ACE inhibitors and ARBs and whether there is an incremental reduction in

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker.

FIG. 1: ACE inhibitors and ARBs affect the RAS at different levels.

blood pressure (BP) for one over the other. Pooling 12,954 patients from 92 double blind randomized trials, Heran et al. concluded that the trough BP reduction was $-8/-5$ mm Hg for both ACE inhibitors.³ The same trough BP reduction was found in a pooled analysis of 13,451 patients from 46 trials.⁴ Using ambulatory BP as an outcome, the reduction of BP with ACE inhibitors and ARBs has been estimated to be $-12.9/-7.7$ mm Hg and $-13.3/-7.8$ mm Hg, respectively.⁵ However, newer ARBs may produce greater BP reduction than ACE inhibitors. In a randomized study of 884 patients, azilsartan 40 and 80 mg doses produced higher reduction in trough BP (20.6 ± 0.95 and 21.2 ± 0.95 mm Hg) as compared to 10 mg dose of ramipril (12.2 ± 0.95 mm Hg).⁶ Olmesartan has also been shown to be more efficacious than perindopril whether it is used for monotherapy or in combination with amlodipine.^{7,8}

EFFICACY FOR SURROGATE CLINICAL OUTCOMES

The goal of treating hypertension is in preventing cardiovascular (CV) events and other target organ pathology. Thus, it is more important to see how these two different RAS blockers fare specifically in terms of prevention of deleterious events.

Overall Mortality

There are no dedicated head-to-head trials comparing ACE inhibitors and ARBs in hypertensive patients without concomitant CVD or other comorbidities. In individual trials investigating patients at higher risk of CVD outcomes (e.g., HOPE), ACE inhibitors (enalapril) showed mortality reduction but it should be noted that less than 50% patients were truly hypertensive.⁹ Vark et al. performed a large meta-analysis which only included trials where the sample population comprised at least two-thirds hypertensive patients being randomized to RAS blockade versus placebo.¹⁰ There was a definite reduction in overall mortality. However, the effect was driven by trials using ACE inhibitors only with no significant reduction seen in the pooled ARB trials. Conflicting results were obtained when the same question was examined in the REACH cohort, in which more than 90% patients were classified as hypertensive. In a propensity matched analysis, ARB use was shown to have better mortality outcome (11.6% vs. 12.6%, $p = 0.005$).¹¹

Prevention of Cardiovascular Events

In the REACH cohort, a composite outcome of CV mortality, myocardial infarction (MI), stroke or other CV hospitalization was lower for patients using ARB as compared to ACE inhibitors.¹¹ However, contradictory results have also been reported, as in a meta-analysis of 108,212 patients by Savarese et al.¹² ACE inhibitors significantly reduced the composite outcome of CV mortality, MI or stroke by a margin of 14.9%. ARB use, although still significantly protective, had a lower reduction of 7%. While ACE inhibitors were found to be protective for MI, stroke and new onset heart failure

(HF) individually also, ARBs were not found to be protective for MI or HF. A more recent network meta-analysis again showed equivalence for both classes with no difference in the risk reduction for CV mortality, MI or stroke.¹³ In patients who have had a stroke, ARB does not appear to be protective against a second stroke as shown by the results of the PROFESSION study.¹⁴

Prevention of Nephropathy

No difference in proteinuria or albuminuria was noted in a meta-analysis including 17 studies looking into this question.¹⁵ Telmisartan and ramipril were found to have similar effects on the trajectories of renal function in patients included in the ONTARGET study. There was no difference in a composite outcome comprising dialysis, a doubling in serum creatinine and death. However, ramipril seemed to protect against worsening of glomerular filtration rate slightly better than telmisartan. The question of nephropathy or albuminuria becomes even more important for diabetic patients and in this group too, there does not seem to be a difference in efficacy of both classes. In a large network meta-analysis, Catala-Lopez et al. have shown comparable CV and renal outcomes.¹⁶

EFFECTS IN SELECT PATIENT SUBSETS

Patients with hypertension frequently have comorbidities which dictate therapy choices. Thus, it is useful to review the evidence for ACE or ARB use in these select patient subsets with compelling indications.

Patients with Coronary Artery Disease

There is no sizeable data suggesting a major benefit for either class in patients with CAD but no HF or left ventricular dysfunction. In fact, in the CAMELOT trial, outcomes with enalapril were poorer than those with amlodipine. However, there is a wealth of data in head-to-head trials comparing patients at higher risk of CV events with similar reduction in MI for both ACE and ARB which can be extrapolated to this population also.¹⁷

Patients with Heart Failure

The HF population is the most well studied with respect to actions of RAS blockade. Both the classes have been proven to be beneficial in reducing overall mortality in this patient subset. The CONSENSUS study established this finding for ACE inhibitors with enalapril while the CHARM study with candesartan was definitive in this respect for ARBs.¹⁸⁻²⁰ While enalapril produced a 31% 1-year mortality reduction in NYHA class IV HF patients, candesartan either added to enalapril or on its own also reduced mortality in similar patients. Along with mortality reduction, enalapril and candesartan also appeared to reduce recurrent admissions in these patients.^{18,21} Based on the results of SAVE, AIR, and TRACE studies, the protective effect of ACE inhibitors in patients who have HF after a MI is well established.²² Interestingly, in a network meta-analysis spanning multiple decades, Burnett

et al. suggest ACE inhibitors but not ARBs provide mortality benefit in these patients as monotherapy and incremental benefit when used in combination with beta blockers or mineralocorticoid receptor antagonists.²³ While this analysis was weighted toward ACE inhibitors just because of the increased time period of follow up for the same compared to ARB, some authors do believe that there is an incremental benefit with ACE inhibitors likely attributable to the increase in other vasoactive mediators and AT2 receptor activation.²⁴

ADVERSE EFFECTS AND PATIENT COMPLIANCE

Both classes of drugs are reasonably well tolerated. The most common adverse effect in patients taking ACE inhibitors is dry cough.²⁵ ACE inhibitors have been estimated to produce cough in 11.48% patients in a pooled analysis.²⁶ Out of these, just under a quarter end up stopping ACE inhibitors. Angioedema is rarer, happening in about 0.3–0.7% patients.^{27,28} About a fifth of angioedema instances may lead to fatalities and there is a predilection for more African-American patients to have angioedema.^{29,30} However, in comparison, ARBs are much better tolerated and have remarkably lower discontinuation rates.³¹ In fact, in pooled analyzes, it is suggested that ARBs have lower discontinuation rates than placebo.³²

COST-EFFECTIVENESS

While any analysis for cost-effectiveness is dictated by geographical variations in availability of generic versions of drugs in various markets and many other factors, some analyzes have actually found ARBs to be more efficacious in the long run, especially in diabetic nephropathy patients.³³ Fixed dose combinations incorporating ARBs with other agents may help also with patient compliance and also control patient cost.

CONCLUSION

The only way to differentiate the efficacy of ACE inhibitors and ARBs would be to run head-to-head randomized trials for each population of interest. However, with the wealth of data already available regarding both these classes' efficacy in improving CV outcomes, it is doubtful that a large trial will be formulated soon. There is no good evidence to support choosing one specifically over the other; however, ACE inhibitors are definitely worse when it comes to adverse effects and needing replacement of drug. Angioedema, although very rare, can be fatal in patients taking ACE inhibitors.

Thus, both are still very favorable first-line antihypertensives with the adverse effect profile weighing the scales mildly toward ARB.

Diuretics as Antihypertensive in Elderly

Anunay Gupta, HS Isser

INTRODUCTION

Hypertension is a common problem in elderly (age older than 60–65 years). Hypertension increases with age, affecting approximately 66% of the elderly population (aged ≥65 years). As life expectancy increases number of elderly needing antihypertensive medications is expected to increase. Elderly patients have a higher absolute risk of cardiovascular (CV) events, compared to younger individuals with the same risk factor profile. A number of placebo-controlled clinical trials have demonstrated that blood pressure (BP) control reduces CV events in elderly patients, even in those aged older than 80 years. Five-year number needed to treat (NNT) estimates indicate that fewer than 100 older people needed to be treated to prevent one event. Despite advances in medical care, hypertension control rates remain low, especially in the elderly population. In India, prevalence of hypertension was 42.7% in elderly (aged more than 60 years) population, was significantly higher in age group more than 80 years (61%) and females (48%).¹ Elderly individuals usually have isolated systolic hypertension (ISH) with normal diastolic pressures.² Most of the recent guidelines suggest that the amount of BP reduction is major determinant of reduction in CV risk in both younger and older patients rather the choice of antihypertensive drug. Even though antihypertensive drugs choice is well-guided today, BP target is still a subject of debate in view of 2017 guidelines of hypertension.³ This chapter reviews diuretics as antihypertensive agent in elderly patients.

ISSUES WITH ELDERLY POPULATION

Elderly patients are more likely to have ISH—systolic blood pressure (SBP) more than or equal to 140 mm Hg; diastolic blood pressure (DBP) less than 90 mm Hg, more than 65% of hypertensive patients aged older than or equal to 60 years and more than 90% of those aged older than 70 years have ISH.² There is a linear increase in both SBP and

DBP up to sixth decade of life after which SBP continues to increase while there is a gradual decline in DBP.⁴ Various pathophysiological mechanisms associated with ISH are increase in arterial stiffness from arteriosclerosis, endothelial dysfunction, elastin calcifications, increased salt sensitivity and increased sympathetic activity.⁴ Aggressive treatment of ISH may also lead to fall in DBP and DBP less than 70 mm Hg especially less than 60 mm Hg have been shown to be associated with increased risk of stroke and coronary heart disease (CHD) in a *post hoc* analysis of SHEP (Systolic Hypertension in the Elderly Program) trial.⁵ Similarly in recently published analysis of landmark SPRINT (Systolic Blood Pressure Intervention Trial) trial it was seen that in patients with isolated hypertension when diastolic pressure fell to less than 55 mmHg, the hazards of increased CV events were at least 25% higher relative to 70 mmHg.⁶ Both thiazide-like diuretics and calcium channel blockers (CCBs) are considered as first-line drugs in ISH. β-blockers should be avoided in this population. Elderly patients frequently have associated comorbidities such as diabetes mellitus, chronic kidney disease, cerebrovascular accident, and parkinsonism which influence the choice of antihypertensive drugs. Elderly population are at risk of postural hypotension leading to falls and injuries. These characteristics must be considered while choosing antihypertensive drugs for this population.

BLOOD PRESSURE GOALS AND TARGETS

Hypertension is one of the primary risk factors for myocardial infarction (MI), stroke, heart failure (HF), renal failure, and most other adverse vascular events in the older population. Eighth Joint National Committee (JNC 8) published in 2014 recommended that in population aged 60 years or older, initiate treatment to lower BP at SBP of 150 mm Hg or higher or DBP of 90 mm Hg or higher and treat to a goal SBP <150 mm Hg and goal DBP <90 mm Hg.⁷ These pressure goals are not supported by all other guidelines and societies. According

to European Society of Hypertension (ESH)/European Society of Cardiology (ESC) 2013 guidelines,⁸ the minority report from the 2013 JNC 8 guidelines,⁹ the 2013 Canadian Hypertension Education Program guidelines,¹⁰ the 2011 UK guidelines,¹¹ the 2014 American Society of Hypertension (ASH)/International Society of Hypertension guidelines,¹² a BP below 140/90 mm Hg has been recommended in elderly between 60 and 79 years of age. In adults aged 80 years and older, a BP below 150/90 mm Hg has been recommended by these guidelines, with a target goal of less than 140/90 mm Hg considered in those with diabetes mellitus or chronic kidney disease. However, 2017 guidelines for high BP in adults have redefined hypertension as SBP more than 130 mm Hg and diastolic BP more than 80 mm Hg.³

CLINICAL TRIALS IN ELDERLY POPULATION

The Medical Research Council (MRC) trial randomized 4,396 patients aged 65–74 to atenolol 50 mg daily; hydrochlorothiazide 25 mg or 50 mg plus amiloride 2.5 mg or 5 mg daily. Mean follow-up was 5.8 years. Primary outcome was strokes, coronary events, and deaths from all causes. After adjusting for baseline characteristics the diuretic group had significantly reduced risks of stroke [31% (3–51%) p = 0.04], coronary events [44% (21–60%), p = 0.0009], and all cardiovascular CV events [35% (17–49%), p = 0.0005] compared with the placebo group. The β-blocker group showed no significant reductions in these endpoints. The reduction in strokes was seen predominantly in nonsmokers taking the diuretics. Thus, in the MRC trial in elderly patients hydrochlorothiazide and amiloride reduced the risk of stroke, whereas β-blockers failed to reduce the risk of stroke despite a similar lowering of BP.¹³

The SHEP trial was another trial which supported use of diuretics in this population.¹⁴ Total 4,736 persons aged 60 years and above with average SBP of 170 mm Hg and average DBP of 77 mm Hg were randomized to chlorthalidone (12.5–25 mg/day) versus placebo, other drugs added were atenolol (25–50 mg/day) with average follow-up of 4.5 years. Stroke was the primary endpoint. Significant improvement in BP was accomplished in the treatment group compared with the group receiving placebo (SBP, 143 mm Hg vs. 155 mm Hg, respectively), leading to significant reduction in stroke (36%), coronary artery disease (CAD; 27%), chronic heart failure (CHF; 55%, 81% in those with previous MI). In a *post hoc* analysis of SHEP trial, it was seen that decrease in DBP of more than 5 mm Hg was associated with increased risk for stroke [relative risk (RR): 1.14; 95% confidence interval (CI): 1.05–1.22], for CHD (RR: 1.08; 95% CI: 1.00–1.16), and for cardiovascular disease (CVD) (RR: 1.11; 95% CI: 1.05–1.16).⁵

The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) trial included 42,418 patients (mean age, 67 years) with hypertension and at least one other risk factor for CAD.¹⁵ Total 57.5% of the participants were aged more than 65 years; therefore, this study is considered a study in the elderly. The patients

were randomized to a treatment group with a thiazide-type diuretic (chlorthalidone 12.5–25 mg/day), a CCB (amlodipine 2.5–10 mg/day), an ACE-inhibitor (lisinopril 10–40 mg/day), or an alpha-blocker (doxazosin). The doxazosin component of the study was terminated early because of a 25% greater incidence of combined CVD events compared with the chlorthalidone arm. At 5 years of follow-up 68.2% patients in chlorthalidone arm 66.3% patients in amlodipine arm and 61.2% patients in lisinopril arm have achieved BP goal of less than 140/90 mm Hg. There were no differences in the primary outcome of fatal or nonfatal coronary events and no mortality difference between the CCB, angiotensin-converting enzyme (ACE) inhibitor, and diuretic groups. The diuretic treatment group had lower HF rates compared with the CCB group [relative risk (RR): 1.33; 95% confidence interval (CI): 1.18–1.49] and lower combined CV outcomes (RR: 1.13; 95% CI: 1.06–1.20), strokes (6.3% vs. 5.6%; RR: 1.15; 95% CI: 1.02–1.30) and HF (RR: 1.20; 95% CI: 1.09–1.34) compared with the ACE-inhibitor group. This trial established that chlorthalidone was superior to doxazosin, lisinopril, and amlodipine in preventing HF in a subanalysis of ALLHAT, chlorthalidone was superior to other agents in preventing HF in patients with the metabolic syndrome and also in patients with diabetes. Even after adjustment for BP, the difference in risk of stroke and HF between treatment arms was statistically significant.

The Hypertension in the Very Elderly Trial (HYVET) trial was published in 2008 and recruited more than 3,800 elderly patients (patients aged ≥80 years; mean, 83.6 years) with systolic hypertension, diastolic hypertension, or ISH. Patients were randomly assigned to take indapamide (thiazide-like diuretics) (sustained release, 1.5 mg) or matching placebo. The ACE-inhibitor perindopril (2 mg or 4 mg), or matching placebo, was added if necessary to achieve the target BP of 150/80 mm Hg. The primary end point of the trial was fatal or nonfatal stroke. Significant reduction in mean BP was achieved in the treatment group (143/78 mm Hg vs. 158/84 mm Hg) at 2 years. The target BP was reached in 19.9% of patients in the placebo group and in 48.0% in the active-treatment group (p <0.001). At 2 years, 25.8%, 23.9%, and 49.5% of patients in the active-treatment group were receiving indapamide alone, indapamide and perindopril (2 mg), and indapamide and perindopril (4 mg), respectively. The study was stopped early as a result of significant reductions in fatal stroke (6.5% in the active group vs. 10.7% in the placebo group) and all-cause mortality (47.2% in the active group, 59.6% in the placebo group). This trial showed that diuretics indapamide use in “Hypertension in the Very Elderly”, reduced the rate of HF by 64%.¹⁶

The only one exception was the ANBP2 study (Second Australian National Blood Pressure Study), a prospective, randomized, open-label study with blinded assessment of endpoints in 6,083 subjects with hypertension who were 65–84 years of age and received health care at 1,594 family practices. Subjects were followed for a median of 4.1 years, and the total numbers of cardiovascular events in the two treatment groups were compared. Treatment with an ACE inhibitor in older subjects was found to be better than treatment with

diuretic agents, despite similar reductions of BP.¹⁷ There were 695 CV events or deaths from any cause in the ACE-inhibitor group (56.1 per 1,000 patient-years) and 736 CV events or deaths from any cause in the diuretic group (59.8 per 1,000 patient-years; the HR for a CV event or death with ACE-inhibitor treatment was 0.89 (95% confidence interval, 0.79–1.00); p = 0.05). Among male subjects, the HR was 0.83 (95% CI, 0.71–0.97; p = 0.02); among female subjects, the hazard ratio was 1.00 (95% CI, 0.83–1.21; p = 0.98); the p value for the interaction between sex and treatment-group assignment was 0.15. The rates of nonfatal CV events and MIs decreased with ACE-inhibitor treatment, whereas a similar number of strokes occurred in each group (although there were more fatal strokes in the ACE-inhibitor group). But design of the ANBP2 study was less rigorous than other studies, it was a prospective, randomized, open-label, blinded-endpoint (PROBE) study that is prone to bias. In the ANBP2 study, 83% of the participants received their assigned treatment, only 58% of participants were randomly assigned to an ACE inhibitor, and 62% of those assigned to a diuretic were still receiving assigned treatment at the end of the study.¹⁷

DIURETICS AS FIRST-LINE ANTIHYPERTENSIVE DRUG

Diuretics have been recommended as first-line antihypertensive agent in elderly according to JNC-7 guidelines.¹⁸ Mechanism attributing to fall of BP initially seen with diuretics is due to the reductions in extracellular fluid and plasma volumes. The persistent antihypertensive effects seen later are due to fall in systemic resistance.

Which Diuretic to be Used?

Among all available diuretics only thiazide diuretics have been evaluated as first-line drug for treatment of hypertension. Chlorthalidone and indapamide (thiazide-like diuretics) are significantly more potent antihypertensive agents than hydrochlorothiazide, (thiazide-type diuretic) at similar dose levels. Chlorthalidone and indapamide have more longer (>24 h) duration of action compared to thiazide which may be responsible for more hypokalemia seen with chlorthalidone.¹⁸ Use of sodium restricted diet along with thiazide diuretics contribute to more BP lowering and reduce the risk of hypokalemia.¹⁹

Thiazide Diuretics: When to Use and When not to Use?

If patient with hypertension and osteoporosis; thiazide-like diuretics have advantages over ACE inhibitors, angiotensin receptor blockers, and CCBs because these drugs stimulate distal tubular reabsorption of calcium, leading to a decrease in urinary calcium excretion. Hence, thiazide diuretics may have a beneficial effect on bone mineral density. In a recently published *post hoc* analysis of the ALLHAT trial the rates of hip or pelvic fractures among patients treated with thiazide-like diuretics, ACE-inhibitors, and CCBs were compared, chlorthalidone had significantly fewer hip or pelvic fractures

as compared with those assigned either lisinopril or amlo-dipine (1.3% vs. 1.7%).²⁰

Thiazides reduce the excretion of calcium as discussed above and uric acid and therefore increase their plasma levels. They should be avoided in patients with gout.²¹ They increase potassium and magnesium excretion, leading to hypokalemia and hypomagnesemia. Diuretics have been implicated to increase blood glucose levels, which has been shown to be related to hypokalemia.²² It was seen in SHEP trial that each 0.5 mEq/L decrease in serum potassium during the 1st year of treatment was associated with a 45% higher adjusted diabetes risk.²³ Thiazide-induced diabetes can be prevented by potassium supplementation or combination with ACE-inhibitor or potassium-sparing diuretics.²⁴

Diuretics cause increased cholesterol and triglyceride levels along rise in low-density lipoprotein cholesterol. The rise in cholesterol was dose dependent and greater in blacks. A reduction in the high-density lipoprotein cholesterol levels was seen in patients with diabetes.²⁵ Whether these effects in lipid profile will have adverse effect is not well-known due to short-term follow-up of most of the trials.

CONCLUSION

Thiazide-type diuretics are inexpensive safe and effective antihypertensives in elderly. Thiazide-like diuretics are as effective as other antihypertensive drugs in elderly and very elderly population as supported by multiple large randomized control trials. British Hypertension Society recommended that diuretics and CCBs should be first-line drugs in hypertensive patients aged more than 55 years. Thiazide-type diuretics prevent HF and stroke in hypertensive patients, and may be superior to other agents in preventing new-onset HF. Diuretics reduced the risk of CHD and all-cause mortality. Chlorthalidone and indapamide should be preferred over thiazide. The benefit of diuretics as first-line antihypertensive drugs should be weighed against side effects such as risk of new onset diabetes, electrolyte imbalance and derangement in lipid profile.

Treating Resistant Hypertension: Stepwise Approach

Binjo Vazhappilly, Julian Thottan, Mohanan Padinhare

INTRODUCTION

Resistant hypertension (rHTN) is defined as blood pressure (BP) that remained above goal despite the concurrent use of three antihypertensive agents of different classes including a diuretic at optimal dosages and whose BP is controlled with four or more medications.¹ Prevalence of rHTN varies from 2 to 40% depending on how rHTN was defined and they generally do not incorporate detailed information regarding medication dosing, treatment adherence, appropriate use of diuretics, and other clinical factors that may affect BP.

STEPWISE EVALUATION OF RESISTANT HYPERTENSION

Resistant hypertension is a diagnosis by exclusion. First, the accuracy of BP measurements using optimal technique needs to be established. Errors should be minimized by avoiding common pitfalls like improper patient positioning, inappropriate cuff size, poor timing of measurements, and equipment-related errors.

Out-of-Office Blood Pressure Monitoring

Since the prevalence of white coat hypertension (WCH) in patients with suspected rHTN based on office BP measurements is very high, 24 hours ambulatory blood pressure monitoring (ABPM) should be part of the routine work-up. The importance of 24-hour ABPM to rule out WCH in the setting of suspected rHTN is demonstrated by de la Sierra et al.² This study showed roughly one-third of patients labeled as rHTN by office BP measurement had WCH. Clinical signs suggestive of WCH are high office BP values without signs of target organ damage and the presence of symptoms associated with hypotension (i.e., dizziness, fatigue, and blurring) that may be related to antihypertensive overtreatment.

When ABPM is not feasible, home BP monitoring may be substituted and has been shown to correlate closely with daytime ABPM readings although it will not provide

information about nocturnal patterns. Automated office measurements can reduce the white coat effect but will miss masked hypertension. Thus, even in the setting of goal office measurements, it might be useful to pursue ABPM when disproportionate target organ damage is present (Flowchart 1).

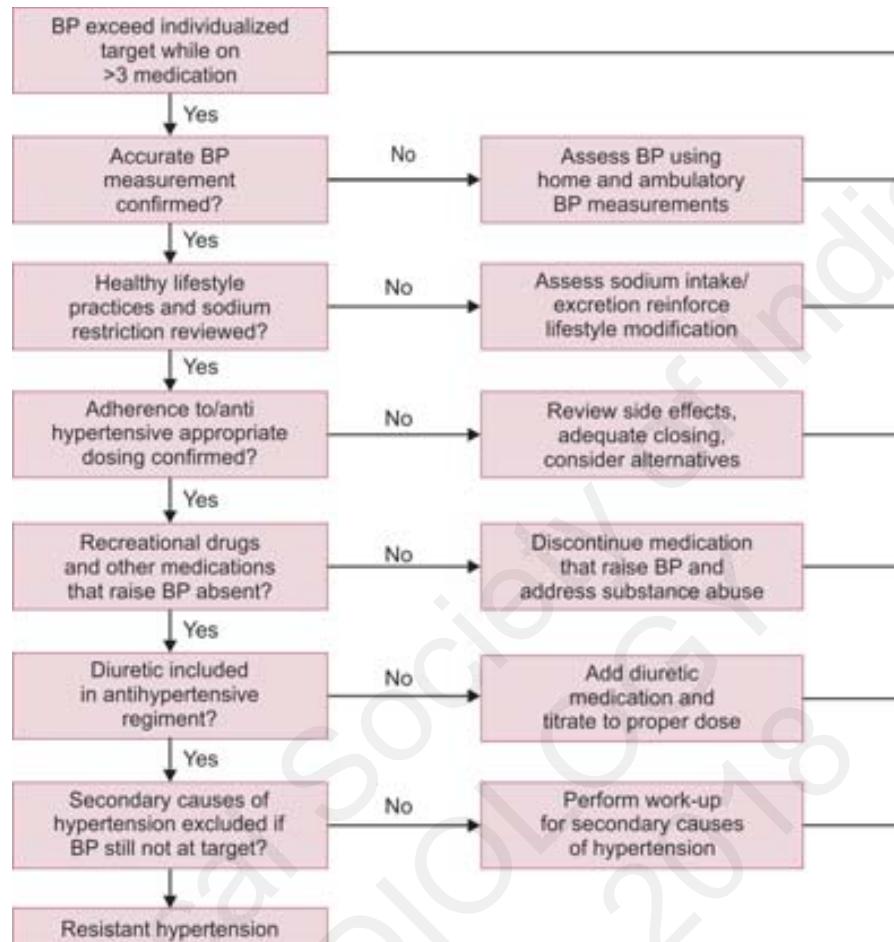

Rule Out Secondary Hypertension

The absence of a night-time drop (dipping of >10% relative to the daytime BP) or any increase of BP during night time ("reverse nocturnal dipping") is often associated with secondary hypertension.³ The most common causes of secondary hypertension are obstructive sleep apnea (OSA), renal parenchymal and/or vascular disease, and primary aldosteronism (PA).

Nondipping or reverse dipping associated with a history of snoring, daytime sleepiness, and morning headache should prompt to suspect OSA. Screening for OSA can easily be done by assessing daytime sleepiness using a questionnaire (Epworth screening questionnaire) and by sleep study to assess apnea-hypopnea index.

Screening for renal parenchymal disease should be performed by urine analysis, serum creatinine concentration, and renal ultrasound if required. Renal artery stenosis (RAS) should be suspected in patients with abrupt progression of the severity of hypertension or recent renal function deterioration [particularly after therapy with angiotensin-converting enzyme (ACE)-inhibitors or angiotensin-receptor blockers (ARB)] or patients presenting with flash pulmonary edema (i.e., Pickering syndrome).

Clinical signs of PA are not very specific. Hyperaldosteronism is classically associated with metabolic alkalosis and hypokalemia. Hypokalemia is present in only approximately 40% of the patients with confirmed PA. Screening can be done by plasma aldosterone-renin ratio (ARR) after adequately preparing the patient (Table 1).

FLOWCHART 1: Systematic approach to patients with suspected resistant hypertension.

Evaluate the Presence of Vascular Remodeling

In patients with true rHTN vascular remodeling is likely to be present. The gold standard method to noninvasively assess arterial stiffness is the measurement of carotid-femoral pulse wave velocity (PWV). Alternatively, pulse pressure (PP) is a valid and widely available proxy of vascular stiffness.⁴ PWV more than 10 m/s,⁵ 24 hours PP more than or equal to 63 mm Hg or central PP more than 55 mm Hg suggests vascular remodeling.⁶ The absence of increased arterial stiffness suggests the presence of pseudoresistance, and we should search for poor treatment adherence, lifestyle factors known to increase arterial BP, and drugs interfering with the antihypertensive treatment.

Poor Treatment Adherence

Nonadherence deserves special attention to identify and address adherence barriers effectively. Around 50% of the patients with apparent resistance were not taking their medication as prescribed, when adherence is assessed by urine analysis.⁷

In another study among patients with rHTN, 10% were completely nonadherent, and 52% were partially or completely nonadherent.⁸ Several strategies have been proposed to assess and improve therapy adherence, including the measurement of drug concentrations in serum or urine, the use of pillboxes recording every opening event, and specific counseling programs. Performing 24 hours ABPM immediately after the patient has taken his or her antihypertensive drugs in the presence of a nurse or physician is an easy way to assess the effect of the prescribed medication.

Check Lifestyle Factors

Obesity, excessive salt intake, and alcohol consumption are frequently associated with rHTN. In hypertensive population, weight loss is associated with modest BP reduction (i.e., systolic/diastolic BP reduction of 2/1 mm Hg per kg of body weight loss). Excessive sodium consumption (>6 g sodium chloride/day) is a major contributor to treatment resistance, particularly when associated with increased arterial stiffness. The BP-lowering effect of decreased sodium consumption is

CTA, computed tomography angiogram; MRA, magnetic resonance angiography; BP, blood pressure.

particularly marked in “salt-sensitive” patients with HT (i.e., Africans and East Asians, obese, and elderly of all ethnicities).⁹

Acute alcohol intake increases BP by centrally mediated sympathetic activation. Chronic heavy alcohol intake (>60 g/day ethanol) increases BP even in normotensive subjects. Interventions targeting simultaneously several lifestyle modifications (i.e., weight loss, lower salt, and alcohol consumption) are more effective than interventions targeting each of these factors sequentially.

Drugs and Other Medications

Several substances and drugs can induce arterial hypertension or interfere with antihypertensive medications. Common that can raise BP is given in box 1.

BOX 1 Substances that can raise blood pressure

- Nonsteroidal anti-inflammatory drugs (NSAIDs)
- Anabolic steroids
- Antidepressants:
 - Monoamine oxidase inhibitors
 - Selective serotonin reuptake inhibitor
 - Selective norepinephrine uptake inhibitors
- Calcineurin inhibitors:
 - Cyclosporin
 - Tacrolimus
- Glucocorticoids
- Erythropoietin
- Contraceptives:
 - Estrogen containing
 - Progesterone containing
- Sympathomimetics
 - Vascular endothelial growth factor (VEGF) inhibitors
 - Tyrosine kinase inhibitors
- Others:
 - Anabolic steroids, caffeine, cocaine, ethanol (in excess)

inhibits the RAAS and the sympathetic nervous system (SNS) activated by “C + D”.¹⁰ RAAS activation is often absent in elderly patients and in patients of African origin.¹¹ In patients with moderate-to-severe impairment of renal function [i.e., glomerular filtration rate (GFR) ≤45 mL/min/1.73 m²], a shift from a thiazide (-like) to a loop diuretic should be considered.

If the patient under “A + C + D” is still hypertensive a clinical evaluation to determine whether sodium and water retention (search for peripheral edema, increased urinary sodium excretion, increased left ventricular (LV) filling pressures, etc.) or sympathetic activation and increased arterial stiffness (increased average heart rate on 24 hours

Treatment Approach for Treatment-resistant Hypertension

Renin-angiotensin-aldosterone system (RAAS) activation plays an important role in the pathophysiology of hypertension. In accordance with guidelines, first step in the treatment of rHTN should be with the combination of A (ACE-inhibitor or ARB) with C [calcium channel blockers (CCB)] plus D (thiazide-like diuretic, i.e., chlorthalidone or indapamide) at the maximal tolerated dosage. This combination acts on different BP regulatory systems in a way that both activated and counter-regulatory mechanisms are inhibited. It promotes natriuresis and vasodilation and “A”

ABPM and increased PWV or PP) predominate. If volume expansion predominates, spironolactone (25–50 mg/day) or eplerenone (50–100 mg/day in the case of gynecomastia with spironolactone) should be added.^{12,13} In the case of increased SNS activity and/or arterial stiffness, an α -blocker (i.e., doxazosin) that may have favorable effects on BP and vascular remodeling should be added.^{14–16} If persistent volume expansion present, add a long-acting loop diuretic (i.e., torasemide) in addition to thiazide. If persistent sympathetic overactivity is suspected, adding a β -blocker with vasodilator properties (i.e., nebivolol which is also NO donor) or a combined α/β -blocker (i.e., carvedilol and labetalol) should be considered.¹⁷ In the case of increased arterial stiffness, aldosterone antagonists have been shown to have favorable effects on BP and vascular remodeling.¹⁸

Device-based Interventions

Attenuation of exaggerated activity of the SNS represents the aim of device-based interventions [i.e., carotid baroreceptor stimulation and renal denervation (RDN)] for the treatment of rHTN. Carotid baroreceptor stimulation decreases central neural sympathetic outflow through electrical activation of this sympathoinhibitory reflexogenic area. RDN decreases sympathetic overactivity by ablation of renal sympatho-excitatory afferents. Carotid baroreceptor stimulation significantly decreases resting heart rate, whereas RDN has no detectable effect on this variable.

Carotid Baroreceptor Stimulation

In humans with rHTN, baroreceptor stimulation has been found to decrease 24-hour ambulatory BP by 10/6 mm Hg at 4-month follow up.¹⁹ Another study showed that unilateral right-sided carotid baroreceptor stimulation may be more effective than left-sided or bilateral stimulation in lowering office BP in patients with rHTN.²⁰ The main disadvantages of this technique are the need for surgical implantation and the lack of data on its effectiveness on cardiovascular (CV) events. The BP-lowering effect of baroreceptor stimulation may be attenuated in rHTN associated with hyperaldosteronism.²¹ It should be considered only after documented failure of adequate drug treatment, and the implantation of the device should be performed by experienced surgeons in selected hypertension centers (class IIb, level C).²²

Catheter-based Renal Denervation

Renal denervation was found to be an effective treatment for rHTN in early trials. However, these results were not confirmed by the Symplicity Hypertension-3 study which failed to show significant BP reduction compared with sham treatment, casting doubts on the efficacy of RDN.^{23,24} SPYRAL HTN-OFF MED trial a multicenter, international trial randomly assigned 80 patients from the United States, Europe, Japan, and Australia who were either drug naïve or had discontinued their antihypertensive medications to either renal denervation (n = 38) or sham control (n = 42). Patients were followed for up to 3 months and the primary endpoint was change in 24-hour blood pressure at the end

of the follow-up period. Drug surveillance was done to ensure patient compliance with absence of antihypertensive medication.

Results showed a significant decrease from baseline to 3 months in office and 24-hour ambulatory blood pressure in the renal denervation group, while no significant changes were noted in the sham control group. Researchers highlighted that the mean difference between the groups favored renal denervation for 3 months change in both office and 24-hour BP. There were no major adverse events reported in either group.

This novel trial²⁵ differs substantially from previous renal denervation trials in terms of the hypertensive population enrolled, the renal denervation technique used, and the absence of concomitant antihypertensive medications. It was postulated that identification of specific subsets of patients who could potentially benefit from RDN, or clinical features that may help to predict outcomes after the procedure, might be of importance.

CONCLUSION

Various steps in identifying and managing rHTN can be concluded as follows:

- Accurate BP measurement by optimal techniques
- Identify individuals with WCH and masked hypertension by out-of-office BP measurement preferably ABPM
- Screen for secondary causes and treat if present
- Confirm guideline-directed medications in optimal doses and its strict adherence
- Check confounding lifestyle factors (obesity, salt intake, and alcohol consumption) and minimize them
- Identify and avoid substances and drugs that interfere with antihypertensive medications
- Add aldosterone antagonist/ α -blocker/ β -blocker with vasodilator properties/combined α - and β -blocker depending on patient's scenario
- Device-based intervention may be beneficial in selected patients.

Secondary Hypertension: When and How to Screen

Anjan Lal Dutta, Soumik Chaudhuri

INTRODUCTION

Essential hypertension is the cause of the vast majority of cases of arterial hypertension. Approximately 5–10% of adults with hypertension have secondary hypertension.¹ Secondary hypertension is defined as increased systemic blood pressure (BP) due to an identifiable cause (Box 1). Secondary forms are less common and screening for them can be expensive and laborious and hence it is not cost-effective to perform complete evaluations for all secondary causes in each and every patient. At the same time, one should be aware of the fact that secondary hypertension

may be “cured” if a correctable cause can be detected in time. Thus, early detection and treatment are important to minimize/prevent irreversible changes in the systemic vasculature which may give rise to persistent hypertension with a poor long-term outcome.^{2,3}

WHO TO SCREEN?

Look for a secondary cause of hypertension while evaluating *all* patients with hypertension.

However, only *test* for secondary hypertension, if indicated based on this comprehensive evaluation.

BOX 1 Causes of secondary hypertension

Renal

- Renovascular hypertension
 - Fibromuscular dysplasia
 - Atheromatous renal artery stenosis
- Other causes
 - Polycystic kidney disease
 - Renal tumors (Wilms tumor, renal cell carcinoma)
 - Renal segmental hypoplasia (Asz-Upmark kidney)

Endocrine

- Adrenal causes
 - Primary hyperaldosteronism (Conn's syndrome)
 - Pheochromocytoma
 - Congenital adrenal hyperplasia (17 α -hydroxylase deficiency, 11 β - hydroxylase deficiency)
 - Glucocorticoid-remediable aldosteronism
- Other endocrine causes
 - Hyperparathyroidism
 - Hyperthyroidism
 - Hypothyroidism
 - Neurogenic hypertension
 - Acromegaly

Other causes

- Obstructive sleep apnea
- Hormonal contraceptives
- Drugs: alcohol, nasal decongestants with adrenergic effects, nonsteroidal anti-inflammatory drugs, monoamine oxidase inhibitors (MAOIs), adrenoreceptor stimulants, buspirone, carbamazepine, bromocriptine, St John's wort
- Neurologic disorders (Binswanger's disease)
- Licorice (when consumed in excessive amounts)
- Scleroderma
- Neurofibromatosis
- Pregnancy
- Heavy alcohol use
- Steroid use
- Nicotine use
- Malformed aorta
- Aortic valve disease
- Coarctation of the aorta
- Atherosclerosis
- Anemia
- Fever
- White coat hypertension
- Perioperative hypertension

General Characteristics Suggestive of Secondary Hypertension (Box 2)

- Age:** The most common causes of hypertension in prepubertal children are renal parenchymal or vascular disease and coarctation of aorta.⁴ Patients in the 2nd, and especially 3rd, decade of life, who are otherwise healthy and without obvious risk factors or strong familial history of hypertension, are prime candidates for secondary form of screening. In the elderly population with coronary artery disease and any other form of atherosclerosis, the presence of severe hypertension can point towards risk factors suggestive of a secondary type like renal artery stenosis (RAS)
- Habitus:** Body habitus can be an important clue in identifying some specific subgroup of patients who present with secondary hypertension. Resistant hypertension in an overweight patient should lead us to look for hypothyroidism, obstructive sleep apnea (OSA)⁵ or Cushing's syndrome
- Atherosclerosis:** Significant RAS ($\geq 50\%$) is present in up to one-third (~30%) of patients who have atherosclerotic disease and hypertension.^{6,7} The following features are suggestive of RAS—deterioration of a previously adequately controlled hypertension, nondipping pattern on ambulatory blood pressure monitoring (ABPM) and a resistant form of hypertension
- Hypertension pattern:** The following group of patients should be screened for a secondary form—significant hypertension at initial presentation ($>180/110$ mm Hg), poorly/inadequately controlled resistant hypertension or hypertensive urgencies or emergencies.⁸ A 10% nighttime drop of BP, as compared to the daytime value (in ABPM), is normal; its absence should arouse suspicion of secondary forms of hypertension such as OSA.^{9,10}

WHAT TO DO BEFORE SCREENING FOR SECONDARY HYPERTENSION?

Rule out the following conditions:

- Pseudohypertension:** Pseudohypertension is defined as cuff diastolic BP at least 15 mm Hg higher than a

BOX 2

Clinical characteristics suggestive of secondary hypertension

- Resistant hypertension (140/90 mm Hg despite three anti-hypertensive drugs including a diuretic)
- Early onset of hypertension (i.e., <30 years) in patients without other risk factors (i.e., family history, obesity, etc.)
- Increased BP in prepubertal children
- Severe hypertension (180/110 mm Hg) or hypertensive emergencies
- Sudden increase of BP in a previously stable patient
- Nondipping or reverse dipping during 24-hour ambulatory BP monitoring
- Presence of target organ damage (i.e., left ventricular hypertrophy, hypertensive retinopathy, etc.)

simultaneously measured intra-arterial BP. It is predominantly found in aged patients and present with persistently high BP but surprisingly do not have corresponding end-organ damage. Their arteries are highly calcified, and hence rigid, requiring increased cuff pressure to compress the artery, resulting in spuriously elevated readings. The Osler's maneuver may help in differentiating this entity but its reproducibility is low.^{11,12}

- Pseudoresistance:** Incorrect methods of measurement of BP (also known as pseudoresistance) can result in falsely increased BP up to 15 mm Hg.¹³ The most common sources of error include choosing a smaller-than-appropriate sized cuff and take the BP immediately after an activity or exertion, without allowing the patient to rest for a minimum of 5 minutes.
- White coat hypertension:** This is a phenomenon in which patients exhibit a BP level above the normal range in a clinical setting, though they do not exhibit it in other settings. It is believed that the phenomenon is due to anxiety experienced during a clinic visit. White coat hypertension is a frequent cause of pseudoresistance with a prevalence of about 20–30%.¹⁴ The 24-hour ABPM is a valuable tool to assess the likelihood of secondary hypertension.
- Poor patient adherence:** Poor patient adherence to therapy is widespread reaching about 40% in patients with newly diagnosed hypertension.¹⁵ This could be due to medication adverse effects, complicated dosing, inadequate patient education or simply the cost of medication. The physician may at times also be the one to blame by failing to optimize therapy to reach target BP control.
- Drug related:** There are a number of medications which may also lead to treatment resistance.¹⁶ The most common are nonsteroidal anti-inflammatory drugs and glucocorticoids. They act via pathways favoring retention of fluid and sodium and can raise systolic BP by 4–5 mm Hg, especially in hypertensive patients.¹⁷ Some drugs increase BP via activation of the sympathetic nervous system and include amphetamines, phenylpropanolamine, cocaine and phenylephrine, among others. Other common drugs that may lead to secondary hypertension include—licorice, oral contraceptive pills, monoamine oxidase inhibitors, cyclosporine A, vascular endothelial growth factor inhibitors, tyrosine kinase inhibitors and alcohol.

CONDITIONS REQUIRING REEVALUATION, AFTER STARTING ANTIHYPERTENSIVE THERAPY

The presence of a few clinical or biochemical responses, after starting antihypertensive therapy, may suggest the presence of secondary hypertension. A reevaluation should be considered if there is:

- Significant deterioration of renal function after initiation of an angiotensin-converting enzyme (ACE) inhibitor (RAS, especially bilateral)*

- Significant hypokalemia with low doses of diuretics (suggestive of mineralocorticoid excess, especially primary aldosteronism).

ROLE OF AMBULATORY 24-HOUR BLOOD PRESSURE MONITORING

Ambulatory BP monitoring is generally regarded as the most accurate method currently to monitor BP.¹⁰ Ambulatory BP should be considered in patients with suspected secondary hypertension as it allows us to evaluate treatment compliance, rule out white coat hypertension and assess for dipping status. Chamber-based BP measurements are primarily targeted to differentiate hypertensive patients from nonhypertensive subjects and hence have diagnostic values, whereas reference values for 24-hour ABPM are based on response-oriented thresholds and are therefore lower than clinical values (Table 1).^{1,18,19} Reverse nocturnal dipping, especially when associated with tachycardia, is suggestive of secondary forms like RAS or OSA.²⁰

ROLE OF ECHOCARDIOGRAPHY IN SECONDARY HYPERTENSION

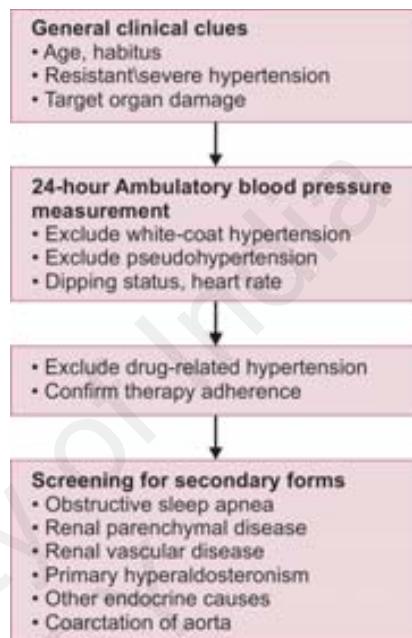

Echocardiography can be a very useful tool in the armory, in patients with secondary hypertension. Left ventricular hypertrophy (LVH) should always be sought for, in hypertensive patients and values incongruous with duration of hypertension may lead us to actively look for secondary causes such as renovascular hypertension or primary aldosteronism.²¹ In patients with OSA, LVH is a quite common and is usually associated with left atrial enlargement and right ventricular hypertrophy.²² In a young hypertensive adult, echocardiography is the investigation of choice for screening coarctation of the aorta.

HOW TO SCREEN?

We shall now discuss how to screen for and diagnose some of the common causes of secondary hypertension (Flowchart 1).

TABLE 1: Thresholds values for office, home and ambulatory blood pressure measurement

Category	Systolic (mm Hg)	Diastolic (mm Hg)
Office and home blood pressure measurements		
Office BP	≥140	≥90
Home BP	≥135	≥85
Ambulatory BP measurements		
24-hour	≥130	≥80
Daytime (or awake)	≥135	≥85
Night-time (or awake)	≥120	≥70

FLOWCHART 1: Screening for secondary hypertension.

Obstructive Sleep Apnea

Obstructive sleep apnea has been recognized as one of the most common causes for secondary hypertension.^{5,23} The prevalence is about 2–30% and increases with age, plateauing at 55–65 years. It is clinically characterized by recurrent episodes of obstructive apneas (complete cessation of breathing) and hypopneas (slow and shallow breathing) and is caused by partial collapse of the upper airways during sleep. The severity of OSA is classified based on the apnea-hypopnea index (AHI)—number of apneas plus hypopneas per hour of sleep.²⁴ Possible pathways to explicate the rise in BP in OSA, include increased sympathetic nervous system activity and modified renin–angiotensin–aldosterone system (RAAS) hemodynamics^{25,26} due to recurrent nocturnal hypoxemia. Moreover, hypoxemia has been associated with systemic endothelial dysfunction^{27,28} even in the absence of traditional cardiovascular risk factors,²⁹ possibly mediated by excessive oxidative stress.^{30,31} Several studies have shown a decrease in nocturnal,³² or in both nocturnal and daytime BP,^{32,33} after successful continuous positive airway pressure therapy of OSA.

Medical History

- Snoring
- Excessive daytime sleepiness (narcolepsy)
- Morning headaches
- Lack of concentration
- Irritability
- Increased frequency of motor vehicle accidents.

Clinical Features

- Narrow upper airway (Large neck, macroglossia)
- 24-hour ABPM (Non-dipper, tachycardia or bradycardia)

- Left ventricular hypertrophy
- Cor pulmonale
- Pulmonary hypertension
- Central obesity
- Pedal edema.

How to Screen?

Screening Questionnaire (e.g., Epworth's) followed by polysomnography.

- AHI 5–15: Mild OSA
- AHI 15–30: Moderate OSA
- AHI more than 30: Severe OSA.

Renal Artery Stenosis

Renal artery stenosis has a bimodal pattern of etiology. In the younger subgroup, i.e., less than 40 years of age, fibromuscular dysplasia of the renal artery is the most common cause. Imaging plays a very important role in diagnosis and suspected patients should be screened with a quick and inexpensive Doppler ultrasound. Renal angiography remains the gold standard for confirmation. As fibromuscular dysplasia is generally present in multiple sites, other vascular beds should also be evaluated.³⁴ In older adults and aged patients, the most common cause of renovascular disease is atherosclerotic disease.³⁴ The prevalence of RAS in a general set of hypertensive patients is anywhere between 1% and 8%^{35,36} but in the presence of generalized atherosclerosis, it can go up to as high as 25–35%.³⁷ The presence of the following features in an adult patient would raise suspicion of RAS:

- Rapid and inappropriate deterioration of renal function with angiotensin receptor blockers (ARB) or ACE inhibitor
- Decompensation in a previously well-controlled smoker or diabetic, hypertensive patient
- Abdominal bruit
- Atherosclerosis (in multiple vascular beds)
- Pickering syndrome (Flash pulmonary edema in the presence of bilateral RAS).^{38,39}

If screening confirms significant RAS, renal angiography with hemodynamic assessment to detect a significant translesional gradient should be considered.⁴⁰ After percutaneous (or surgical) treatment of RAS, as long as BP and renal function (GFR) remain stable and well-controlled, no further examinations are necessary. Otherwise, renal perfusion or vessel patency should be assessed with duplex ultrasonography or magnetic resonance imaging (MRI).

Medical History

- Smoking
- Diabetes mellitus
- Atherosclerotic disease
- Worsening of renal function with ACE inhibitor or ARB
- Pickering syndrome-flash pulmonary edema.

Clinical and Laboratory Features

- 24-hour ABPM (Severe hypertension, reverse nocturnal dipping)
- Coronary artery disease

- Left ventricular hypertrophy
- Flash pulmonary edema
- Impaired renal function
- Secondary hyperaldosteronism
- Abdominal bruits
- Peripheral vascular disease.

How to Screen?

Duplex sonography or computed tomography (CT) scan or MRI as initial screening investigation.

- *No stenosis:* No further investigation
- *Stenosis/ambiguous result:* Renal angiography and hemodynamic assessment.

Is there Really any Use of Screening for Atherosclerotic Renal Artery Stenosis?

Despite there being substantial improvement in imaging techniques over the past decade, doubts still linger whether intervention in atherosclerotic RAS (with angioplasty) actually results in any tangible mortality benefits. There are a number of studies which have compared conservative medical therapy versus revascularization and similar rates of cardiovascular events, renal episodes and death was seen in both these groups.⁴¹ Furthermore, it is difficult to establish a linear cause-effect relationship between atherosclerotic RAS and hypertension, and currently available tests lack enough sensitivity or specificity to truly predict how much of the rise in BP can be attributed to stenosis. Unsurprisingly, the true contribution of RAS to hypertension can only be acknowledged in the postoperative phase, once the BP stabilizes to normal levels (or does not!).⁴² Prolonged hypertension, with poor renal function, and advanced nephrosclerosis is thus a poor candidate to select for revascularization.

There is one specific subgroup known as the Pickering syndrome, and is characterized by recurrent bouts of flash pulmonary edema, in the presence of bilateral RAS.^{38,39} Emergent revascularization can indeed prove to be the difference between life and death in this situation. Nevertheless, most randomized trials have showed very poor-to-insignificant benefits of revascularization in patients of RAS.

However, the advent of catheter-based renal denervation for the management of resistant hypertension has definitely upped the enthusiasm and vigor in this field and more subjects are actively being screened for RAS. Nonetheless, the data at this time is simply not adequate to evaluate the long-term benefits of renal denervation on BP (SYMPLICITY HTN 2 and 3) and more studies are required to confirm whether this novel technique will truly be a game changer or not, in the management of resistant hypertension.⁴²

Primary Hyperaldosteronism

Primary hyperaldosteronism, also referred to as Conn syndrome, is a condition where there is an inappropriately high plasma aldosterone level, which is independent of the

feedback loop of renin–angiotensin system and cannot be suppressed by sodium loading. It is characterized by:

- Hypertension
- Increased aldosterone secretion from the adrenal glands
- Decreased plasma renin activity ((PRA)).

The prevalence of primary hyperaldosteronism is between 1.4% and 23%,⁴³ with a higher prevalence in resistant hypertensives. The common causes for primary aldosteronism are:

- Idiopathic hyperaldosteronism
- Aldosterone-secreting adenoma
- Idiopathic adrenal hyperplasia
- Rarely, glucocorticoid-remediable aldosteronism.

Medical History

- Fatigue
- Muscle weakness
- Polyuria, polydipsia
- Constipation.

Clinical Features

- 24-hour ABPM (Severe hypertension, decreased nocturnal dipping)
- Hypokalemic symptoms
- Left ventricular hypertrophy
- Myocardial fibrosis
- Muscle weakness.

Laboratory Findings

- *Blood:* Aldosterone ↑
 - Renin ↓
 - K⁺ ↓
 - Na⁺ ↓
 - Mg²⁺ ↓
 - Metabolic alkalosis.
- *Urine:* Aldosterone ↑
 - K⁺ ↑
 - Na⁺ ↓
 - Metabolic acidosis.

How to Screen?

Screen for the following three parameters (Table 2):

1. Aldosterone–renin ratio (ARR)

TABLE 2: Aldosterone–renin ratio cut-off values for the diagnosis of primary aldosteronism

Plasma aldosterone concentration (PAC)	Plasma renin activity (PRA)		Direct renin concentration (DRC)	
	ng/ mL h	pmol/ L min	mU/L	ng/L
ng/dL	> 27	> 2.1	> 3.3	> 5.4
pmol/L	>750	> 59	> 90	> 150

Conversion factor: Aldosterone 1 ng/dL → 27.7 pmol/L. Conversion factor PRA 1 ng/mL h → 1 pmol/L min divided by 12.8. Conversion factor: PRA 1 ng/mL h → DRC 1 mU/L divided by 8.2. Conversion factor: PRA 1 ng/mL h → DRC ng/L divided by 5.2.

2. Plasma renin activity
3. Plasma aldosterone concentration (PAC).
 - If PRA ↑, PAC ↑, ARR↑: Consider secondary hyperaldosteronism
 - If PRA ↓, PAC ↓, ARR↓: Consider other causes
 - If PRA↓, PAC ↑, ARR↑: Investigate further by:
 - *Confirmatory tests:* Sodium loading, captopril suppression tests
 - *Imaging:* CT/MRI scanning
 - Adrenal vein sampling for lateralization.

UNCOMMON CAUSES OF SECONDARY HYPERTENSION

Renal Parenchymal Disease

- It has a prevalence of 2–10%⁴
- Most common cause of secondary hypertension in children and also a common cause in adults⁴⁴
- Signs and symptoms:
 - Loss of adequate BP control
 - History of diabetes mellitus
 - History of smoking
 - Generalized atherosclerosis
 - Previous renal failure/nocturia
 - Edema, loss of muscle mass
- Screen with urinalysis (Protein, erythrocytes, leucocytes)
- Measurement of serum creatinine is an initial screening tool
- Diagnosis should be done with renal ultrasound.

Cushing's Syndrome

- Rare syndrome with prevalence of less than 1%.⁴⁵
- Typical age range is 25–45 years; affects women 3–8 times more than men⁴⁶
- Signs and symptoms include:
 - Hypertension is very common (>80%)
 - Obesity
 - Facial plethora
 - Buffalo hump
 - Hirsutism
 - Purple striae on abdomen
- Diagnosis by positive results in at least two of the following tests:
 - 24-hour urinary cortisol (>55 µg/24 h)
 - Low dose dexamethasone suppression test (1.8 µg/dL)
 - Late evening salivary cortisol
- Specificity of these tests is 84–96% in obese patients with positive features.

Thyroid Disorders

- Prevalence of 1–3%⁴⁷
- Both hyper- and hypothyroidism have been associated with arterial hypertension.
- In hypothyroidism, diastolic BP is particularly elevated since low cardiac output is compensated by peripheral vasoconstriction to maintain adequate tissue perfusion

- In contrast, hyperthyroidism is associated with increased cardiac output and predominately systolic BP elevation
- Signs and symptoms:
 - *Hyperthyroidism:* Palpitations, weight loss, heat intolerance, exophthalmos, tachycardia
 - *Hypothyroidism:* Bradycardia, weight gain, fatigue, muscle weakness
- Thyroid-stimulating hormone (TSH) levels are most useful in screening for thyroid disorders.

Pheochromocytoma

- *Prevalence:* 0.2% of hypertensive patients
- The clinical features are due to paroxysmal rises in plasma levels of catecholamines and are characterized by the classical “5 Ps”:⁴⁸
 - Paroxysmal hypertension
 - Perspiration
 - Palpitation
 - Pounding headache
 - Pallor.
- Pheochromocytoma screening is to be considered when one or more of the following parameters are present:
 - Hypertension (resistant) with features of increased adrenergic drive (the “5 Ps”)
 - Adrenal mass with features suggestive of a pheochromocytoma including, but not limited to, size more than 4 cm with hemorrhagic or cystic changes).
 - Family history of pheochromocytoma
 - Presence of genetic syndromes which have a known association with pheochromocytoma (von Hippel-Lindau syndrome, multiple endocrine neoplasia II, von Recklinghausen’s disease (Type 1 neurofibromatosis), familial carotid body tumors).
- Screening tests for pheochromocytoma include:
 - Measurement of plasma free-metanephrine or urinary fractionated metanephrine levels
 - 24-hour catecholamine levels in urine
- If screening is positive, imaging with abdominal/adrenal MRI or CT is indicated
- If abdominal imaging is negative, scintigraphic localization with ¹²³I-metiodobenzylguanidine (MIBG) or additional imaging (i.e., whole body MRI or others) is indicated.

Coarctation of Aorta

- Aortic coarctation is the second most common cause of hypertension in children and young adults
- It is characterized by constriction of the lumen of the aorta usually near the ligamentum arteriosum
- Some of the common symptoms include pounding headaches, claudication of legs, muscle cramps and nose bleeds
- The presence of hypertension, with difficult to palpate femoral pulses, should raise a suspicion of coarctation. Other common findings include posterior ribs notching on a chest X-ray (due to collateral circulation) and systolic murmurs in the precordial area or the back

- The investigation of choice for screening is echocardiography. Other alternatives include MRI or CT scans⁴⁹
- Percutaneous balloon angioplasty is as efficacious as early surgical repair⁵⁰
- As per the latest guidelines,^{51,52} patients with coarctation of aorta should undergo follow-up every 2 years in centers which handle specialized care for congenital heart disease, especially in older subjects. Follow-up should include echocardiography and measurement of BP along with imaging modalities like MRI scanning. Subjects with prolonged hypertension should undergo lifelong follow-up.

WHEN SECONDARY HYPERTENSION MAY PRESENT AS RESISTANT HYPERTENSION

- Some patients, especially middle-aged or elderly ladies, with hyperaldosteronism (*Adrenal hyperplasia, not Conn syndrome*) may not respond to conventional antihypertensive agents. The ARR may or may not be deranged in them and the only clue sometimes may be an unprovoked level of low potassium (~3 mEq/L). These patients tend to respond well to a therapeutic trial of mineralocorticoid receptor antagonists
- Some patients of OSA may not be obese. They have a history of snoring at night and present with increased daytime fatigue as a primary symptom, and not necessarily narcolepsy. The diagnosis of OSA is not readily made in them and they are regarded as resistant hypertension patients
- When an elderly male patient, previously well-controlled on antihypertensive agents, tends to suddenly decompensate, with or without flash pulmonary edema, consider atherosclerotic RAS.

CONCLUSION

Secondary hypertension accounts for a very small subset of hypertensive patients (<10%). It is thus neither practical nor cost-effective to screen for secondary causes in all patients and should only be considered when the index of clinical suspicion is high. On a more ominous note, even with diagnosis and appropriate therapy of the cause of hypertension, BP seldom ever returns to baseline levels. This could hint at either irreversible vascular remodeling occurring before adequate treatment is initiated or the presence of attendant essential hypertension as well.

It is, thus, imperative to diagnose and treat subjects of secondary hypertension in a timely manner and ameliorate reversible causes. This prevents long-term, irreversible changes in the systemic vasculature and decreases the risk of developing persistent hypertension and significant end-organ damage. The initial evaluation of all patients with hypertension should include consideration of the possibility of secondary hypertension but screening and testing for secondary hypertension should be based on the presence of suggestive clinical clues.

Managing Low Diastolic Blood Pressure in Elderly Hypertensive

HK Chopra, AK Pancholia

INTRODUCTION

Prevention of cardiovascular disease (CVD) by reduction of systolic blood pressure (SBP) and diastolic blood pressure (DBP) by antihypertensive drugs is the primary goal. However, several reports, but not all, have shown that, in hypertensive subjects treated with drugs, low DBP is frequently associated with increased mortality.¹ It is very difficult to evaluate this finding because it is difficult in epidemiological studies to assess a J-shaped association with mortality apart from that in humans, the decrease of DBP is related to both the aging process² and the result of drug treatment, making the net drug effect quite difficult to define. Apart from that isolated systolic hypertension (ISH) is difficult to treat and aggressive treatment may lead to excessive lowering of DBP. In subjects more than 50 years of age with advanced renal failure,³ the increased aortic stiffness and low DBP were independent predictors of cardiovascular (CV) risk. DBP is a component of pulse pressure (PP), increased PP is the main hemodynamic consequence of increased aortic stiffness. In a population of 16,913 subjects followed for 13 years,⁴ low DBP alone was a significant predictor of CV and non-CV mortality among persons aged more than 50 years (most >70 years). However, the evaluation of the underlying pathophysiological mechanisms was limited, particularly regarding hemodynamic parameters (Fig. 1).

There are problems related to the new guidelines, as ACC/AHA guideline 2017⁵ has reduced the BP targets further to 130/80 mm Hg in elderly and the use of antihypertensive drugs to reduce SBP to that target may lead to further lowering of DBP and leading to further damage. There are increased chances that by reducing patients' SBP down to 120 mm, which is a target, recommended by recent clinical trials, the DBP falls so low that will lead more harm. According to the recent SPRINT trial,⁶ there is recommendation for the intensive lowering of SBP for some high-risk patients, the physicians should not look at driving down SBP in isolation without considering implications of lowering the DBP.

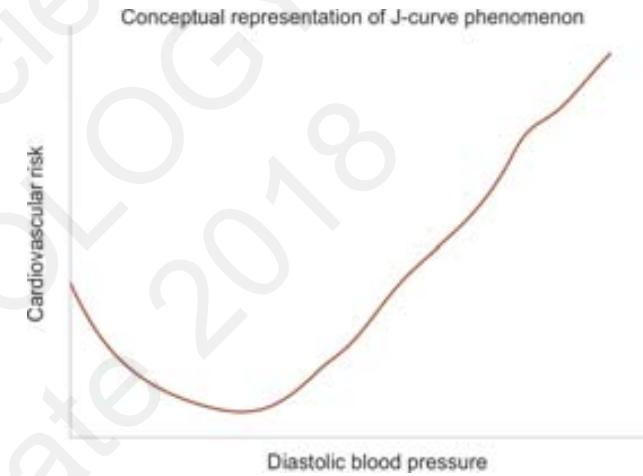

FIG. 1: J-curve concept.

PATHOPHYSIOLOGY OF THE J-CURVE

Four potential pathophysiological mechanisms have been proposed to explain the existence of a J-curve. First, the J-curve is suggestive of more severe underlying chronic illness, which thereby increases mortality.⁷ Second, low DBP could also be a marker of cardiac function. Indeed, in the population of North Karelia,⁴ especially in patients more than 70 years of age, the DBP-mortality relation was considered as a direct main result of cardiac failure. Third, the J-curve reflects increased arterial stiffness suggestive of advance vascular disease and of increased mortality.^{8,9,10} Fourth, low DBP may reduce coronary perfusion during the diastole, especially in subjects with coronary heart disease.¹¹ Even in the absence of evident contractile dysfunction in older subjects, subendocardial myocardial dysfunction may exist.¹² The frail elderly with a high burden of CV disease, even in the absence of evident severe coronary heart disease, in a nonhypertrophied fibrotic heart, oxygen delivery may be impaired in the case of DBP less than 60 mm Hg and further could impair subendocardial contractility.

DIASTOLIC BLOOD PRESSURE CONTROL: HOW LOW IS TOO LOW? CLINICAL TRIAL EVIDENCES

Isolated diastolic hypotension (IDH) is a relatively uncommon complication of antihypertensive therapy that may complicate the therapy in elderly. Elderly persons more often have ISH with a wide PP and normal or sometimes even low diastolic pressure. A large number of studies, notable amongst them the Systolic Hypertension in the Elderly Program (SHEP),¹³ have demonstrated the substantial benefits of treating this form of hypertension, but DBP lowering is an inevitable problem in treating these patients. This reality leads us to some important questions: At what point in the treatment of ISH does the potential harm of low DBP outweigh the benefit of lowering SBP? Is the increased event rate associated with diastolic hypotension a result of treatment, or is it seen even in placebo treated patients? In order to address these issues, investigators reanalyzed the data from the SHEP trial.¹⁴ The researchers observed a higher incidence of CVD events in patients with ISH whose DBP were lowered to less than 70 mm Hg. Furthermore, it was observed that the relative risk of CV events nearly doubled in those patients whose DBP were reduced to below 55 mm Hg. However, there were some problems with the data because, again, the number of patients with DBP less than 55 mm Hg were small and on careful analysis of this study it was observed that even levels of 45 mm Hg were not harmful. These phenomena were noted in the treatment arm but not the placebo arm. It is unclear whether the increase in the event rate associated with low DBP in the treatment arm was a direct consequence of diastolic hypotension or instead due to unmasking of subclinical disease that was manifested by antihypertensive therapy. Therefore, it can be concluded for patients whose DBP levels fall to about 55–60 mm Hg should be carefully monitored and other CV risk factors should be treated more aggressively in this subset of patients.

Based on these results the recommendation is to treat patients with ISH to lower SBP to less than 140 mm Hg, as recommended by the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure⁷ or less than 130 mm by recent ACC/AHA guideline.⁵ However, caution should be exercised in patients whose DBP is around 56–60 mm Hg since at this point the risk may approach benefit. In this subset of patients, it would be prudent to offer aggressive control of other CV risk factors.

LOW DIASTOLIC BLOOD PRESSURE AND ATHEROSCLEROSIS IN ELDERLY SUBJECTS

The Rotterdam Study

This study demonstrated a J-shaped relationship between DBP and the common carotid artery intima-media thickness. The J-shaped curve was most noticeable in patients with relatively high PP. It has been suggested that an increased

intima-media thickness of the common carotid artery may not reflect atherosclerosis and may, at least in part, be a reflection of an adaptive response of the vessel wall to changes in shear and tensile stresses.¹⁵ Still, increased intima-media thickness of the common carotid artery has consistently been associated with elevated CV risk factor levels,^{16,17} prevalent CVD¹⁷ and atherosclerosis elsewhere in the arterial system.^{18–20}

In addition, progression of the common carotid artery intima-media thickness over time has been associated with risk factors for atherosclerosis,²¹ and the increased intima-media thickness has been demonstrated to be a strong predictor of myocardial infarction.²² The Cardiovascular Health Study²³ included 2,189 subjects who were not receiving antihypertensive treatment and were free from CVD. The study demonstrated that for all levels of SBP, there existed a continuous inverse association between DBP and the intima-media thickness of the common carotid artery, with no evidence of a J-shaped relationship. In another study of older individuals with and without ISH,²⁴ it was observed that a DBP below 75 mm Hg was a strong marker for carotid atherosclerotic plaques. This association was limited to the subset of subjects with ISH only. The fall of DBP is because of reduced arterial compliance of the aorta and large arteries, that is, in turn has been associated with atherosclerotic abnormalities.^{25,26} As a consequence, a considerable proportion of older subjects with a relatively low DBP may have existing vascular damage (i.e., increased arterial stiffness and atherosclerosis), in particular, those with a relatively high PP.

ISOLATED DIASTOLIC HYPOTENSION AND INCIDENT HEART FAILURE IN ELDERLY

Recent analysis demonstrates that IDH was an independent risk factor for incident heart failure (HF) among community-dwelling older adults, which was similar in magnitude to the effect of ISH on incident HF in this cohort. It has been demonstrated that the effect of IDH on incident HF was homogeneous across a wide spectrum of older adults, including those with SBP more than 140 mm Hg. Although, diastolic hypotension has been shown to be associated with adverse CV outcomes.²⁵

Isolated diastolic hypotension is also primarily a manifestation of impaired aortic compliance associated with aging, which results in an increased SBP and a reduced DBP, thereby leading to a wide PP.²⁷ As a result of this there can be an increased afterload and myocardial oxygen demand leading in turn to myocardial ischemia and subsequent systolic and diastolic dysfunction.^{28,29} In frail older adults poor outcomes associated with a DBP less than 60 mm Hg have been reported to be independent of aortic compliance and left ventricular ejection fraction.³⁰ Hypertension or uncontrolled SBP is unlikely to explain the association between IDH and incident HF, because the association persisted after excluding those with SBP more than 140 mm Hg. Further studies, are needed to explain the detailed mechanisms by

which IDH is associated with incident HF. Poor outcomes have been observed with a low DBP in patients with hypertension and coronary artery, excessive DBP reduction should be avoided in these patients.³¹ A DBP 60 mm Hg may be a reasonable value to maintain in older adults with ISH. Future hypertension guidelines need to focus on optimal DBP parameters for older adults receiving antihypertensive therapy.

CONCLUSION

Isolated systolic hypertension is very common in elderly population. Some patients with ISH may be treated to the level that uncovers the subclinical disease and some may even be over treated. In older patients who are treated for ISH, a DBP of less than 70 mmHg (and especially <60 mm) recognizes a high-risk group that deserve special monitoring and even more aggressive treatment for other CV risk factors. Recent hypertension guidelines have reduced the target further creating a real challenge for physicians in treating hypertension in elderly. Further studies are needed to determine whether such an intensive drop in DBP and associated increase risk of CVD events could be prevented by more careful titration of antihypertensive therapy while maintaining the SBP control.

Ambulatory Blood Pressure Monitoring—When to Order and How to Interpret?

Rajan J Manjuran, Sultan R Salih

INTRODUCTION

Systemic hypertension (SH) is the most important cardiovascular (CV) risk factor leading to significant morbidity and mortality worldwide.^{1–5} The 2010 Global Burden of Disease Study identified hypertension as the main cause of morbidity accounting for 7% of global disability-adjusted life years.⁶ Classically, hypertension has been measured and evaluated using blood pressure (BP) measurement taken in the office setting—OBP. Although it measures the BP reading at the point in time, this reading cannot account for observer technique, variability of BP and may be falsely elevated or falsely reduced and will not be indicative of the BP throughout the day and night. The BP recorded by a physician is generally higher than that recorded by a nurse.⁷ These shortcomings can be overcome by the use of home BP monitoring (HBPM) and ambulatory BP monitoring (ABPM). The advantages of ABPM far outweigh the convenience and availability of OBP. HBPM has few advantageous over ABPM in that it can detect BP readings over longer period of time and involves the patient with his hypertension management. But ABPM can record nighttime BP and monitor variations in BP over short time, say 24–48 hours. This is a short review of ABPM and the rational for its use in daily practice.

HISTORY AND RELEVANCE OF ABPM

The idea that OBP is not the true BP is as old as 1940s. Ayman and Goldshine, in 1940, instructed 34 of their hypertensive patients to record BP at home, either themselves or by family members.⁸ In all these 34 patients followed up for an average of 21 visits, the BP recorded outside the office was around 50 mm Hg systolic and 25 mm Hg diastolic less than the OBP. The credit for development of ABPM must go to Maurice Sokolow (1911–2002), an internist from San Francisco. He noticed near normal life expectancy in many of his hypertensive patients. In 1962, he and his colleagues developed the first semiautomatic ABPM device. There was a BP cuff that was

manually inflated like in the sphygmomanometer, and the Korotkoff sounds were recorded on a tape recorder. He demonstrated the variability of BP during the day and lack of correlation with OBP. He also demonstrated correlation between ABPM and higher event rate over a 10-year period in patients whose OBP were similar and is considered a landmark trial in hypertension.⁹ Higher ABPM values have been correlated with more subclinical end organ damage.¹⁰ Based on the SYST-EUR study on patients with isolated systolic hypertension,¹¹ the Dublin study,¹² and the PAMELA population study,¹³ Mancia et al.¹⁴ derived a relationship curve which show that the CV events and mortality have a steeper relationship with ABPM than OBP and hence can predict these events earlier. The prediction of events is significant even after adjusting for OBP values.¹⁵ This higher predictability of events can be due to the higher number of readings that are obtained. Thus, it increases the reliability and reproducibility compared to OBP. Currently, the ABPM monitors are of much smaller in size and use more accurate oscillometric technique of recording and digital storage of the readings.

PROCEDURE

Ambulatory BP monitoring is done using recorders that automatically records BP at set intervals for a set duration of time (Fig. 1). These can record BP during routine daily activities of the patient. The present day ABPM use oscillometric method for BP recording. The monitors are small and light weight so that they can be carried around with ease. A BP cuff is wrapped around the patients arm and is connected to the monitor which is worn using a belt around the waist or the shoulder. The cuff inflates and deflates to record BP. The patient is instructed to stop moving, not to talk, to keep his arm still at heart level and not to exert while BP is being recorded. The patients are advised to maintain a diary of events throughout the day which can be correlated with the ABPM readings.

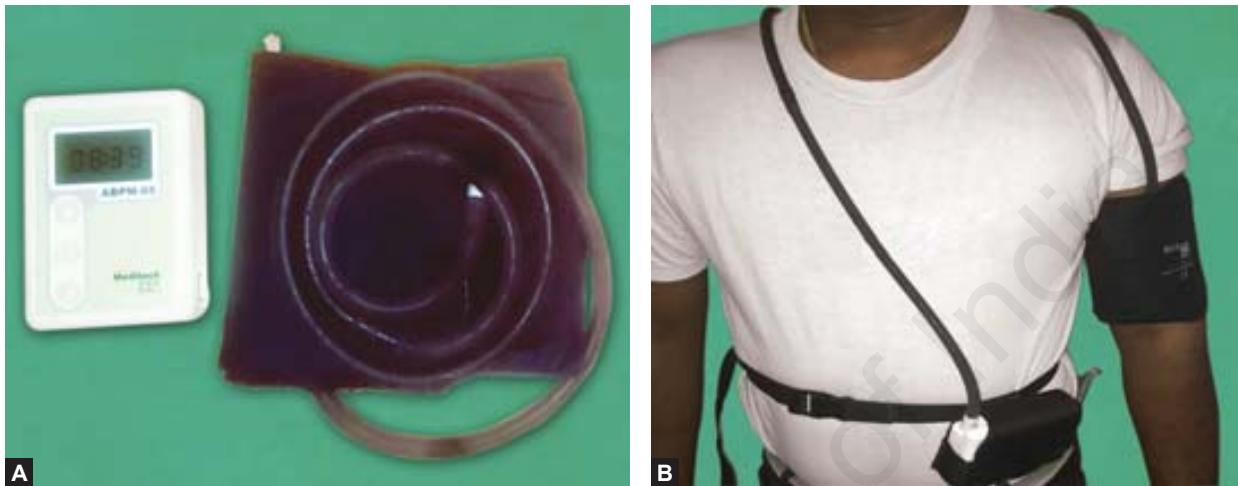

FIG. 1: (A) Ambulatory blood pressure monitor (ABPM) device and cuff; (B) ABPM device connected to the patient.

The monitors are programmed to record BP at intervals of 15–30 minutes during the daytime and 30 minutes to 1 hour during the nighttime. The nighttime is set according to the routine sleep-on and sleep-off time of the patient. These recordings are then downloaded onto computer and analyzed. The BP readings are grouped into 24-hour, daytime and nighttime mean. The sleep-on time and sleep-off time can be adjusted after recording is over. Usually, the nighttime is set from 10 pm to 6 am.

There are a large number of ABPM equipment in the market. These devices have to be validated based on internationally accepted protocols. European Society of Hypertension (ESH) International protocol for the validation of BP measuring devices of 2010 is the commonly used protocol.¹⁶ The device must record BP within 5 mm Hg of a mercury sphygmomanometer reading. The software for analysis is also important and recommendations have been included in the 2013 ESH Position paper on ABPM.¹⁷

For an ABPM recording to be valid it has to have at least 70% of the expected BP recordings. There must be at least 20 valid BP readings in the daytime and 7 valid reading in the nighttime. Not meeting of these criteria can result in ABPM recording not indicating the true mean day and nighttime recordings. In patients, with irregular rhythm like atrial fibrillation, ABPM cannot be relied.

INDICATIONS

The most common indications for ABPM are:

- Suspected white-coat hypertension; treated or untreated
- Suspected masked hypertension; treated or untreated
- Patients with a high risk of future cardiovascular events (even if clinic BP is normal)
- Identifying abnormal 24-hour BP patterns:
 - Dipping status
 - Daytime hypertension
 - Siesta dipping or postprandial hypotension
 - Nocturnal hypertension.

- Assessment of treatment:
 - Assessing 24-hour BP control
 - Identifying true resistant hypertension
 - Assessing morning hypertension and morning BP surge
 - Screening and follow up of obstructive sleep apnea
 - Assessing short-term BP variability
 - Identifying ambulatory hypotension
 - Assessing endocrine hypertension
 - Evaluation of medication-related symptoms.

Definition of Hypertension using ABPM, Normal, and Abnormal Patterns

The 2017 American College of Cardiology/American Heart Association (ACC/AHA) hypertension guidelines and 2013 European Society of Cardiology/European Society of Hypertension (ESC/ESH) guidelines defined hypertension using ABPM as given in Table 1.^{18,19}

The main advantage of ABPM is the nighttime BP recordings. Normally, nighttime BP readings (both systolic and diastolic) are lower than the daytime readings. Based on the nocturnal dip of BP patients can be classified as follows:

- *Normal dippers:* The mean nighttime BP must be 10–20% lower than the average daytime BP to be called normal nocturnal dipping (Figs. 2 and 3). Dippers may also be defined by a mean night or mean day BP ratio less than

TABLE 1: ACC/AHA and ESC/ESH guidelines defined hypertension as follows

	Systolic BP (mm Hg)	Diastolic BP (mm Hg)
24-hour mean	≥130	≥80
Day-time mean (awake time)	≥135	≥85
Nighttime mean (sleep time)	≥120	≥70

ACC/AHA, American College of Cardiology/American Heart Association; ESC/ESH, European Society of Cardiology/European Society of Hypertension.

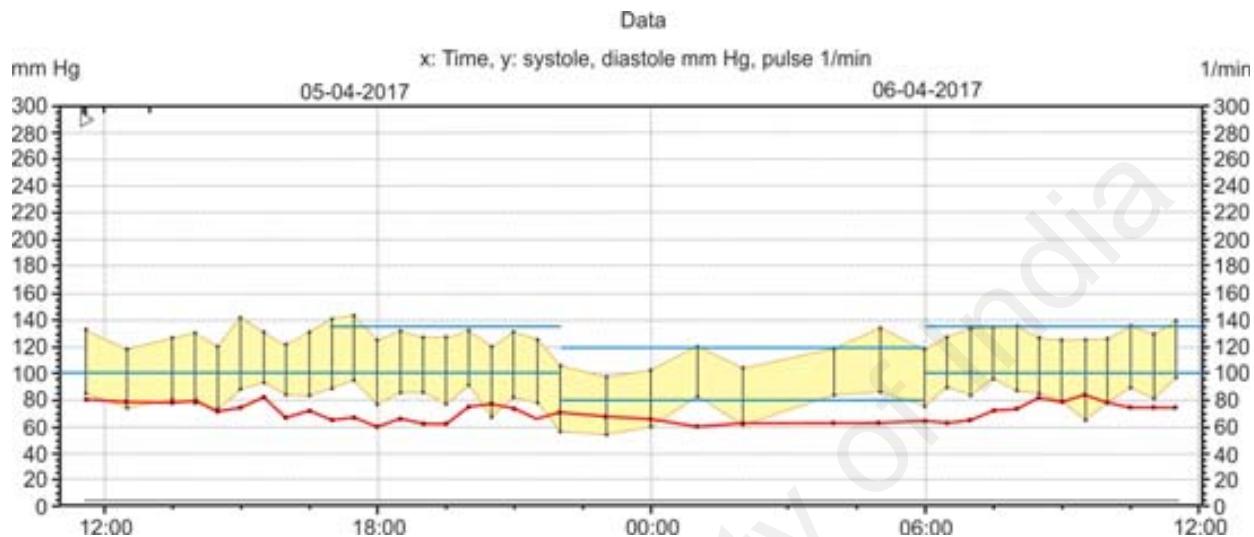

FIG. 2: Normal ambulatory blood pressure monitor record. The 24-hour, daytime and nighttime mean blood pressures are normal with 15% dipping at night.

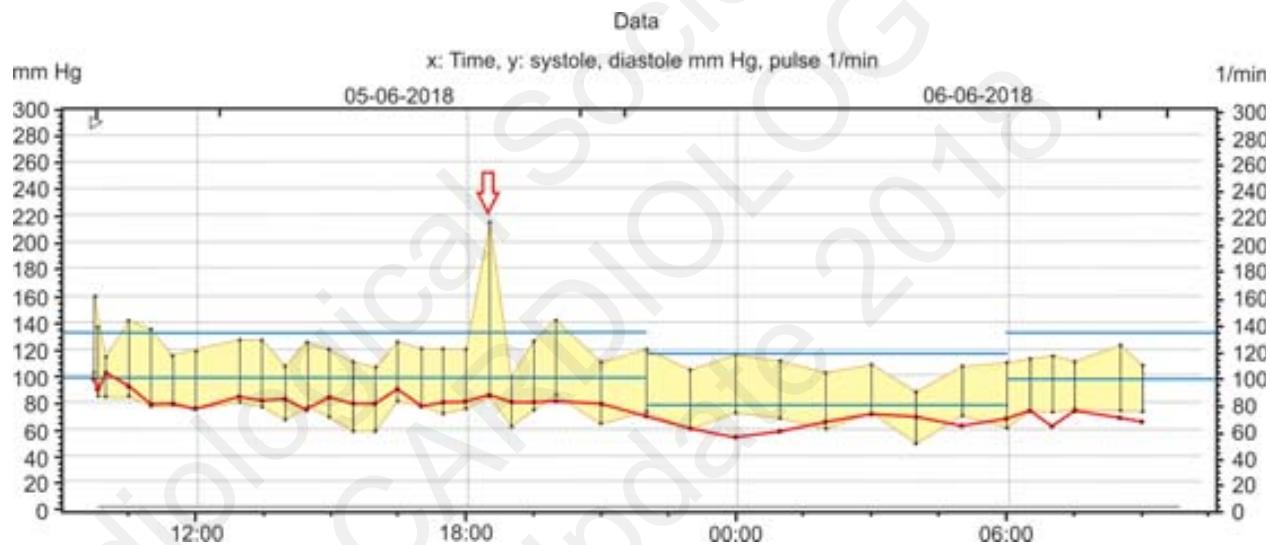

FIG. 3: Normal ambulatory blood pressure monitor record. The 24-hour, the day time and nighttime, mean blood pressures (BPs) are normal. Three is 10–15% dipping of nocturnal BP. There is a single abnormal BP reading of 220/80 mm Hg which is a wrong reading. This is excluded from analysis to avoid wrong results (red arrow). There are adequate number of BP readings to consider this report as valid. We can also suspect a white coat effect because the first BP recording is above the normal threshold.

- or equal to 0.9. These are patients with lowest CV risk compared to the other categories based on dipping status.
- **Nondippers:** The mean nighttime BP is lower than daytime BP, but the magnitude of reduction is less than 10% (Fig. 4). In these individuals, there is higher incidence left ventricular hypertrophy, ventricular arrhythmias, and major CV events compared to normal dippers.²⁰⁻²³ An increase in CV mortality has also been shown in nondippers in the Ohasama²⁴ and PAMELA²⁵ studies. On the renal side, these patients have been shown to have greater risk of albuminuria, lower glomerular filtration rate and impaired sodium excretion.²⁶⁻²⁹ More strokes, silent cerebral infarcts, and lower brain matter volume has also been shown to be associated with nondipping.³⁰⁻³² All

these show the higher end organ damage with nondipping status. Hence, not only just daytime BP control but also adequate fall in BP at night is needed to reduce morbidity and mortality associated with SH.

- **Reverse-dippers or night BP risers:** Contrary to the normal dipping pattern, mean BP at night is higher than the daytime mean BP (Fig. 5). Cardiovascular events are highest in this group, even higher than the nondippers.³³ In these, patients a four times CV mortality risk has been shown in the Ohasama study.²⁴ Majority of these patients have either obstructive sleep apnea or diabetes mellitus (DM). Better control of the causative factor may ameliorate the mortality risk and convert these patients to either a nondipper or dipper.

- *Hyperdippers or extreme dippers:* The mean nighttime BP is greater than or equal to 20% lower than the mean daytime BP. Most studies could not find associations between extreme dippers and outcomes, usually due to the low prevalence. But extreme dipping is not benign. Mild cognitive impairment and silent cerebrovascular disease has been shown to be higher in extreme dippers.³⁴⁻³⁶
- There exist various phenotypes of patients based on their OBP and ABPM.

- *Normotension:* An individual is said to be a true normotensive if both his OBP and ABPM values are in concordance with each other and do not meet criteria for hypertension (Figs 2 and 3). This is the category with the lowest CV risk.
- *Sustained hypertension:* An individual is said to have sustained hypertension if both his OBP and ABPM are in concordance and meet criteria for hypertension. They have higher CV morbidity and mortality as has been shown in large trials based on OBP.¹⁻⁶
- *White coat hypertension:* Also called isolated clinic hypertension. An individual is said to have white coat hypertension if his OBP readings are diagnostic of hypertension but ABPM values are normal. Although previously considered benign, these patients have been shown to have a higher risk of all-cause mortality in a recent study.³⁷ Also patients with white coat hypertension are more likely to progress to sustained hypertension and hence the need for early intervention and lifestyle modification.³⁸ Incidence of new onset DM is also higher in these patients.³⁹
- *Masked hypertension:* An individual is said to have masked hypertension if his OBP values are normal, but ABPM is diagnostic of hypertension. About 10% of population is said to have masked hypertension.¹³ Patients with type 2 diabetes mellitus have higher prevalence of masked hypertension.⁴⁰⁻⁴² They have higher CV morbidity and mortality compared to normotensives. A recent study

showed these patients have the highest risk and a stronger correlation with all cause and CV mortality than sustained hypertension.³⁷ They also have a higher progression to sustained hypertension and DM.^{38,39}

- *Nocturnal hypertension:* An individual is said to have isolated nocturnal hypertension if his OBP is normal and ABPM shows elevated nighttime mean BP with normal daytime mean BP (Fig. 4). These patients also have higher CV events compared to normal population.

There are other additional parameters that can be measured with ABPM which cannot be done with OBP.

- *Blood pressure variability:* BP is not a static parameter and has fluctuations throughout the day and night and over weeks to months. Although not a true measure of BP variability (BPV), ABPM gives enough readings to suggest an increased variability in BP over short-term period (Fig. 6). BP variability over short- and long-term have been independently associated with higher CV risk and renal damage.⁴³⁻⁵⁰ Increased BPV over the short-term period has been shown to increase subclinical organ damage^{50,51}
- *Morning BP rise:* There is a rise of BP in the early morning hours starting a few minutes before waking to a few minutes after waking (Fig. 5). Number of stroke and myocardial infarctions have been noted to be more frequent in this period. Rise in heart rate, cortisol and other parameters have also been implicated other than BP rise.⁵²⁻⁵⁴ This morning rise of BP is regarded as a physiological phenomenon although there have been some studies which show association of adverse events with excessive morning rise of BP.⁵⁵⁻⁵⁷ But these findings have not been validated in large population based studies like PAMELA.^{50,58} The significance of morning BP surge is hence debated.
- *Blood pressure load:* It is defined as the percentage of readings in the ABPM report that are above the threshold value for that time period, daytime or nighttime. It is

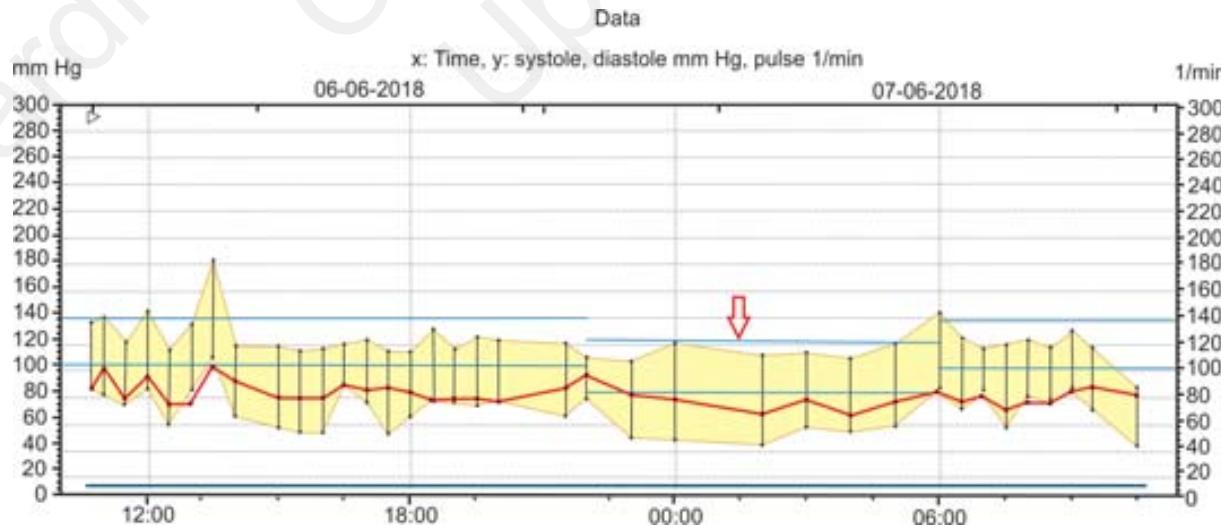

FIG. 4: Ambulatory blood pressure monitor record showing a normal daytime mean blood pressure (BP) with <10% fall in nocturnal BP (red arrow) which indicates nondipping. The nighttime mean BP is above the threshold for hypertension suggestive of isolated nocturnal hypertension.

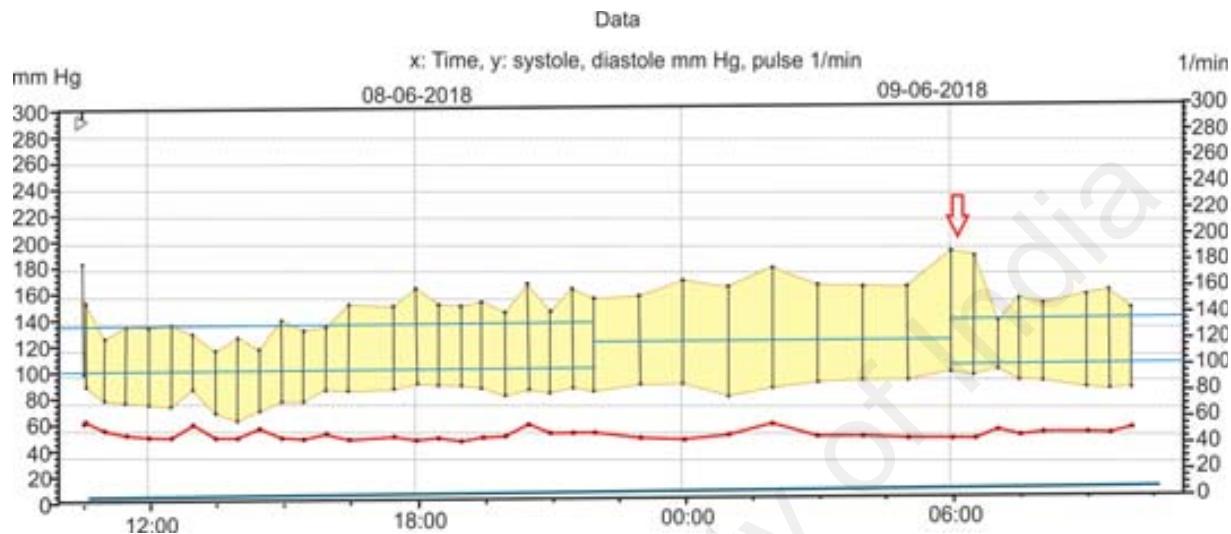

FIG. 5: Ambulatory blood pressure monitor record showing sustained hypertension with reverse dipping pattern. Also note the blood pressure surge in the morning (red arrow).

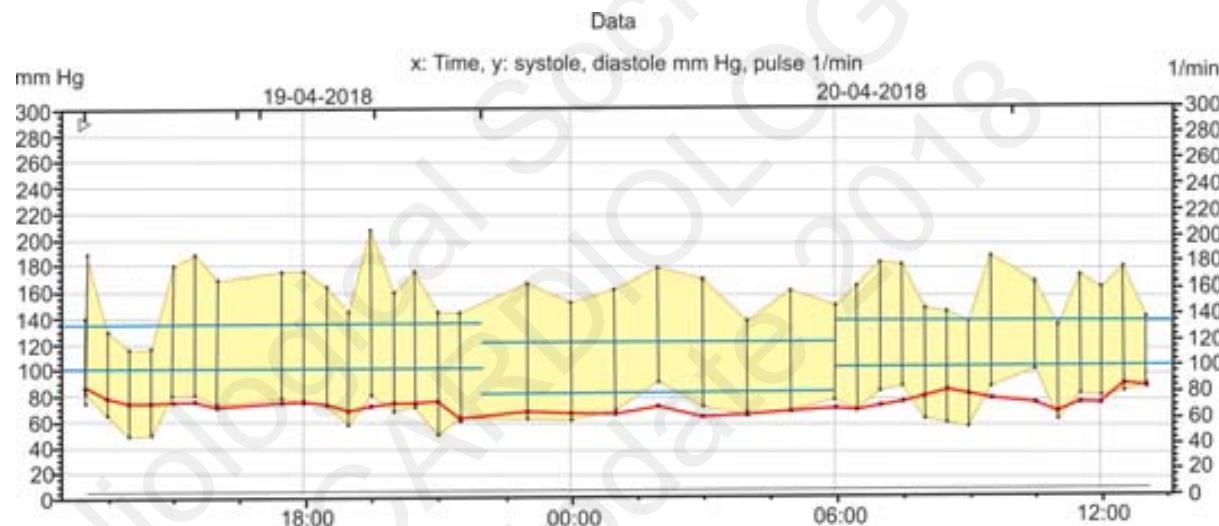

FIG. 6: Ambulatory blood pressure monitor record showing sustained hypertension with nondipping pattern and blood pressure variability.

an indicator of the time for which the patient stays hypertensive. But it is a poor indicator as it does not reflect the magnitude of hypertension and individual BP readings cannot be compared to the mean time period threshold. These shortcomings have more or less been addressed with BP variability.

- **Postprandial hypotension:** It is also called Siesta dipping. Fall in BP after meals can be documented with ABPM. This is recognized if the patients maintain a diary of events throughout the monitoring period.
- **Ambulatory hypotension:** Although not the ideal method, ABPM can provide readings to suggest that a patient has an ambulatory hypotension. Like postprandial hypotension, recognition of ambulatory hypotension requires the maintenance of diary of events.

MERITS AND DRAWBACKS

In addition to the above-mentioned merits of stratifying risks better and identification of special categories of hypertension, some more merits need to be mentioned. It can avoid unnecessary drug treatment of white coat hypertension. It can also help individualize the treatment for each patient. For the evaluation of duration of drug effect ABPM is ideal as it can record nighttime BP. Also placebos are said to have negligible effect on ABPM results.⁵⁹

Although ABPM has a lot of merits it is not without drawbacks. There have not been large randomized trials making use of ABPM for the CV outcomes. ABPM requires a special BP monitor which is able to record the BP at set intervals and there is a need for a computer to analyze the data. This increases the cost of the procedure and

reduces the widespread availability. But the cost factors become favorable in the long run. The BP recordings obtained in patients of irregular heart rhythms especially atrial fibrillation are not reliable. Some patients complain of disturbed sleep due to the recurrent inflation and deflation of the BP cuff, which may in turn lead to elevated nighttime readings. Compared to HBPM there is no active participation of patient in the management of hypertension. Most countries with healthcare based on insurance there is no reimbursement or reimbursement only for limited indications leading to under use of ABPM even if available and indicated.

FUTURE DIRECTIONS

As discussed above, OBP is largely insufficient in predicting events and treating hypertension. ABPM is here to stay and future guidelines may be entirely based on ABPM than OBP, hence providing the best prognosis for patients. With gaining popularity and huge impact of ABPM, various organizations have started maintaining registries based on ABPM. An ABPM-based registry will give a better outlook and provide more data for optimizing the use of ABPM. With the emergence of central aortic blood pressure measurement (CAABPM) noninvasively using cuff-based methods with greater accuracy, the next direction ABPM might take is the CAABPM. There has been an integration of mobile devices into the health monitoring, like the apple watch being able to detect subclinical atrial fibrillation. Wireless bluetooth-based BP monitors have been released and with slight programmability these can also double up as ABPM devices and with associated software can be the future compact ABPM devices. These can transfer the data to a mobile device and be analyzed, alleviating the need for a computer. With Wi-Fi based printing, using mobile device based ABPM, the cost of a computer and space occupied can be saved.

CONCLUSION

At present OBP is the accepted method of recording BP and is correlated with CV morbidity and mortality. However, ABPM which records the BP during day and night is a superior method of BP assessment and has been better correlated with morbidity and mortality, including end organ damage, compared to OBP. Various patterns of BP variations during night have been recognized by ABPM and each has its own prognostic significance. ABPM is the only technique which can detect white coat and masked hypertension. ABPM can guide the choice and timing of antihypertensive drug administration. The drawback of ABPM is the lack of large randomized trials using the technique, the cost and lack of easy availability. With the refinement of technology and greater acceptance by the treating physicians, ABPM in the near future will be the accepted method of BP recording for evaluation and management of a patient of systemic hypertension.

Home Blood Pressure Monitoring: Current Status

Vidyut Jain, Avani Jain

INTRODUCTION

Hypertension is the most common preventable cause of cardiovascular diseases and cerebrovascular events. Home blood pressure monitoring (HBPM) is the self-monitoring system that can be adopted into the care for patients with hypertension.¹ A growing body of evidence supports that the recording of blood pressure (BP) at home or outside clinic provides more accurate information and thereby prediction of future events. Till recent the gold standard for these predictions used to be 24-hour ambulatory blood pressure monitoring (ABPM) that measures daytime and nighttime pressures.² The objective of this paper is to perform a systematic review of the available evidence on the usefulness of HBPM in the diagnosis and treatment of hypertension.

REVIEW OF LITERATURE

In last two decades, many studies have analyzed the clinical usefulness of ABPM as a valuable technique that significantly improves the management of hypertensive patients.¹ However, because of its cost, the need for trained clinic staff, and the interference with patients' usual activities, ABPM is currently recommended in only selected cases.^{1,2}

Regarding HBPM, only in the last decade convincing evidences has been available. Observations in many studies published in 2008, and onward created great interest in clinical application of this method of BP monitoring.³

In the present era, discussion on the application of HBPM in clinical practice can be focused on: (1) diagnostic value in hypertension, i.e., white coat and masked hypertension; (2) usefulness in assessing the antihypertensive drug efficacy and adjusting the dose and different molecules; (3) management of hypertension, especially regarding compliance with treatment and percentage of hypertension control rate; (4) comparison with other modalities, i.e., ABPM. Some other area of interest can be used of HBPM in special populations (children, patients with chronic kidney disease). Analysis of HBPM data can be further informative for prediction of target-organ damage, morbidity, or mortality pattern in different subgroup.

Diagnostic Capability of HBPM

In last two decades, various studies assessed the diagnostic accuracy of HBPM comparing it with ABPM highlighting sensitivity and specificity. Data are presented in table 1.

TABLE 1: Analysis of study for diagnostic performance of home blood pressure monitoring as compared to ambulatory monitoring as the reference method

Study	Number	Subject	Diagnosis	Specificity	Sensitivity
Nesbitt et al. ⁵ 1977	199	Untreated	Hypertension	84	93
Stergiou ⁶ 1998	189	Treated	White coat HBP	57	85
Comas ⁷ 1999	58	Treated	White coat HBP	84	82
Agarwal 2006 ⁹	104	Hemodialysis	hypertension	80	84
Stergiou et al. ⁸ 2008	133	Untreated	Hypertension	74	76

Masding et al. ¹¹ 2009	55	Untreated	Diabetes II	100	79

HBP, home blood pressure.

In earlier studies which compared HBPM with ambulatory or office BP measurements in the diagnosis of sustained, white coat, or masked hypertension utilized mainly aneroid devices, but recent studies used validated oscillometric devices. Emphasis of these studies was on several advantages of home compared to office measurements, including the detection of the white-coat and the masked hypertension phenomena in clinical practice.^{2,3}

Table 1 shows various studies comparing the sensitivity-specificity and diagnostic accuracy of HBPM, office, and ambulatory BP as reference in untreated, treated, as well as subjects with diabetes type 2, chronic renal failure, or hemodialysis, and children and adolescents.⁴⁻⁶ Apparently, moderate agreement was seen between two methods of BP monitoring with higher specificity and lower sensitivity and positive predictive value. HBPM can easily detect masked hypertension and white coat hypertension as much as ABPM which is accepted as standard tool for the same. HBPM analysis was similar in the different populations included in these studies particularly in children and adolescents. HBPM appears to have considerable more potential in the assessment of elevated BP in children, and may prove an important tool when further data will be available.¹²

HBPM in Treated Hypertension

The main application of HBPM is its use in the long-term follow-up of treated hypertension. In SHEAF (Self-measurement of blood pressure at Home in the Elderly: Assessment and Follow-up)¹³ study where 4,939 elderly treated hypertensive were followed for 3.1 years and data showed that even in apparently office controlled BP masked hypertension was present in about 42% thus exposing them to high risk (hazard ratio of 2.06) while comparing them with patients with low office and home BP in another group of patient with white coat reaction this risk was low (hazard ratio was 1.18). Thus, HBPM can better analyze the cardiovascular risk.¹⁴

HBPM for Treatment Adjustment

A comparative analysis of studies involving randomized controlled antihypertensive treatment adjustment based on home versus clinic or ambulatory BP is discussed.¹⁵⁻²⁰ Larger BP decline was noted in HBPM group in two trials.^{21,22}

The difference in BP values in untreated and treated subjects was significant in home BP group. There by it is presumed that HBPM can offer more appropriate direction in management of drug therapy.

In another study termed THOP, which enrolled 400 subjects with elevated office BP to decide about therapeutic management based upon office or home BP where in monitoring was done for 1 year for outcome emphasized that adjustment based on HBPM required less intensive drugs.²³

In HOMERUS study, 160 patients with hypertension were included for treatment adjustment. It has similar observation to that reported in THOP that for the same target of BP based on HBPM requirement of drugs was less after 1 year follow-up as compared with ambulatory BP.²⁴

In a study reported by Zarnike which included 98 subjects to titrate therapy based on either ambulatory BP or home BP reading having high daytime diastolic BP with intention to attain the goal of diastolic BP of 80 mm Hg or less, no significant difference was observed in two groups at 6 months follow-up.²⁰

HBPM in the Assessment of Antihypertensive Drug Effects

To find out the utility of HBPM for analyzing efficacy of medication used for BP control meta-analysis of 30 studies involving 6,794 subjects showed that antihypertensive treatment reduces home BP by approximately 20% less than office BP.²⁴ The paradox observed may be due to the difference in baseline BP levels. Thus, larger decline in mean pressure may be due to white coat and placebo effect.^{21,22}

Early morning rise in BP is nowadays believed to have significant impact in outcome of BP trials.²⁵ The stress is on to evaluate the relationship of either BP value on target organ damage and it is postulated that home BP is more relevant to clinic BP and equivalent to ambulatory BP in predicting the long-term outcome.²⁶ It has been noted in many studies that home BP measurements gives us more reliable information on treatment-induced changes in BP.²⁷⁻³² Other important observation is that the morning:evening home BP ratio provides information on action and duration of antihypertensive drugs as the trough:peak ratio assessed by 24-hour ABPM.^{33,34}

In assessment of effect of antihypertensive drug Zamke further reported larger BP decline in group of patient comparing with central BP with HBPM.²⁰ In another study by Niranen in patient with daytime diastolic BP of 86-110 mm Hg studied for 6 months similar decline was noted both ambulatory and HBPM group.¹⁹ In a published report by Verberk et al. of 364 patient treated for hypertension comparing central with HBPM for 12 months, higher effect in HBPM was seen.²³

In a study of 206 hypertensive patients the effect of treatment on left ventricular wall thickness was assessed by monitoring their BP by office, HBPM and ambulatory BP methods for 1 year and it was observed that office BP monitoring in predicting left ventricular hypertrophy was less informative.²⁶

HBPM in the Assessment of Resistant Hypertension

Ambulatory blood pressure monitoring is considered to be better for the evaluation and management of patients with resistant hypertension.¹ However, a small study provides a direct comparison with ambulatory monitoring and confirmed the usefulness of home BP in resistant hypertension (Table 1). Now both American and European guidelines have also included resistant hypertension is an indication for HBPM.

HBPM and Hypertension Control

A meta-analysis of 18 randomized controlled trials (RCTs) including 2,714 hypertensive subjects allocated to HBPM or to usual care showed a significant 10% greater chance of reaching the BP target with home monitoring.³⁴ This difference though small, yet if applied in the entire population of hypertensive subjects, is expected to have an important impact on cardiovascular disease prevention.

In an RCT in 441 uncontrolled hypertensive patients, from general practice, HBPM resulted in a small but significant improvement of BP at 6 months, with no additional cost; this benefit was sustained after a year.³⁵ Report from J-Home study which included 2,363 hypertensive patients, highlights that 33–46% of patients had better control of their BP adjusted on HBPM the same stand true for patient with chronic kidney diseases where the accurate monitoring BP is needed for diagnosis and treatment.³⁶

In an another challenging telemedicine study, 111 subjects with uncontrolled BP on single drug therapy were trained to self-monitor their home BP and self-titrate drug treatment after informing the monitoring center. Most of them were compliant, i.e., 78% in this 8-week program, 80% were satisfied. BP was well controlled in 71% by self-titrating and a significant decline in home BP was achieved.³⁷

Many evidences and data are available from recently published studies which have testified the utility of HBPM for initial diagnosis, control of BP, and long-term control of BP. The wide application of this method in the management of hypertension in clinical practice has been endorsed by recent American and European guidelines.^{2,3}

Home BP monitoring requires patient to be well informed, some patient may overuse the device, and prone to anxiety and more fluctuation and have tendency to titrate the dose of drug every day and resulting into poor net control of BP. Detection of excessive BP-lowering effect of antihypertensive drugs in patients with white coat phenomenon can help in avoidance of over treatment. Similarly under treatment seen in patient with masked hypertension can be better judged.³⁸

Role of HBPM in Clinical Practice

The available evidence justifies the significant role of HBPM in decision making in hypertensive patients. The ABPM and HBPM despite their similarities, assess different aspects of the BP profile. Regarding the application of HBPM in the diagnosis of hypertension, particularly in cases with diagnostic disagreement with office measurements (white-coat or masked hypertension) remains good choice. A modified version of this strategy has been suggested which allows treatment decisions to be made on the basis of home measurements in subjects with home BP less than 125/75 mmHg (no drug therapy) or greater than 135/84 mmHg (initiation of drug therapy), whereas in intermediate home BP values, ambulatory BP can be helpful.³⁹

The detection of masked hypertension often poses controversies in terms of who are the subjects to be screened. Many patients with borderline office BP levels, or elevated office BP normalized on repeat.

Blood pressure measurement, as anxiety factor, is reduced. The other group likely to benefit are those at high total cardiovascular risk and all treated hypertensive. Home BP monitoring is also useful in order to solve the discrepancies of diagnosis of office and home measurements (white coat or masked hypertension).⁴⁰

Home blood pressure monitoring can be considered as the optimal method for the long-term follow-up and adherence for drug management because of its wider availability and easy affordability as compared to ABPM.^{3,41} The evidence shows that hypertension control rates also improves by implementing HBPM all treated hypertensives.^{2,3} A statement by the American Heart Association and the American Society of Hypertension endorsed that, as it is the case with home monitoring of glucose in diabetes, HBPM device may be prescribed by healthcare providers,² but it should be assured that patient should not take treatment decisions exclusively on the basis of home BP measurements. Many studies have shown that hypertensive patients observe over and under report their home BP values.⁴²

CONCLUSION

In the present era value of both HBPM and ABPM remains extremely useful in hypertension management, with some overlap of their clinical indications. However, because of the important scientific advancement taking place in the field of HBPM, it may be expected that the number of HBPM applications and indications will be increasing, making this approach more acceptable over other methods. Further studies on HBPM with prognostic stratification of hypertensive patients are needed to increase its utility. Finally, automated BP measuring devices combining the functionalities and advantages of both ABPM and HBPM will yield more useful data for better management of hypertension.

SECTION 5

Chronic Coronary Artery Disease

Best Method for Risk Stratification in CAD—Anatomy, Physiology, or Both

Pawan K Sharma, Kewal C Goswami

INTRODUCTION

The prevalence of cardiovascular diseases, especially coronary artery disease (CAD), is increasing in India like an epidemic and has become an important public health problem. The disease of circulatory system is the number one cause of mortality amongst the top eight registered causes of death. In 2015, the diseases of circulatory system was responsible for 33.2% of all the registered deaths with males accounting for 32.8% and females being 33.9%. Out of these, ischemic heart disease was listed in 26.9% as the cause of death. The diseases of pulmonary circulation and other heart diseases were responsible for 45.3% of deaths.

The age distribution of diseases of circulatory system was 19.1% between ages 25 and 34 years, 27.3% between ages 35 and 44 years, 35.6–45.6% for age of more than or equal to 45 years and 25.2% for population of more than or equal to 70 years of age.¹

This data suggests that almost 75% of deaths occur in the younger working age group leading to massive economic burden on the society. In the INTERHEART study, 8 common risk factors explained more than 90% of acute myocardial infarctions (MIs) in South Asian and Indian patients.² These risk factors were dyslipidemia, smoking or tobacco use, hypertension, diabetes, abdominal obesity, lack of physical activity, less intake of fruits and vegetables, and psychological stress. The interventions to prevent and treat heart disease could be very cost effective because most of the deaths occur in the younger working age group. A vast number of patients are seen in the medical centers or hospitals for treatment of CAD. Therefore, in addition to primary prevention, the secondary prevention by identifying appropriate risk stratification and revascularization strategies can play a significant role in preventing morbidity and mortality.

In the outpatient settings, various stress tests can be helpful in defining the extent of ischemia and coronary risks and decide whether medical therapy is optimal or patient should be referred for revascularization. While in

the catheterization laboratory, the risks involved in treating severe CAD by percutaneous coronary intervention (PCI) can be assessed by various risk scores and the most commonly used risk score now a days is the SYNTAX score (SS).

In order to standardize the severity and extent of CAD, the SS was developed in 2006 as part of the SYNTAX (Synergy between PCI with Taxus and Cardiac Surgery) trial.³ The SS can be useful in predicting adverse ischemic events in patients undergoing PCI.^{4–6}

METHODS FOR RISK STRATIFICATION IN CAD

Noninvasive Methods

- Exercise treadmill test (ETT)
- Myocardial perfusion SPECT study
- Stress echocardiography
- Coronary calcium score assessment
- Coronary computed tomography (CTA) angiography without or with fractional flow reserve (FFR).

Invasive Methods (in the Catheterization Laboratory)

- Invasive coronary angiography
- Invasive coronary angiography with FFR.

RISK STRATIFICATION USING NONINVASIVE METHODS

If a patient is having symptoms suggesting acute coronary syndrome, then he should directly go to the catheterization laboratory for defining the coronary anatomy and possible revascularization. If a patient has no symptoms or has mild symptoms but CAD is suspected, then the risk can be assessed by noninvasive testing which would help to decide the need for medical therapy or invasive coronary angiography.

Exercise Treadmill Test

Treadmill test is most commonly used for assessing the exercise capacity of an individual with interpretable baseline ECG. The exercise tolerance is measured in metabolic equivalents (METs). One MET unit is defined as the energy expenditure at rest equivalent to an oxygen uptake of about 3.5 mL O₂/min/kg body weight. The sensitivity of ETT has been reported between 65 and 70%.⁷ Although, ETT helps in identifying high risk patients who may have severe CAD, but the leads showing ST depression do not localize the site of ischemia or the culprit vessel and do not assess the extent of myocardial ischemia.

Myocardial Perfusion SPECT Study

The risk of cardiac mortality is considered low if less than 1%, intermediate 1–3%, and high-risk more than 3% per year. A normal myocardial perfusion SPECT study (MPS) means a low-risk for cardiac events.⁸ The risk of having cardiac events increases with worsening of perfusion abnormalities.⁹ Therefore, patients with normal myocardial perfusion study or with mild abnormalities on the perfusion study can be treated medically without having any anatomical assessment by angiography. On the other hand, patients with significantly extensive and severe defects are considered at high-risk for having cardiac events and should be referred for coronary angiography and possible revascularization. Similarly, patient with mild perfusion abnormalities but certain high risk features still should be referred for coronary angiography. These high-risk features include poor left ventricular systolic function,¹⁰ transient ischemic dilatation,¹¹ increased lung uptake, and diabetes,¹² atrial fibrillation,¹³ those having pharmacological stress test,¹⁴ high pretest probability of CAD,^{15,16} very abnormal stress ECG.¹⁷

If patients have normal or mild ischemia, the medical therapy as initial treatment strategy has been shown to have better survival than referring patients for revascularization. When there is moderate-to-severe ischemia as defined by more than 10% of the total myocardial ischemia, the revascularization has a better survival benefit over the medical therapy. This supports the finding that myocardial perfusion study can help stratify the risks of revascularization versus medical therapy in individual patients.¹⁸

Stress Echocardiogram

Based on 16-segment analysis, the stress echo helps to locate and define the extent of wall motion abnormality predicting the culprit vessel causing the ischemia. On an average, the sensitivity of stress echo is around 84% and specificity is about 87%.¹⁹

Coronary Calcium Score

The coronary calcium score is useful in risk stratification of asymptomatic patients with intermediate clinical risk but it does not provide much prognostic value in patients with known CAD. Although, 95% of patients having first MI have abnormal coronary calcium score but still about

5% people can have MI without having any coronary artery calcification.²⁰ If the coronary calcium score is more than 400 and patient is free of symptoms, the patient can be referred for stress testing to assess the risk. In asymptomatic patients with coronary calcium score less than 100, no further testing is warranted. However, if the coronary calcium score is between 100 and 400 and patient has risk factors such as metabolic syndrome, diabetes, chest pain, advanced age, the stress test may be useful.²¹ It appears that patients with high calcium score but normal myocardial perfusion study are at low-risk in the short-term but may be at higher risk in the long-term. Therefore, aggressive medical therapy with statins is recommended in this population.²²

Coronary Computed Tomography Angiogram

Sometimes, the MPS is normal in patients with significant multi vessel disease due to balanced ischemia. Therefore, it may be replaced by the coronary CTA because the coronary CTA will more likely be abnormal in patients who would need some revascularization. If coronary CTA is normal, then aggressive medical therapy would be appropriate. If the coronary CTA shows severe CAD, then patient can be directly referred for coronary angiography.

If the results of coronary CTA are equivocal for any severe disease or if it clearly shows severe disease but the anatomy is not suitable for any kind of revascularization, then the patient can be referred for stress myocardial perfusion testing to assess for extent of ischemia before considering revascularization. The stress MPS can also be considered in patients with very dense calcification because coronary CTA is not very helpful in such situations.

On the other hand, coronary CTA may be useful in patients with questionable MPS results or if there is discrepancy between the clinical picture and ECG changes during stress and MPS results.

It is possible that with increasing role of coronary CTA, the MPS may be limited to patients with equivocal CTA or to assess the extent of ischemia in patients with known CAD.

It is, therefore, suggested that the noninvasive assessment of coronary anatomy by coronary CTA has a complimentary role to the physiological assessment with myocardial stress testing and FFR.

Anatomical SYNTAX Score Derived from Coronary Computed Tomography Angiogram (Developed in 2013)

Coronary CTA is a noninvasive method to obtain similar information about coronary anatomy as invasive angiography. Overall, a good correlation has been found between the SS calculated by coronary CTA and the invasive coronary angiography. Coronary CTA can risk stratify patients by the presence and severity of obstructive disease along with the presence of nonobstructive coronary plaque. Patients with absence of obstructive coronary disease and coronary plaque have a very low-risk of coronary events (<0.3% annual risk).²³

Mortality and coronary event rates increase as number of vessels with obstructive disease or total plaque burden increases.²⁴

Noninvasive Functional SYNTAX Score (Developed in 2015)

Coronary CTA technique is useful in generating a three-dimensional (3D) coronary tree for a specific patient. By using the computer generated fluid dynamics, blood flow in the vascular bed can be simulated and a noninvasive FFR can be calculated. This FFR derived from CT, i.e., FFR_{CT} has shown to have a high correlation with invasive FFR.²⁵ The coronary CTA technique can be very useful in calculating a noninvasive functional SYNTAX score (fSS) by recalculating the SS counting only the ischemia-producing lesions with FFR_{CT} less than 0.80. In some cases, the FFR_{CT} cannot be calculated due to image artifacts, extensive coronary calcification or prior revascularization with metallic stents. Overall, the FFR_{CT} can be performed in more than 85% of cases.²⁶ This noninvasive way of calculating FFR_{CT} provides a combined anatomical and physiological risk stratification before an invasive procedure is undertaken. On the other hand, FFR_{CT} also has the potential advantage of calculating fSS after the invasive coronary angiography without needing a pressure wire.

RISK STRATIFICATION USING INVASIVE METHODS

Risk Scores

The first risk score described in 1977 was the Duke Jeopardy Score²⁶ which was validated in 1985.²⁷ It demonstrated that by estimating the myocardium at risk on the basis of the particular location of coronary artery stenosis gave more prognostic information than the number of diseased arteries involved. The prognostic ability of this score was significantly improved by including the degree of coronary artery stenosis and by attributing a higher score to the disease of the left anterior descending artery than to other coronary arteries.

Later on, depending on the type of lesion, another classification was proposed which was designed as a guide to estimate the possibility of successful balloon angioplasty and its possible complications.^{28,29} Lesions were classified as types A, B, or C, based on the angiographic characteristics such as lesion length, tortuosity, calcification, thrombus, bifurcation, total occlusion. The success rate of balloon angioplasty with type A lesions was more than 85%, type B: 60–85%, and type C: less than 60%. In addition to predicting outcomes after balloon angioplasty, it also predicted the outcomes whether patient received bare-metal stent³⁰ or drug-eluting stent.³¹

The SYNTAX Score

Based on the number, location, complexity and functional impact of obstructive lesions noted on invasive coronary angiography, the SS was developed in 2006 and provides a standardized coronary artery tree. The distributions of the

coronary arteries are mapped based on the ARTS (Arterial Revascularization Therapies Studies) investigators' modification of coronary tree segments.^{32,33} The amount of jeopardized myocardium depends on the fraction of blood supplied to the left ventricle by each coronary segment.³⁴ A clinically significant lesion is defined as a diameter narrowing of more than or equal to 50% in vessels with a minimum diameter of more than or equal to 1.5 mm. The sum of individual lesion scores gives the final SS which is purely an anatomical tool and is described as low 0–22, intermediate 23–32, or high more than 32.⁴

Prognostic Value of SYNTAX Score

The SYNTAX trial showed that in patients with multi vessel and/or left main (LM) CAD,⁴ at 1 year follow-up, major adverse cardiovascular and cerebrovascular events (MACCE), which included all-cause death, MI, stroke, and target vessel revascularization (TVR), were significantly lower in the coronary artery bypass graft (CABG) group (12.4%) compared with the PCI group (17.8%, $p = 0.002$). At 1 year, MACCE rates progressively increased in patients with higher SS who were treated with PCI. Even the 5 year follow-up results of the SYNTAX trial showed that CABG was associated with significantly lower MACCE rates in patients with SS more than 32 and between 23 and 32 compared with the PCI cohort.³⁵

It has been noted that SS more than 34 is associated with significantly higher rates of ischemic events in patients undergoing PCI for unprotected LM than in those undergoing CABG. These results suggest that CABG should be considered in patients with higher SS with multi vessel is ease and in patients with unprotected LM CAD.³⁶ Similarly, in patients with Non ST-segment elevation acute coronary syndrome and ST-segment elevation MI, patients in the upper tertile of SS had significantly higher rates of ischemic events than did patients in the lower 2 tertiles. At 1 year, the SS was an independent predictor of all-cause death, cardiac death, and MI.^{37–39}

In contrast to patients undergoing PCI, SS seems not to influence clinical outcomes after CABG. Both mortality and composite ischemic outcomes in patients undergoing CABG are independent from SS.^{4,40,41}

Various Risk Scores Derived from SYNTAX Score

Since, SS is purely an anatomical score and it does not take into account the effect of clinical factors, patients with equivalent scores may have different short- and long-term outcomes, depending on the presence of comorbidities.⁴² To overcome these limitations and to improve the predictive ability of SS, different clinical-based scores have been combined with SS. These are global risk classification (GRC), clinical SYNTAX score (cSS), logistic clinical SS, fSS, residual SYNTAX score (rSS), CABG SYNTAX score, and SYNTAX score II (SS II).

Global Risk Classification (Developed in 2010)

The GRC is a combination of SS and Euro SCORE (European System for Cardiac Operative Risk Evaluation). The GRC

showed a net reclassification improvement of 26% in patient undergoing PCI for LM CAD.⁴³ Additionally, GRC can identify a low-risk cohort of patients that could be safely treated with PCI.⁴⁴

Clinical SYNTAX Score (Developed in 2010)

The cSS is determined by multiplying the SS with the modified ACEF (age, creatinine clearance, and ejection fraction) score. The cSS has a better discriminatory power for 5-year mortality and MACE than either SS alone or modified ACEF score did.⁴⁵ However, the main limitations of cSS is that it has a poor discriminative power for ischemic outcomes in the lower 2 tertiles and that its prognostic performance is poorer for pooled patients with double- and triple-vessel CAD than for patients with only triple vessel CAD.⁴⁵

Logistic Clinical SYNTAX Score (Developed in 2011)

The logistic cSS variables were selected on the basis of logistic regression coefficients, thus developing score charts for individual risk assessment. This score had substantial improvement in the predictive ability for 1-year all-cause death compared with SS.⁴⁶

Functional SYNTAX Score (Developed in 2011)

The anatomically severe lesion may not be physiologically significant when assessed by FFR, therefore, fSS was proposed which incorporated FFR with SS. The fSS reclassified 32% of patients from the high to medium risk SS whereas 59% of the cases were reclassified from medium-risk to the low-risk group.⁴⁷ The fSS was also associated with better inter- and intra-observer reproducibility.

Residual SYNTAX Score (Developed in 2012)

Since, incomplete revascularization is associated with an increased risk of adverse ischemic outcomes after PCI in patients with high SS,³⁶ the rSS was proposed to quantify residual CAD after PCI. The rSS calculation is similar to SS, except that it is calculated after PCI. The rSS is an independent predictor of all cause death, cardiac mortality, MI, unplanned revascularization, and MACE at 1 year.⁴⁸

Coronary Artery Bypass Graft SYNTAX Score (Developed in 2013)

The original SS can be used only for native CAD and not for patients with CABG, therefore, CABG SS was developed.⁴⁹ First the baseline SS of native vessels is calculated and then points are subtracted depending on the graft functionality and final CABG SS is calculated. The major limitation of this score is that it does not take into consideration the type of graft used. The study suggests higher all cause death and MACE in patients with high CABG SS but larger studies are needed to validate its prognostic capabilities.

SYNTAX Score II (Developed in 2012)

The SS II combines anatomical SS with patient's clinical characteristics and the anatomical presence of unprotected LM coronary disease. These clinical characteristics include the age, creatinine clearance, left ventricular ejection fraction, peripheral vascular disease, female sex, and chronic obstructive pulmonary disease. This score predicts the

4 years all-cause mortality in patients with LM/multi vessel CAD and helps making a decision between CABG or PCI in such patients. A nomogram for SS II has also been proposed for bedside application.⁵⁰

POTENTIAL USES AND LIMITATIONS OF THE TRADITIONAL SYNTAX SCORE

The traditional SS can be used as a standardized tool is assessing the extent and severity of CAD in a uniform fashion and enrolling patients in randomized controlled trials. It may help clinicians to decide the most appropriate revascularization modality (PCI vs. CABG). It may also help predict procedural outcomes, especially when discussing with patients and their relatives regarding potential outcomes associated with a given revascularization strategy.⁵¹

The SS has a major limitation that it is purely an angiographic score and does not take into account the role of comorbidities for risk stratification of patients undergoing PCI. Secondly, the SS has significant inter-observer variability commonly noted on visual estimation of vessel stenosis. Similar to any angiographic assessment, the SS does not identify vulnerable plaques or predict coronary plaque burden. SS does not predict the effect of viable or nonviable myocardium beyond the stenosis. The SS cannot appreciate the major differences in the operator skills and experience in dealing with complex procedures, the effect of new revascularization techniques or availability of various devices.

CONCLUSION

In patients with normal or mild ischemia on stress study, the medical therapy has better survival and should be tried first. High-risk patients with large area of myocardium at risk (>10% myocardium) should be referred for coronary angiography and will benefit from revascularization strategy. In asymptomatic patients with coronary calcium score less than 100, no further cardiac work up is needed whereas asymptomatic patients with coronary calcium score more than 400 should be referred for myocardial perfusion stress for risk stratification.

The SS II which involves the combination of anatomical and physiological variables along with clinical comorbidities represents a significant improvement in predicting the prognosis and procedural outcomes of revascularization strategies such as PCI or CABG in today's clinical practice.

With improvements in coronary CTA techniques and computer models, the calculation of fSS with the possibility of determining FFR noninvasively⁵² may have a significant effect in predicting prognosis of different revascularization strategies. The newly developed technique of calculating CTA-derived SS provides an accurate assessment of patient's coronary tree prior to cardiac catheterization. Furthermore, the physiological assessment by calculating the FFR_{CT} with the calculation of the noninvasive fSS will allow for an individualized risk stratification of CAD without unnecessarily undergoing invasive coronary angiography.

Thus, the integration of coronary anatomy and physiology with the comorbidities offers a personalized risk stratification of CAD to help the physicians in the decision making process for an appropriate revascularization strategy.

Screening for Coronary Artery Disease in Asymptomatic Adults

Pratap Chandra Rath, Md Abdul Azeez Asad

INTRODUCTION

Cardiovascular disease (CVD), particularly coronary artery disease (CAD), is the most important cause of death in the world. Screening asymptomatic individuals for CAD for preventive management is therefore important prior to the development of adverse events [myocardial infarction (MI), sudden cardiac arrest] that have significant morbidity and mortality.¹

RATIONALE FOR SCREENING

Advanced CAD can exist with minimal or no symptoms, with sudden and rapidly progressive manifestations. The initial manifestation of CAD in as many as 30% patients is an acute MI, unstable angina, or sudden cardiac death (SCD). The rationale for early detection of CAD is that it might allow identification of persons at elevated risk of major adverse cardiac events (MACEs) so that appropriate intervention, either as medical therapy (aggressive lipid lowering) for risk factors or coronary revascularization therapy, can be given to improve their prognosis. Other reasons for screening include detection of CAD in certain high-risk occupations (e.g., pilots, bus drivers, etc.) where an acute event could endanger large numbers of people. Also, individuals with higher risk of coronary heart disease (CHD) who are initiating an exercise program might benefit from screening.²

SCREENING TESTS

The available screening tests can be divided into invasive [e.g., coronary artery angiography (CAG)] or noninvasive and functional or anatomic.

Though catheter-based CAG is the gold standard for detection of CAD, it is relatively expensive and is associated with a minor but definite risk of serious complications like atheroembolism, bleeding, MI, arrhythmias, renal failure due to iodinated contrast media, stroke, and death. Hence, for the

detection of CAD in asymptomatic individuals, noninvasive techniques are usually preferred.³

Functional or stress testing provides physiologic evidence of clinically significant coronary artery stenoses by demonstrating the effects of diminished coronary flow reserve (CFR) on symptoms, electrocardiogram (ECG) changes, myocardial perfusion defects on scintigraphy or positron emission tomography (PET), or regional wall motion abnormalities on echocardiography.³

The following tests are available for the noninvasive diagnosis of CHD and are summarized in table 1:

- Exercise ECG
- Echocardiography using either exercise or pharmacologic stress
- Radionuclide myocardial perfusion imaging (rMPI) using either exercise or pharmacologic stress and imaging with either single photon emission computed tomography (SPECT) or PET
- Cardiac magnetic resonance (CMR) imaging
- Coronary computed tomography (CT), either for detection of coronary artery calcifications (CAC) or for assessing coronary artery stenosis with coronary computed tomography angiography (CCTA)
- Hybrid imaging, using either SPECT/CT, PET/CT, or PET/magnetic resonance imaging (MRI).

Electrocardiogram at Rest and Stress

The ECG at rest may show prior coronary ischemia by means of changes, such as prominent Q-wave and T-wave inversion. However, its sensitivity is very low.⁴

Twenty-four hours ambulatory ECG can increase the diagnostic efficiency in detecting ECG signs of transient ischemia, but its sensitivity for CAD is low (19–62%).⁵

Electrocardiogram during exercise showed sensitivity and specificity of 68% and 77%, respectively, in CAD diagnosis in a meta-analysis⁶ with approximately 24,000 patients who underwent conventional CAG and stress ECG. Higher

TABLE 1: Screening methods for detecting asymptomatic coronary artery ischemia

Screening methods	Detection of prevalent coronary heart disease (CHD)	Comments
	Functional tests	
Resting electrocardiogram (ECG)	Low sensitivity and specificity	Widely available, low cost
Exercise ECG	Moderate sensitivity (45–61%) and specificity (70–90%)	Widely available, low cost
Stress echocardiography: 1. Exercise stress echo 2. Pharmacologic stress echo (dobutamine, adenosine, and dipyridamole)	The sensitivity and specificity are satisfactory (80–85%) Able to assess left ventricular (LV) function and valvular abnormalities	Low cost, widely available Operator dependent Difficulty in interpreting the images in obese persons
Radionuclide single proton emission computed tomography (SPECT), myocardial perfusion imaging (MPI)	Good sensitivity (80–90%) and specificity (75–90%) The most widely used test to assess silent myocardial ischemia	Moderate to high cost Widely available High negative predictive value (95%) Image quality affected by body habitus and large breasts Screening of asymptomatic patients not prognostically useful unless high-risk patients are selected
Myocardial perfusion imaging (MPI) with positron emission tomography (PET)	High sensitivity for myocardial viability studies Accurate global and regional measurements of myocardial perfusion, blood flow, and function at stress and rest in a single study	Better image quality because of higher spatial resolution, less scattered, and fewer attenuation artifacts Lower radiation exposure than SPECT Costly, not universally available
	Anatomical tests	
Coronary artery calcium score (CAC)	CAC more prevalent in people with diabetes than nondiabetics Closely associated with total coronary artery atherosclerotic plaque burden Predicts incident ischemia, CHD morbidity and mortality	Moderate to high cost No differentiation between obstructive and nonobstructive CHD Up to 25% of patients have minimal or no CAC at the time of screening
Multidetector row computed tomography (MRCT) angiography	High sensitivity (83–99%) and specificity (93–98%)	Good sensitivity, specificity, and negative predictive value. High radiation doses High cost
Magnetic resonance imaging (MRI)	Good sensitivity (83–90%) and specificity (72–84%) Delayed gadolinium hyperenhancement linked to increased risk of major cardiovascular events Not adequately investigated	Able to assess myocardial structure and function and characterize ischemic, inflammatory and various types of cardiomyopathies High cost

sensitivity was found when CAD affects three arteries. The positive predictive value of the ECG per year in predicting CAD is estimated to be 70%.⁷ However, this test is often inconclusive and inappropriate due to physical disability, vascular, and neuropathic changes or resting ECG changes.

Stress Echocardiography

This noninvasive test detects motion abnormalities of the heart during exercise or pharmacological stress (dobutamine) and provides information about the size and location of the ischemic area, as well as left ventricular (LV) function.⁴ In asymptomatic diabetic patients, the sensitivity and specificity for CAD diagnosis are, respectively, 81% and 85%.⁸ A 3-year follow-up of asymptomatic diabetic patients with negative

stress ECGs showed probability of a CV event lower than 2% every year. Limitations include difficulty in interpreting the images in obese and chronic obstructive pulmonary disease (COPD) patients and interobserver variability. The use of intravenous ultrasound contrast agents can improve endocardial border delineation and hence diagnostic accuracy.³

Radionuclide Myocardial Perfusion Imaging

Stress testing (exercise or pharmacological using adenosine or dipyridamole) combined with either SPECT or PET is more sensitive for the diagnosis of CAD, in both people

with and without diabetes.^{9,10} This can suggest location of lesion, extent of myocardial ischemia, and LV function⁴ with better sensitivity (80–90%) and specificity (75–90%) when compared with stress ECG and a high negative predictive value (95%).^{11,12}

Radionuclide myocardial perfusion imaging has an important role in the diagnosis of silent myocardial ischemia and risk stratification of diabetic patients with suspected CAD. Detection of ischemia in asymptomatic diabetes (DIAD) study reported any perfusion defect or LV function abnormality in about 22% of asymptomatic diabetics.¹³

The prevalence of asymptomatic LV dysfunction [ejection fraction (EF)<50%] is 6% in men and 0.8% in women of the general population. Transient ischemic dilation (TID), defined as the apparent presence of LV dilation on post stress relative to rest images, has been linked to increased CVD risk.¹⁴ The left ventricular shape index (LVSI), derived as the ratio of maximum 3-D short- and long-axis LV dimensions, for end-systole and end-diastole, has been shown to be an independent predictor of congestive heart failure (CHF) hospitalization.¹⁵

Limitations of SPECT include high cost and poor diagnostic image quality in obese patients, as well as in women and men with large breasts. Also, global reductions in myocardial perfusion, such as in the setting of left main or three-vessel CHD, can result in underestimation of ischemic burden.³

Positron emission tomography provides better image quality with higher spatial resolution, less scatter, and fewer attenuation artifacts and lower radiation. Myocardial perfusion imaging with PET allows accurate global and regional measurements of myocardial perfusion, myocardial blood flow, and function at stress and rest in a single study session. Fluorodeoxyglucose (18F-FDG) PET imaging has high sensitivity for the detection of hibernating or viable myocardium.¹⁶ Coronary flow reserve (CFR=stress divided by rest myocardial blood flow) assessed by PET integrates the effects of focal stenosis, diffuse disease, and coronary microvascular function.¹⁶

ANATOMIC (IMAGING) TECHNIQUES

Cardiac Magnetic Resonance Imaging

This test provides an accurate means of assessing myocardial structure and function and enables characterization of the range of myocardial diseases from ischemic to inflammatory and various types of cardiomyopathy. Delayed gadolinium enhancement CMR is a marker of prior MI in patients with unsuspected CAD and has been linked with a 4-fold increased risk of MACE and a 7-fold increased risk of mortality.¹⁷

Coronary Artery Calcium Score

Coronary artery calcium (CAC) is a noninvasive method that detects the amount of calcium in the coronary artery,⁴ using multidetector row CT or electron beam tomography. Agatston et al.¹⁸ developed a CAC algorithm based on calcification density of the plaques. In nondiabetic persons, the CAC score

threshold at which the prevalence of ischemia increases substantially is more than 400 Agatston units,¹⁹ with lower thresholds in diabetic patients. The Multi-Ethnic Study of Atherosclerosis (MESA), with 6,814 patients without known CAD, concluded that the inclusion of the CAC in the coronary disease risk factors improved risk stratification for CAD.²⁰ However, Qu et al. did not find a significant association between coronary events and CAC in 269 individuals with diabetes mellitus (DM) followed up for 6 years.²¹

Coronary Artery Calcium Score Limitations

Coronary artery calcium exposes the patient to ionizing radiation. The average effective dose ranges from 0.7 to 1.8 mSv, around ten times the effective dose of a chest X-ray. Kim et al.²² studied the lifetime excess cancer risk due to radiation exposure from a single examination at the age of 40 years and showed that for a median dose of 2.3 mSv, this risk reached 9 cancers per 100,000 men and 28 cancers per 100,000 women.

Multislice Computed Tomography Angiography

Computed tomography angiography (CTA) is a relatively simple and noninvasive method to visualize the coronary artery and detect the degree of stenosis (Fig. 1). It also provides information about the composition of the plaques, the presence of remodeling, and extension of coronary lesions.⁴

When compared to invasive angiography, multislice computed tomography (MSCT) with 64 rows of detectors, demonstrated high sensitivity (between 83 and 99%), specificity (93–98%) and negative predictive value (99%) in a total of 542 patients in nine studies.²³ However, MSCT is not able to provide functional information. Any benefit of CT angiography to identify patient subgroups for different treatment strategies remains unproven and is thus not currently routinely recommended.²⁴

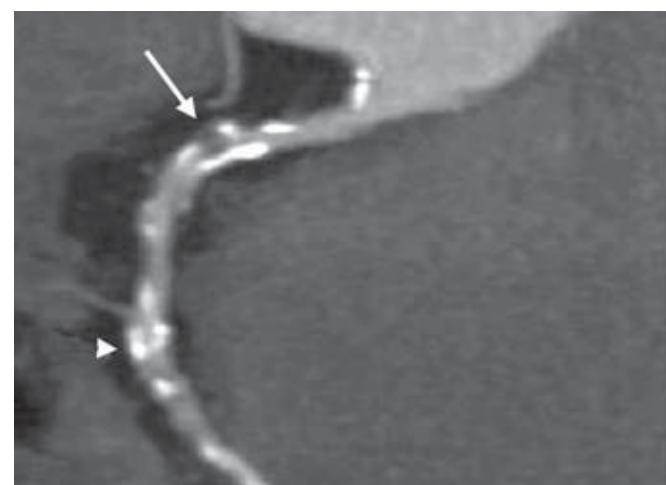

FIG. 1: Image of coronary computed tomography-angiography showing calcified plaques in right coronary artery.³²

TABLE 2: Testing in asymptomatic patients at risk for stable coronary artery disease: 2013 European Society of Cardiology guidelines on the management of stable coronary artery disease

Recommendations	Class ^a	Level ^b
In asymptomatic adults with hypertension or diabetes a resting ECG should be considered for CV risk assessment	IIa	C
In asymptomatic adults at intermediate-risk (see SCORE for definition of intermediate-risk—www.heartscore.org) measurement of carotid intima-media thickness with screening for atherosclerotic plaques by carotid ultrasound, measurement of ankle-brachial index or measurement of coronary calcium using CT should be considered for CV risk assessment	IIa	B
In asymptomatic adults with diabetes, 40 years of age and older, measurement of coronary calcium using CT may be considered for CV risk assessment	IIb	B
In asymptomatic adults without hypertension or diabetes a resting ECG may be considered	IIb	C
In intermediate-risk asymptomatic adults (see SCORE for definition of intermediate—risk—www.heartscore.org), (including sedentary adults considering starting a vigorous exercising program), an exercise ECG may be considered for CV risk assessment particularly when attention is paid to non-ECG markers such as exercise capacity	IIb	B
In asymptomatic adults with diabetes or asymptomatic adults with a strong family history of CAD or when previous risk assessment testing suggests high-risk of CAD, such as a coronary artery calcium score of 400 or greater stress imaging tests (MPI, stress echocardiography, and perfusion CMR) may be considered for advance CV risk assessment	IIb	C
In low- or intermediate-risk (based on SCORE) asymptomatic adults stress imaging tests are not indicated for further CV risk assessment	III	C

^aClass of recommendation.^bLevel of evidence.

CAD, coronary artery disease; CMR, cardiac magnetic resonance; CT, computed tomography; CV, cardiovascular; MPI, myocardial perfusion imaging; SCORE, systematic coronary risk evaluation.

OTHER METHODS FOR THE ASSESSMENT OF CARDIOVASCULAR RISK

Ankle-Brachial Index

Ankle-brachial index (ABI) is cost-effective, and can be done at the patient's bedside. Fowkes et al.²⁵ reported, in a meta-analysis of 48,294 healthy individuals, that a low ABI (≤ 0.9) was associated with increased 10-year CV mortality. However, a recent double blind randomized controlled trial did not find any improvement in outcomes after a mean follow-up of 8.2 years.²⁶

High-Sensitivity C-Reactive Protein

A large meta-analysis²⁷ has shown that C-reactive protein (CRP) predicted vascular death in 160,039 individuals without known vascular disease after adjustment for age and sex. However, it predicted nonvascular death, e.g., death from cancer to the same extent. Recent European Society of Cardiology (ESC)²⁸ and American College of Cardiology/American Heart Association (ACC/AHA)²⁹ guidelines did not recommend high-sensitivity CRP (hs-CRP) measurement in asymptomatic low- or high-risk individuals (class III, level B).

Lipoprotein-associated Phospholipase A2

This is an enzyme expressed by inflammatory cells in atherosclerotic plaques and a marker of vascular inflammation. Tsimikas et al.³⁰ showed a significant relationship between lipoprotein-associated phospholipase A2 (Lp-PLA2) activity and incident CVD, but only a modest increase in C-statistic, from 0.717 to 0.737 ($p = 0.31$), compared to established risk factors alone.

Carotid Intima-Media Thickness

The measurement of the average thickness of the intima-media thickness (IMT) of the carotid artery aids in the stratification of CV risk.³¹ However, the technique is not standardized with considerable variability in the IMT measurements between observers.

The ESC recommends measuring IMT by ultrasound to identify subclinical cases of CVD.²⁸ ACC/AHA 2013 guidelines have not recommended for or against carotid IMT (CIMT) measurement in asymptomatic individuals (Table 2).

SAFETY OF SCREENING TESTS

Unfavorable effects of screening tests include discomfort during the test, risks related to the screening test per se (e.g., allergic reactions, long-term radiation effects, or injury of coronary vessels during CAG), false-positive test results (with further unnecessary investigations), and false reassurances due to false negatives, and overdiagnosis.

Current Recommendations for Screening in Asymptomatic Adults

AHA/ACC 2013 Guideline on the Assessment of Cardiovascular Risk: A Report of the American College of ACC/AHA Task Force on Practice Guidelines Assessment of CAC

IIb recommendation among individuals for whom a risk-based treatment decision is uncertain after formal risk estimation.

Recommendation 1

If, after quantitative risk assessment, a risk-based treatment decision is uncertain, assessment of one or more of the following—family history, hs-CRP, CAC score, or ABI—may be considered to inform treatment decision making. The National Heart, Lung, and Blood Institute (NHLBI) grade E (expert opinion); ACC/AHA class of recommendation (COR): IIb, level of evidence (LOE): B.

Recommendation 2

Routine measurement of CIMT is not recommended in clinical practice for risk assessment. NHLBI grade N (no recommendation for or against); ACC/AHA COR III: no benefit, LOE: B.

CONCLUSION

In asymptomatic individuals, a variety of tests are available for screening for CAD, including functional and anatomical imaging as well as new biomarkers. However, the use of these tests has not translated into net clinical outcomes and hence their utility must be limited, after careful consideration in patients with intermediate to high-risk for CAD. These are not indicated and therefore must be avoided as a routine strategy in low-risk individuals.

Optimal Medical Management for Chronic Stable Angina in 2018

Satyavan Sharma, Naresh D Munot

INTRODUCTION

In clinical practice, the terms stable ischemic heart disease (SIHD), stable coronary artery disease (SCAD), and stable angina (SA) are used interchangeably. The pathological process underlying SIHD is an atheromatous plaque that obstructs or gradually narrows epicardial coronary arteries.

Typical SA presents with a retrosternal discomfort (constriction, pain, pressure, heaviness or burning) related to effort or mental stress, which is transient, and responds either to rest, nitrates, or disappearance of the precipitating factors. The discomfort is due to more than 70% narrowing of one or several of the major coronary arteries or more than 50% of the left main coronary artery. Microvascular dysfunction and coronary vasospasm may aggravate the impairment of coronary flow. The Canadian Cardiovascular Society (CCS) has proposed a specific system for grading of angina, which has gained widespread acceptance.¹

This chapter aims to focus on the role of Optimal Medical Management or Therapy (OMT) in today's practice.

LESSONS LEARNT FROM RANDOMIZED TRIALS

The management of SIHD consists of medical therapy (MT), percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG).

The earlier trials compared MT to CABG and subsequently there have been multiple randomized trials which compared contemporary techniques. From earlier trials, it was apparent that MT was associated with low event rates (Table 1). A meta-analysis of 12 trials of stenting versus MT indicates that the initial improvement in relief of angina with PCI over MT is not sustained in the current era of MT.² In addition, no randomized trial or meta-analysis has demonstrated a reduction in death or myocardial infarction (MI) with PCI vs. MT for SIHD.

TABLE 1: Cardiac death rates on medical therapy with different extents of coronary artery disease

Extent of CAD	Annual mortality with medical therapy (%)
1-vessel	1.4
2-vessel	2.4
1-vessel >95% proximal LAD	3.4
2-vessel >95% proximal LAD	4.2
3-vessel	4.2
3-vessel >95% in at least 1	5.4
3-vessel >75% proximal LAD	6.6
3-vessel >95% proximal LAD	8.2

CAD, coronary artery disease; LAD, left anterior descending.

Source: Modified from Mark DB, Nelson CL, Califf RM, et al. Continuing evolution of therapy for coronary artery disease. Initial results from the era of coronary angioplasty. Circulation. 1994;89:2015-25.²¹

The findings of the most debated contemporary trial, "COURAGE" (Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation) comparing OMT versus OMT plus PCI, indicated that as an initial medical strategy in patients with SIHD, PCI did not reduce death, MI or other major cardiovascular (CV) adverse events when added to OMT.³ The patients in the COURAGE trial were symptomatic at baseline and had appreciable clinical comorbidity, a high prevalence of myocardial ischemia, and extensive angiographic coronary artery disease (CAD). Subgroup analysis of the COURAGE trial³ revealed consistency among clinical groups and found no difference between PCI plus OMT versus OMT alone in patients with multivessel CAD, low ejection fraction (EF), class II or class III angina or diabetes. During an extended follow up of 15 years, there was no difference in survival between an initial strategy with PCI plus OMT versus OMT alone in patients with SIHD⁴ as shown in table 2.

TABLE 2: Mortality in subjects on optimal medical therapy with percutaneous coronary intervention (PCI) versus without PCI on extended follow-up of COURAGE trial⁴

Mortality	With PCI	Without PCI
7 years	7.6% (85)	8.3% (95)
15 years	24.7% (284)	24.4% (277)

OMT, optimal medical therapy; PCI, percutaneous coronary intervention.

Two imaging substudies from the COURAGE trial provided discordant results between noninvasive assessment of ischemia and the potential benefits of revascularization.^{5,6} The discordance of these two substudies supports the equipoise regarding whether the extent and severity of myocardial ischemia are favorably affected by PCI. The question whether PCI can reduce the risk for CV death or MI in selected patients at higher risk for ischemia remains under investigation. ISCHEMIA trial is underway and is designed to answer this question.

Fractional flow reserve (FFR)-guided PCI strategy plus best available MT was also compared with best available MT alone in the FAME-2 trial.⁷ Findings from both the COURAGE and FAME-2 studies show that PCI reduces ischemia and need for further revascularization. Neither the FAME-2 nor the COURAGE showed a reduction in the incidence of death or MI with PCI. Based on data from randomized trials, it appears reasonable to pursue a strategy of initial MT for patients with SIHD and CCS class I or II and to reserve revascularization for those with severe symptoms, symptoms despite OMT, or with high-risk features.

The Bypass Angioplasty Revascularization Investigation 2 Diabetes (BARI 2D) trial tested treatment strategies for patients with SIHD and diabetes.⁸ The hypothesis was that a strategy of prompt revascularization (either surgical or percutaneous) will reduce long-term rates of death and CV events as compared to MT. A strategy of prompt coronary revascularization in patients who have been treated with intensive MT for diabetes and SIHD did not significantly reduce the rate of death or any other major CV event.

In the recently published ORBITA (Objective Randomised Blinded Investigation with optimal medical Therapy of Angioplasty in stable angina) trial,⁹ in patients with medically treated angina, PCI did not improve exercise time by more than that of a placebo procedure.

WHAT CONSTITUTES OPTIMAL MEDICAL THERAPY?

Given the impressive results of MT in multiple trials, a question arises as to what should be called as an OMT. In the COURAGE trial, MT comprised not only of antianginal medication, but also agents which modify atherosclerosis (Table 3). It is also important to realize that a high percentage of patients achieved guideline-directed targets. The excellent results of COURAGE are attributed to large number of drugs and extraordinary achievement of targets. In true sense, OMT involves antianginal and atherosclerosis modifying drugs and strict adherence to guideline-directed targets for risk

TABLE 3: Medications used in COURAGE trial³

Medication	OMT plus PCI (n = 1,149)	OMT alone (n = 1,138)
ACEI or ARB	717 (62%)	734 (65%)
Statins plus other antilipids	1,081 (94%)	1,108 (97%)
Aspirin	1,097 (96%)	1,077 (95%)
Beta-blockers	975 (85%)	1,008 (89%)
Calcium channel blockers	459 (40%)	488 (43%)
Nitrates	714 (62%)	825 (72%)

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; OMT, optimal medical therapy; PCI, percutaneous coronary intervention.

TABLE 4: Guideline-directed targets achieved in COURAGE trial³

Target achieved at 5-year follow-up	Percentage
LDL cholesterol <85 mg/dL	70%
Systolic BP <130 mm Hg	65%
Diastolic BP <85 mm Hg	94%
HbA1c <7.0%	45%

HbA1c, glycated hemoglobin; LDL, low-density lipoprotein; BP, blood pressure.

factor control. In COURAGE, these were achieved for low-density lipoprotein (LDL), glycated hemoglobin (HbA1c), and systolic and diastolic BP in a significant percentage of patients at 5 years of follow-up (Table 4). There were high rates of adherence to the regimen of diet, regular exercise, and smoking cessation.

In the light of above data, it is obvious that comprehensive management of SA involves many aspects and will be discussed under the following headings:

- Treatment of coexisting conditions that precipitate or worsen angina
- Management of coronary risk factors
- Interventions for secondary prevention including life style changes
- Pharmacotherapy for angina.

Treatment of Coexisting Conditions that Precipitate or Worsen Angina

Medical conditions like anemia, marked weight gain, occult thyrotoxicosis, fever, infections, and tachycardia can increase myocardial demand or reduce delivery and can contribute to onset of angina or exacerbation of SA. Identification and treatment of these conditions is important.

Management of Coronary Risk Factors

Lifestyle interventions can potentially prevent more than 90% of all cardiovascular disease (CVD) deaths. Nine risk factors accounted for 90% of the risk for MI in men and 94% of the risk in women in the INTERHEART study.¹⁰ The factors were abnormal lipids, smoking, hypertension (HT), diabetes,

abdominal obesity, psychosocial factors, low consumption of fruit and vegetables, alcohol consumption, and lack of physical activity.

Management of Dyslipidemia

Dyslipidemia should be managed according to lipid guidelines with pharmacological and lifestyle interventions. The 2013 American College of Cardiology/American Heart Association (ACC/AHA) guidelines for cholesterol management advocate high-intensity statin therapy in all patients with established ischemic heart disease and less than 75 years of age, in the absence of contraindications, with less emphasis on LDL target goals.¹¹ Other interventions (fibrates, resins, nicotinic acid, and ezetimibe) may lower LDL cholesterol, but no benefit in clinical outcomes has been reported for these alternatives.

Cigarette Smoking

Smoking remains one of the most important risk factors for CAD. It can aggravate angina and also add in the progression of atherosclerosis. Smoking cessation lessens the risk of coronary events and all strategies for smoking cessation should be adopted in smokers. Nicotine replacement therapy is safe and should be considered in individual cases.

Hypertension

Epidemiological links between increased blood pressure (BP) and CAD severity and mortality are well established. HT predisposes to vascular injury, accelerates the development of atherosclerosis, increases myocardial O₂ demand, intensifies ischemia in patients with preexisting obstructive CAD, and predisposes to atrial fibrillation (AF). BP control is an essential component of the management of patients with SA with a goal of less than 130/80 mm Hg according to the 2017 ACC/AHA guidelines.¹²

Management of Diabetes Mellitus

Diabetes mellitus (DM) is a strong risk factor for CV complications, increases the risk of progression of coronary disease and should be managed carefully, with good control of HbA1c to below 7.0% generally and 6.5–6.9% on an individual basis. Glucose control should be based on individual considerations, depending on the patient's characteristics including age, presence of complications, and diabetes duration.

Obesity

Obesity is usually associated with a constellation of other risk factors and can be associated with an increased risk of death in CAD. Weight reduction in overweight and obese people is recommended in order to achieve favorable effects on BP, dyslipidemia and glucose metabolism.

Diet

A healthy diet reduces CVD risk. Energy intake should be limited to the amount of energy needed to maintain (or obtain) a healthy weight—that is, a BMI less than 23 kg/m².

Physical Activity

Clinical practice guidelines for prevention of CVD recommend more than 150 minutes of moderate intensity or more than 60–75 minutes of vigorous exercise each week. Guidelines on secondary prevention of SIHD have recommended similar levels of regular moderate or vigorous exercise.¹³ A large scale study, STABILITY,¹⁴ from 39 countries in patients with SIHD demonstrated that low volumes of physical activity are associated with large risk reductions for CV and all-cause mortality. Increasing volume of physical activity yields additional health benefits.

Interventions for Secondary Prevention Including Lifestyle Changes

The objectives and different means for prevention of secondary events are described in table 5.

Aspirin

Aspirin remains the cornerstone of pharmacological prevention of arterial thrombosis. The benefits of aspirin in reducing vascular events, MI, and sudden death have been documented in several studies and meta-analysis. Administration of aspirin daily is advisable in patients with SIHD and no contraindication to this drug. Dosing at 75–162 mg daily appears to have comparable effects on secondary prevention as 160–320 mg daily and is associated with a lower bleeding risk. Thus, aspirin 75–162 mg daily is preferred for secondary prevention in absence of coronary stenting.¹⁵

Clopidogrel, a thienopyridine derivative, may be substituted for aspirin in patients with aspirin hypersensitivity or those who cannot tolerate aspirin.

Angiotensin-converting Enzyme Inhibitor and Angiotensin Receptor Blockers

The beneficial effects of angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs) include reductions in left ventricular hypertrophy, vascular hypertrophy, progression of atherosclerosis, plaque rupture, and thrombosis. These drugs are not beneficial for the treatment of angina; however, they have benefits in reducing the risk for future ischemic events.

Angiotensin-converting enzyme inhibitors should be prescribed in patients with SIHD who have DM, HT, reduced ($\leq 40\%$) left ventricular ejection fraction (LVEF), chronic kidney disease (CKD), or other vascular disease unless contraindicated.¹⁵ Those patients who cannot tolerate ACEIs are candidates for ARBs.

TABLE 5: Prevention of secondary events

Objectives	Measures
<ul style="list-style-type: none"> • Reduce plaque progression • Stabilize plaque • Prevent thrombosis 	<ul style="list-style-type: none"> • Aspirin • Statins • ACEI or ARBS • Lifestyle modification

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker.

Statins

Patients with documented CAD are regarded as being at very high risk and should be treated with statins. The treatment target is LDL-C less than 70 mg/dL and/or more than 50% reduction if the target level cannot be reached.

Antioxidants

According to current evidence, there is no basis for recommending supplemental folate, vitamin E, vitamin C, or beta carotene for the purpose of improving CV outcomes.

Lifestyle Changes

Certain changes in lifestyle can be useful in reducing episodes of angina. It is useful to counsel about dietary habits, physical activity, and types of work the patient can do.

Pharmacotherapy for Angina

Antiangular drugs are classified as first- or second-line drugs. There are also certain drugs which are not commonly used or are investigational (Box 1).

First-line Antiangular Drugs

First-line antiangular drugs alter the hemodynamics and can cause significant changes in the heart rate (HR) and BP. These include nitrates, β -blockers, and calcium channel blockers (CCBs). These drugs reduce anginal symptoms and prolong exercise duration and/or time to ST-segment depression on the electrocardiogram (ECG). Frequently, a combination of these drugs is necessary for symptom control. None of these drugs has been shown to be disease modifying. The first-line drugs are briefly discussed below.

Nitrates

Nitrates act by different mechanisms. The main mechanism is venodilatation, causing preload reduction and resultant relief in angina. They also cause arteriolar dilatation.

Glycerol trinitrate (GTN), isosorbide dinitrate (IDN), and isosorbide-5-mononitrate (IMN) are the commonly used

nitrates. They can be used via sublingual, oral, sustained oral, oral spray, transdermal patch, buccal, and intravenous route.

For quick relief, short-acting nitrates (GTN and IMN) are given sublingually and can be repeated every 5 minutes till complete relief of pain or maximum of 4–5 tablets. GTN spray (nitrolingual) can also be used for quick relief and the dose is 0.4 mg per spray. The long-acting nitrates used for angina prophylaxis are nitroglycerine, IDN, and IMN.

On prolonged administration, tolerance can develop to nitrates, and the same can be prevented by dosing free intervals. Common side effects include headaches, tachycardia, facial flushing, hypotension, and syncope. Coadministration of nitrates with a phosphodiesterase-5 inhibitor or alcohol can cause hypotension and should be avoided. Left ventricular outflow obstruction in hypertrophic cardiomyopathy can be worsened by nitrates.

Beta-blockers

Beta-blockers lower the HR, prolong diastolic filling, and improve the myocardial blood flow. They also reduce the cardiac output, and inhibit renin release, thus lowering BP and systolic wall stress. Beta-blockers are the standard of care after episodes of myocardial ischemia and in patients with heart failure (HF) with low EF. Mostly β 1 selective agents like metoprolol tartrate (short acting) or succinate (long-acting), bisoprolol, and carvedilol, with additional α -antagonist activity are preferred. Nebivolol, a highly selective β 1 blocker, has additional nitrate-like properties by generating nitric oxide and is preferred in elderly and in patients with chronic obstructive pulmonary disease.

Side effects and contraindications to β -blockers are summarized in table 6. Abrupt withdrawal of β -blockers after prolonged administration can precipitate angina. Withdrawing the drug should be done in a stepwise manner over the course of 2–3 weeks. The β -blockers may mask the clinical signs of hyperthyroidism and precipitate thyroid storm with abrupt discontinuation.

Calcium Channel Blockers

All CCBs (nondihydropyridine and dihydropyridine) have similar antiangular efficacy, cause epicardial vasodilatation, and are specifically useful in relieving vasospastic angina. Nondihydropyridine CCBs additionally reduce myocardial

TABLE 6: Side effects and contraindications to beta-blockers

Side effects	Contraindications
<ul style="list-style-type: none"> • Increased insulin resistance • Hampers exercise tolerance • Depressive symptoms • Sexual dysfunction • Raynaud's phenomenon • Aggravates peripheral arterial disease 	<ul style="list-style-type: none"> • Relative: <ul style="list-style-type: none"> ◦ Diabetes (masks hypoglycemia symptoms) ◦ Chronic obstructive pulmonary disease • Absolute: <ul style="list-style-type: none"> ◦ Severe bronchospasm ◦ Advanced atrioventricular block ◦ Sick sinus with bradycardia ◦ Untreated pheochromocytoma

BOX 1 Classification of antiangular drugs

First-line drugs:

- Beta-blockers
- Calcium channel blockers:
 - Dihydropyridine, e.g. amlodipine
 - Nondihydropyridine, e.g. verapamil, diltiazem
- Nitrates

Second-line drugs:

- Ranolazine
- Nicorandil
- Trimetazidine
- Ivabradine

Other drugs:

- Molsidomine
- Allopurinol
- Others (L-arginine, Bosentan, GLP-1 mimetics, etc.)

oxygen demand via negative inotropic and chronotropic action, whereas dihydropyridine CCBs improve bioavailability of nitric oxide and improve endothelial function.

Pedal edema, constipation, headache, and dizziness are common side effects. Ankle edema is due to increased capillary hydrostatic pressure from arteriolar dilatation. Nondihydropyridine CCBs can cause bradycardia and heart blocks. They may also precipitate or worsen congestive HF in those with systolic dysfunction. CCBs inhibit lower esophageal sphincter function and can cause gastroesophageal reflux.

There can be drug interactions with CCBs due to inhibition of hepatic microsomal enzymes. They may raise levels of statins and other drugs. Magnesium supplements may enhance the actions of CCBs by antagonizing calcium.

Second-line Antianginal Drugs

Many patients with chronic angina remain symptomatic despite receiving the combination of two or more first-line drugs at maximum tolerated dosages. Most of these drugs except nicorandil do not lower the BP. Table 7 summarizes important characteristics of second-line drugs. A brief discussion of each agent is described here.

Ranolazine

The antianginal efficacy of ranolazine has been established in the MARISA, CARISA, MERLIN-TIMI 36, ERICA, and TERISA trials.¹⁶ Ranolazine was approved by the United States Food and Drug Administration (FDA) in 2006 for management of chronic SA. Ranolazine inhibits the late inward sodium current and prevents intracellular calcium overload and diastolic relaxation failure. It prolongs the QT interval and is contraindicated in patients with congenital or acquired long-QT syndrome. An ECG should be obtained at baseline and follow-up to evaluate the drug's effect on QT interval. Ranolazine clearance is reduced in renal insufficiency and it is contraindicated in severe renal failure or moderate-to-severe hepatic impairment. Initial dose of ranolazine is 500 mg twice daily. For patients who remain symptomatic, 1,000 mg twice daily may be used. At very high doses of up to 2,000 mg/day, syncope and postural hypotension can occur due to α -adrenergic receptor blockade.

TABLE 7: Characteristics of second-line antianginal drugs

Drug	Mechanism of action	Dose	Contraindications	Major adverse effects
Ivabradine	Decrease pacemaker activity in sinus node	5–7.5 mg bd	Severe liver disease, low heart rate, and allergy	Visual disturbances
Nicorandil	Opening K ⁺ channels	20 mg bd	Low blood pressure and CCF	Oral, intestinal, and perianal ulceration
Ranolazine	Inhibition of Na ⁺ channels	500–2,000 mg daily	Liver cirrhosis	Nausea, dizziness, and QT prolongation
Trimetazidine	Inhibition of reduction of ATP, stimulation of glucose consumption by myocardium	20 mg tds or 35 mg bd	Pregnancy, breastfeeding, allergy, Parkinson's disease, tremors, movement disorder, seizures, and severe renal failure	Gastric discomfort, headache, and movement disorders

bd, twice a day; tds, thrice a day; CCF, congestive cardiac failure; ATP, adenosine triphosphate.

Ivabradine

Heart rate reduction is a recognized strategy for preventing myocardial ischemia and angina pectoris in patients with stable CAD. Ivabradine, by lowering the HR, has been shown to increase exercise capacity and reduce anginal frequency and severity. Ivabradine blocks transmembrane f-channels and disrupts I_f ion current flow. This blockade and disruption prolong diastolic depolarization and slow sinoatrial node firing, which in turn lowers the HR in a dose-dependent manner.

Post hoc analyses of a randomized trial have suggested that ivabradine might improve CV outcomes such as death, MI, or hospitalization for HF in patients with stable disease.¹⁷ However, data from SIGNIFY trial¹⁸ fail to confirm these findings. While ivabradine improved angina in patients with CCS class II angina or higher taking OMT, there was a concern about an increase in the risk of CV death and nonfatal MI. The use of ivabradine in patients with SA who do not have clinical HF is not recommended.

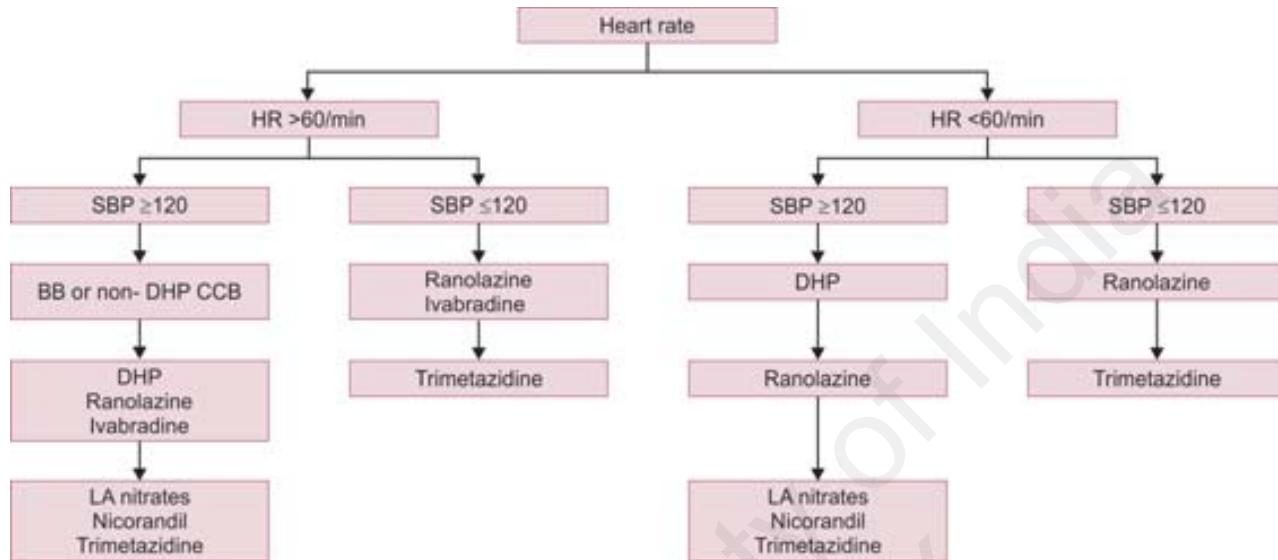

The common side effects include bradycardia, transient visual disturbances (phosphenes), and AF. Other adverse effects include first-degree atrioventricular block, headache, dizziness, uncontrolled BP, and ventricular extrasystoles.

Ivabradine has been approved by US FDA for reducing risk of hospitalization for HF in stable chronic HF patients with low EF (<35%), who are in sinus rhythm but not for angina. On the other hand, the European Medicines Agency (EMA) has also approved ivabradine for chronic SA in individuals not tolerating β -blockers.

Trimetazidine

Trimetazidine inhibits fatty acid β -oxidation and increases glucose utilization by myocardium, thereby preventing reduction of adenosine triphosphate (ATP) levels after hypoxia or ischemia and preserving ionic pump function. It also decreases free radical generation and prevents intracellular calcium overload and acidosis. Trimetazidine increases work capacity and delays the ECG changes and symptoms during exercise. As it has no effect on HR and BP, it can be used as an add-on drug with the first-line "hemodynamic" drugs.

The EMA has approved trimetazidine as an add-on drug in patients poorly controlled with first-line drugs. The US FDA has not approved the drug.

BB, β -blocker; CCB, calcium channel blocker; DHP, dihydropyridine; HR, heart rate; SBP, systolic blood pressure.

FLOWCHART 1: A tailored therapeutic approach for initiating therapy.²²

Nicorandil

Nicorandil opens the ATP-sensitive potassium channels, with additional nitric oxide donor action, effectively leading to direct coronary dilatation. It prevents angina and myocardial ischemia by its vasodilator action on systemic and coronary vessels. It does not cause tachyphylaxis or impair endothelial function.

The European Society of Cardiology (ESC) guidelines state “For second-line treatment it is recommended to add long-acting nitrates or ivabradine or nicorandil or ranolazine, according to HR, BP, and tolerance (IIa—B)” and may be considered in patients with microvascular angina with refractory symptoms (IIb—B). The National Institute for Health and Clinical Excellence (NICE) in the UK also recommends nicorandil for these purposes. Nicorandil is EMA—but not FDA—approved.

OTHER DRUGS FOR ANGINA

Molsidomine dilates venous capacitance vessels (reducing preload), dilates coronary arterial segments, exerts a platelet stabilizing effect by inhibiting thromboxane, and has a nitric oxide-donating effect. It has been available in Europe since 1977 but has not been approved by the US FDA.

Allopurinol, a xanthine oxidase inhibitor, is also antian- ginal. Allopurinol 600 mg/day increased times to ST-segment depression and to chest pain.¹⁹ In optimally treated SCAD patients, allopurinol reduced vascular oxidative stress, while in HF patients it conserved ATP.

L-Arginine, Bosentan, GLP-1 mimetics and DPP-4 analogues, Mildronate, Fasudil, Estrogen/Progesterone are other investigational drugs for angina and at present do not have a role in clinical practice.

How to Choose the Appropriate Antianginal Drug?

The guidelines do not provide any suggestions to guide choice within each step or among steps. A systematic therapeutic approach, tailored to individual profiles [BP, HR, diabetes, and left ventricle (LV) systolic function] and drug characteristics is necessary. Flowchart 1 describes an initial approach for selecting drugs for MT of chronic SA. Table 8 details the drug combinations which should be avoided during treatment of angina.

Stable Angina and Hypertension

In patients with SA, who require antihypertensive treatment, ESC guidelines suggest the use of renin-angiotensin system blockers, β -blockers, CCBs, and long-acting nitrates for symptomatic relief. These drugs, in addition to BP control, also present additional benefits in terms of symptom relief and favorable prognosis. The BP threshold levels in such patients have already been discussed.

TABLE 8: Drug combinations to be avoided or used with caution

Drug combination	Reason
Ivabradine + ranolazine + nicorandil*	No safety data
Ivabradine + nondihydropyridine CCBs *	Significant HR reduction
Beta-blockers + nondihydropyridine CCBs^	Significant HR reduction

*To be avoided

^Can be used with caution

CCB, calcium channel blocker; HR, heart rate.

Stable Angina and Heart Rate

There is robust evidence suggesting that increased HR in patients with CAD is harmful, since it increases myocardial oxygen demand leading to ischemia and anginal symptoms. Current ESC guidelines recommend the use of HR lowering agents such as β -blockers, nondihydropyridine CCBs, and ivabradine in order to decrease HR. Excessive HR reduction is not advisable, since it may lead to chronotropic incompetence-related symptoms. The SIGNIFY trial¹⁸ showed an increased risk of CV events and AF in patients with an excessive decrease in HR and ignited a debate about the HR threshold. Recently, a threshold level of 60 beats/min (except for ivabradine, which should not be initiated in HRs <70 beats/min) has been suggested. The use of drugs in patients with low HR is tricky and drugs with minimal or no HR effects are advised.

Atrial fibrillation may aggravate angina symptoms since it increases HR and thus myocardial oxygen consumption. Hence, in patients with SA and AF, HR lowering antianginal drugs such as β -blockers and nondihydropyridine CCBs should be preferred.

Diabetes with Stable Angina

The presence of DM leads to more extensive vascular disease and a more severe ischemic burden (both anginal and silent). When treating DM with angina, drugs that have a positive or at least a neutral metabolic profile have to be preferred. The use of β -blockers in diabetics has been debated given the higher incidence of new onset DM or worsening of the glycemic profile in these patients. It seems that these unfavorable effects are limited to the majority of the nonvasodilating β -blockers. In effect, vasodilating β -blockers present a favorable metabolic profile since they improve insulin sensitivity and they do not cause deleterious effects on lipid profile.

Ranolazine is an antianginal drug with favorable effects in reduction of HbA1c levels and may be preferred in patients with angina and DM for symptomatic relief.

Left Ventricular Systolic Function and Stable Angina

A large majority of HF cases with reduced EF are linked to CAD. In the subgroup of patients with HF and SA, it is preferable to administer drugs that not only reduce anginal symptoms, but also improve prognosis.

On the basis of the MERIT-HF, COPERNICUS, COMET, CIBIS-II studies, β -blockers, particularly metoprolol, carvedilol, and bisoprolol, are recommended for the long-term management of patients with angina and LV systolic dysfunction.²⁰ Beta-blockers reduce angina, delay HF, reduce the rate of rehospitalizations, and improve prognosis. Ivabradine is also useful in reducing angina and HF hospitalizations. Nitrates have a useful role, combining vasodilating and antianginal effect.

CONCLUSION

As highlighted in the manuscript, the therapy of SA should include aggressive treatment of risk factors, lifestyle modifi-

cations, and medications. The aim of therapy is preventing angina and reducing adverse CV outcomes. Therapy should be initiated with one or two first-line drugs, namely a β -blocker or CCB. Nitrates may be added for acute episodes of angina and prophylaxis. Ranolazine, nicorandil, and ivabradine can be used as add-on therapy. Addition of an ACEI or ARB is advised in those with HT, DM, CKD, previous MI and reduced LVEF less than or equal to 40%. The final choice of drugs should be individualized depending on patient profile and safety considerations.

Beta-Blockers in Chronic Stable Coronary Artery Disease: Current Status

J Shiv Kumar, M Sitaram, Sajith Pavitran, G Nagarjuna

INTRODUCTION

Coronary artery disease (CAD) is a major cause of death and disability all over the world. CAD is typically a chronic disease with progression over a period of years or decades.¹

Angina pectoris remains a major presenting symptom among patients of CAD, with numerically more patients of chronic stable CAD attending cardiology clinics than myocardial infarction (MI) (8.3% vs. 2.8%).²

Among the various remedies available for angina pectoris nitrates, β -blockers, calcium channel blockers (CCB) and angiotensin-converting enzyme inhibitors (ACEIs) and β -blockers have retained their important position because of their predictable response and their safety profile in different clinical situations.

The introduction of a new range of β -blockers with additional pharmacological properties has ensured the β -blockers their place in the prescriptions for CAD in years to come.

INCIDENCE AND PREVALENCE

The 2016 heart disease and stroke statistics update of American Heart Association (AHA) reports that 15.5 million adults (6.2% of adult population) have CAD, including 7.6 million (2.8%) with MI and 8.2 million (3.3%) with angina pectoris. These estimates of CAD increase with age in both sexes. An individual's risk factor burden translated in to marked differences in life time risk of CAD and these differences are consistent across all races in both cohorts.²

It is well known that despite paucity of symptoms, the extent of nonobstructive CAD is associated with worse prognosis, compared with adults without CAD.

The incidence of CAD and CAD mortality has been steadily decreasing in the USA and other Western countries, while the incidence of CAD is increasing alarmingly in Southeast Asian countries including India. With the increasing average lifespan of individuals across the globe, the global burden of chronic stable CAD is poised to increase sharply in future,

with predictable concerns about spiraling costs of public health care.

PATHOPHYSIOLOGY OF CORONARY ARTERY DISEASE

Atherosclerosis is a chronic inflammatory process triggered by accumulation of cholesterol containing low-density lipoprotein (LDL) particles in the arterial wall. Major etiological factors include hyperlipidemia, hypertension, diabetes, and cigarette smoking—all of which are thought to initiate and promote vascular inflammation.

Atherosclerotic disease of the epicardial coronary arteries has been recognized as the cause of angina pectoris for more than two centuries, and sudden thrombotic occlusion of an epicardial coronary artery has been well established as the cause of acute MI for more than 100 years.

However, the epicardial arteries are only one segment of the arterial circulation. They give rise to myriads of smaller blood vessels, and arterioles which constitute the coronary microcirculation—the main site of regulation of myocardial blood flow.

The coronary arteries are classified as three components:

1. Proximal conductance vessels (500 μm to 3–5 mm)
2. Intermediate (periarteriolar vessels 100–500 μm)
3. Distal (arteriolar vessels <100 μm).

The cardiac pump is an aerobic organ that requires continuous perfusion with oxygenated blood to generate the adenosine triphosphate (ATP), the vital substrate for ventricular contraction.¹ The role of coronary circulation is to provide an adequate match between myocardial oxygen demand and supply. The integrated coronary response to increase in oxygen demand is an excellent example of autoregulation in regional blood flow in human body.³

It consists of:

- Metabolic vasodilators
- Periarteriolar autoregulation
- Flow mediated, endothelium-dependent vasodilatation

- Extravascular tissue pressure
- Neurohumoral control.

Small arteries and arterioles are richly innervated by both sympathetic and parasympathetic nerve terminals that play an important role of regulation of coronary blood flow.

Neural and biohumoral regulation of the coronary microcirculation has been receiving increasing attention in the recent years and the effect of sympathetic overactivity over the coronary microcirculation has been the focus of renewed interest.

Sympathetic nervous system in the heart controls the circulatory adaptation in coronary bed through the following pathways:

- Beta 1-adrenoceptors mediated chronotropic, inotropic, and dromotropic effects
- Beta 2-adrenoceptors mediated vasodilatation of smaller coronary arterioles
- Alpha 1-adrenoceptors causing vasoconstriction in coronary vessels constriction
- Alpha 2 vasoconstriction in microcirculation.

This paradoxical vasoconstriction in smaller coronary arteries and microcirculation is believed to help preserve flow in the vulnerable inner layer of left ventricle (LV) especially during exercise.

Parasympathetic neural response over coronary arteries is one of uniform vasodilatation.

Nitric oxide (NO) production and release are the main mechanism of endothelium mediated vasodilatation.

Defective release of NO might be the etiological factor in patients with chest pain and normal coronaries as well as in patients with chronic stable angina.

Myocardial oxygen demand is the ultimate determinant of clinical outcomes and the importance of the supply versus demand equation in the coronary vascular bed is well recognized.

Myocardial oxygen demand is based on three factors namely: (1) heart rate (HR), (2) ventricular systolic pressure, and (C) LV size. Of these, HR and systolic LV pressure seem to be the key determinants of oxygen consumption of the heart and the double product [HR × systolic blood pressure (SBP)] is considered to be a reliable index of the same. These variables increase the workload of the LV and also increase the wall stress in the LV, indirectly increasing the resistance to coronary filling.⁴

Drugs that reduce the HR and BP thus aid in improving the LV function by reducing the LV wall stress and improving diastolic coronary blood flow.

PHARMACOTHERAPEUTICS OF BETA-BLOCKERS

Beta-adrenoceptors are G protein coupled transmembrane proteins. Their main antianginal action lies in the intracellular part of the β-receptor that is coupled to the G protein complex Gs (stimulating) and Gi (inhibitory). Agonists bind to the ligand site and stimulate the β-adrenergic receptors (β₁, β₂, and β₃ subtypes). This binding triggers adenylyl cyclase to convert cyclic ATP to cyclic AMP which acts as a second

messenger initiating a cascade of events that are organ dependent. Interaction with Gs complex mediates positive inotropic and chronotropic actions while interaction with Gi complex may mediate the antiapoptotic effect of β₂ receptors.

Beta-blockers exert several cardioprotective effects. Despite the action of β₁ inhibition in blocking coronary vasodilation, there is overall benefit in coronary circulation because of the slowing of the HR and prolonging the diastole (the main period of coronary flow). In addition, by reducing cardiac output and by inhibition on renin release from the juxtaglomerular cells, β-blockers lower the BP and thus reduce systolic heart stress.⁵

The main mechanisms of protection of ischemic myocardium by β-blockers have been tabulated in box 1.

NEWER GENERATIONS OF BETA-BLOCKERS

Beta-blockers have remained as the main stay in treatment of CAD and their utility has been further enhanced by the synthesis of β-blockers with selective action on the β-receptors.

Although the β-blockers as a group have similar therapeutic effects, their pharmacological properties are markedly different. The classification of β-blockers and their individual properties are outlined in table 1.⁶

Beta-blockers exert their antianginal effect mostly by their action of β₁ receptor inhibition. Selective β₁-blockers (like atenolol, bisoprolol, metoprolol, and nebivolol) have minimal effect on β₂-receptors localized in bronchial muscle and thus may be preferable in patients with chronic obstructive airway disease or bronchial asthma. However, these drugs become less selective at higher doses and may begin to block β₂-adrenoceptors in the tracheobronchial tree causing bronchospasm. Furthermore β₁ selective blockers should be used with caution in patients with peripheral vascular disease.

The vasodilator activity of some of the newer generation of β-blockers is achieved through two pathways:

BOX 1 Possible mechanisms of protection of ischemic myocardium by beta-blockers

- Reduction in myocardial oxygen demands via:
 - Negative inotropic action
 - Reduction of heart rate
 - Blood pressure decrease
- Increase of coronary blood flow via:
 - Increase in diastolic perfusion time by reducing heart rate
 - Augmentation of collateral blood flow
 - Redistribution of blood flow to ischemic areas
- Alterations in the myocardial substrate utilization
- Decrease the microvascular damage
- Stabilization of the cell and lysosomal membranes
- Shift the oxyhemoglobin dissociation curve to the right
- Inhibition of the platelet aggregation
- Protection of myocardial cell against catecholamine-induced transmembrane potassium shifts

TABLE 1: Classification and physiological actions of β -adrenergic receptors and β -blockers used in angina pectoris

Drug	ISA	Plasma half-life (h)	Lipid soluble	Plasma protein binding (%)	Dosage for angina (mg)
Non-cardioselective					
Propranolol (inderal)	–	8–11	+++	90	80–320
Nadolol	–	20–24	0	98	40–80
Penbutolol					
Sotalol	–	7–8	0	5	80–240 BID
Timolol	–	4–5	+	60	10 mg/BID
Cardioselective					
Acebutolol	++	8–13	0	15	400–1,200
Atenolol	–	6–7	0	10	50–200 QD
Bisoprolol	–	9–12	+	30	10 mg/QD
Metoprolol	–	3–7	+	12	50–200/BID
Vasodilatory (nonselective)					
Labetalol	–	6–8	+++	90	300–600
Pindolol	β_1, β_2	4	+	55	2.5–7.5
Carvedilol	–	6	+	95	12.5–25
Selective					
Nebivolol	–	6–10	++	98	2.5–10

- Combined β - and α -adrenergic receptor blockade (labetalol and carvedilol).
- Direct vasodilator activity through activation of NO synthase and release of NO (nebivolol).

Carvedilol may also ameliorate myocardial ischemic effects by different mechanisms:

- Inhibition of monocyte adhesion to endothelium
- Scavenging oxygen free radicals
- Protection of endothelial function
- Direct vasodilation
- Inhibition of LDL protein oxidation.

Nebivolol has greater selectivity for β_1 -receptors than all other β -blockers. The NO potentiating vasodilatory effect of nebivolol is unique among β -blockers and at doses below 10 mg/day does not inhibit the increase in HR normally seen with exercise.^{7,8}

ADVERSE EFFECTS OF BETA-BLOCKERS

- Negative metabolic effects:
 - Increase in insulin resistance and predisposition to diabetes
 - Weight gain
 - Worsening of glycemic control.
- Bradycardia and heart block
- Worsening of peripheral vascular disease and Raynaud's phenomena
- Bronchospasm.

In a meta-analysis of clinical trial experiences over 20 years, it was proven that β -blockers provide equal reduction of angina and cardiovascular (CV) adverse events compared to CCBs or nitrates.⁸

Beta-blockers in CAD with LV dysfunction needs special mention in view of increasing benefits noted in this subset.⁹

The Cardiac Insufficiency Bisoprolol Study (CIBIS) trial (1994) showed 32% reduction in all-cause mortality in New York Heart Association class III and IV patients of ischemic and nonischemic cardiomyopathy treated with β -blockers.¹⁰

The Metoprolol CR/XL Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF) trial (2002) established the role of β -blockers in patients with heart failure where 34% reduction in mortality was noted in patients taking metoprolol versus placebo.¹¹

The Carvedilol Post-Infarct Survival Control in LV Dysfunction (CAPRICORN) (2001) trial was the only large randomized clinical trial where patients of recent MI and LV dysfunction were studied in the era of reperfusion and the subjects followed up for 1.3 years showed significant reduction in CV mortality in the group treated with carvedilol.¹²

The Carvedilol Prospective Randomized Cumulative Survival (COPERNICUS) trial (2001) showed that in CAD patients with reduced EF (as low as <25%) carvedilol reduced 12 months mortality figures by 38% and risk of death or hospitalization by 31%.¹³

GUIDELINES FOR USE OF BETA-BLOCKERS IN ANGINA

American Heart Association has made the following recommendations in 2012 regarding β -blockers in treatment of stable ischaemic heart disease.¹⁴

AHA recommendations

Class I

- Beta-blocker therapy should be continued for 3 years in all patients with normal LV function after MI or ACS (264–266) (level of evidence B)

- Beta-blockers therapy should be used in all patients with LV systolic dysfunction (EF 40%) with heart failure or prior MI, unless contraindicated (level of evidence A).

Class II

BB may be considered as chronic therapy for other CAD patients (level of evidence C).

The European Society of Cardiology (ESC) guidelines have noted that β-blockers may be protective in patients with stable angina but without support of firm placebo-controlled clinical trials. It was pointed out that a recent retrospective study (REACH registry)¹⁵ found that the risk of CV events was not lowered in CAD patients without prior MI despite using β-blockers. In summary it was mentioned that there was evidence for prognostic benefits from the use of β-blockers in post-MI patients or in heart failure and that extrapolation from these data suggested that β-blockers may be the first-line antiangina therapy in stable CAD patients without contraindications.¹⁶

ESC Recommendations for Beta-blockers

- For angina relief class: I, level A
- For asymptomatic patients with large area of ischemia (>10%): class IIb level C.

CONCLUSION

Beta-adrenergic blockade has always remained the first-line of treatment for patients with chronic stable angina along with nitrates. The symptomatic relief from angina and reduction of recurring ischemic events even in the face of mild-to-moderate LV dysfunction, will continue to make this class of drugs a front line management choice. However, the reduction in mortality is seen only in the post-MI angina group of patients. There are new additions to subclasses of β-blockers with additional therapeutic benefits, but the clinician is well advised to be conversant with a few of the proven agents and their side effects rather than change drugs frequently.

Revascularization in Chronic Stable Angina—Current Status

Parneesh Arora, Upendra Kaul

INTRODUCTION

Chronic stable angina (CSA) also labeled as stable coronary artery disease (CAD) or stable ischemic heart disease (SIHD)¹ refers to patients with angina, its equivalent, or no symptoms who experience episodes of reversible myocardial supply demand mismatch, in absence of acute myocardial infarction (MI) or unstable angina. Nearly 300,000 percutaneous coronary interventions (PCIs) are performed annually in patients with SIHD in USA alone² and probably numbers in India would be much higher. As per National Interventional Council (NIC) registry for 2011, 22.3% of 152,332 PCI were for SIHD.³ Data from randomized trials conflicts with current practice which is probably based on premise that wherein, epicardial stenosis is the cause of angina, ischemia, myocardial infarction, and death and these can be prevented by revascularization. This was probably outcome of landmark angiography-based studies which documented natural history of epicardial CAD and its adverse impact of survival.⁴ Other studies correlating abnormal exercise stress test findings with presence of obstructive CAD⁵ added fuel to the fire.

However, the trials subsequently did not bear out initial enthusiasm and need to be considered in order to understand current approach to patients with SIHD.

EVIDENCE FROM TRIALS

The proof whether PCI affects hard outcomes over medicine comes from randomized trials.

Prevention of Death and Myocardial Infarction

Trials comparing optimal medical therapy (OMT) to PCI, consistently showed disappointing result. The first trial to be done was ACME⁶ trial (Angioplasty Compared to Medicine) in 1992 in 212 patients which though reported improvement

in angina (64% vs. 54%) and exercise tolerance, but did not reduce mortality or MI. Subsequently, MASS⁷ (Medicine, Angioplasty, or Surgery Study) included high-risk patients, with proximal left anterior descending (LAD) artery stenosis was negative for reduction of mortality and MI. RITA-2⁸ (Second Randomized Intervention Treatment of Angina) a large trial of 1,000 patients, death or MI were less frequent with medical therapy than PCI (3.3% vs. 6.3% p = 0.02). Angina improved more with PCI with 16.5% absolute excess of grade 2 or worse angina in the medical therapy group at 3 months (p <0.001).

In the stent era, MASS II⁹ trial involving 611 patients with SIHD and proximal LAD stenosis, medical therapy reduced composite end point of cardiac mortality, MI, or refractory angina compared to PCI.

The landmark COURAGE¹⁰ (Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation) trial compared initial strategy of PCI with protocol mandated OMT, with OMT alone in 2,287 patients with angina or objective evidence of ischemic and significant CAD (>70% stenosis). Crossover from OMT to PCI for refractory angina was permitted. After 4.6 years, there was no difference in death or nonfatal MI between two groups with 30% crossover from OMT group to percutaneous transluminal coronary angioplasty (PTCA). A meta-analysis in 2012¹¹ also did not show improvement in survival [odds ratio (OR) 0.98; 95% confidence interval (CI): 0.83–1.15] or in MI (combined OR 1.12; 95% CI: 0.93–1.34).

High-risk Subgroups

- *Diabetes mellitus:* The BARI 2D¹² trial of 2,368 patients with type 2 diabetes mellitus and stable CAD did not show any difference in mortality or major adverse cardiac events (MACE) at 5 years between PCI with medical management versus intensive medical management group. Subgroup analysis for amount of jeopardized myocardium, number of diseased vessels, numbers of

lesions, proximal LAD disease, abnormal left ventricular function, prior revascularization, presence of total occlusion was also negative indicating the events are not prevented by PCI

- *Proximal LAD:* In COURAGE trial MACE were more in patients with proximal LAD stenosis more than 90%, however, PTCA did not improve these outcomes ($p = 0.79$)¹³
- *Three vessel CAD and low ejection fraction:* Again in COURAGE trial though survival was reduced in this subgroups of patients, however there was no benefit from initial PTCA and OMT compared to OMT alone.¹⁴

Hemodynamic Assessment of Significance of Epicardial Stenosis

With disappointing results from previous anatomy-based trials, tools to assess hemodynamic significance of epicardial CAD were developed. The hypothesis was that probably replacing oculostenotic reflex with ischemic PCI reflex, would lead to improved outcomes. Fractional flow reserve (FFR) is one such method and cut-off of FFR less than 0.8 was suggested for hemodynamically significant stenosis.

The FAME¹⁶ (Fractional Flow Reserve versus Angiography for Multivessel Evaluation) trial randomized 1,005 patients to angiography-guided PTCA or FFR-guided PTCA. FFR-guided PTCA was associated with fewer PTCA and reduction in end point of death, MI or revascularization at 2 years. However, FAME-2¹⁷ trial which randomized 888 patients to initial PCI + medical therapy against medical therapy alone did not show any difference in death, or MI at 2 years following. The subsequent analysis after excluding events in first 7 days, cited balance in favor of PCI group for reduction of MI. The criteria for diagnosis periprocedural MI were however questioned. The trial was terminated prematurely because composite end point favored FFR groups driven solely by urgent revascularization which was also criticized because of confounding factors.

In the recently published ORBITA¹⁸ (Percutaneous Coronary Intervention in Stable Angina) trial 200 patients with ischemic symptoms having more than 70% single vessel stenosis were randomized to PCI (105 patients) and placebo procedure (95 patients), FFR was 0.69. There was no significant difference in primary end point of exercise time increment between groups at 6 weeks. In a subsequent analysis however it was shown that the stress echocardiography findings did improve in patients undergoing PCI and patients with lower FFR values benefitted more.¹⁹

CURRENT APPROACH TO REVASCULARIZATION FOR SIHD

Primary to understanding the current approach to SIHD is to understand that ischemia can result from dysfunction anywhere along vascular delivery conduit from aorta to microvasculature. This will help not only in selecting appropriate medical therapy for patients but also to

select patients who would benefit from revascularization. Assessment of hemodynamic severity of stenosis in coronary artery is an integral part of selecting patients for intervention.

Assessment of Hemodynamic Severity of Epicardial Stenosis

- Fractional flow reserve is defined as ratio of mean distal coronary pressure to mean aorta pressure and requires induction of maximum hyperemia with pharmacological agents most common being adenosine. Incorporating stenosis severity, myocardial territory and viability, collateral perfusion, FFR can assess functional significance of a coronary stenosis. There is overall an acceptable correlation with noninvasive functional testing.²⁰ The cut-off value of 0.80 has been validated in multiple prospective randomized trial.²¹ Trials with FFR-based revascularization and their outcomes are shown in table 1²²
- Instant wave-free ratio (iFR) has been introduced as an alternative for FFR. This offers drug-free index of stenosis severity with accuracy comparable to FFR²³ and does not require induction of hyperemia. Instant wave-free ratio-guided revascularization has been proven to be noninferior to FFR-guided revascularization for MACE at 1 year follow up in two large randomized multicenter trials.^{24,25}

INDICATIONS FOR CORONARY ANGIOGRAPHY

Current indications for coronary angiography for patients with SIHD as per American College of Cardiology are mentioned in table 2.²⁶

CHOICE OF REVASCULARIZATION PCI OR CORONARY ARTERY BYPASS GRAFTING

- *Percutaneous coronary intervention versus coronary artery bypass grafting (CABG) overall:* Out of all trials available, the only large randomized trial comparing CABG and drug-eluting stents (DES) in current era is the SYNTAX Trial²⁷ (SYNergy between percutaneous coronary interventions with TAXus and cardiac surgery). In this trial patients were randomized to receive either DES or CABG. MACE of death, stroke, MI or repeat revascularization during 3 years after randomization occurred in 20.2% of CABG patients and 28.0% PCI with DES patients ($p <0.001$), largely driven by less MI and less repeat revascularization in CABG group. At 5 years follow-up MACE was 26.9% for CABG and 37.3% for PCI ($p <0.0001$) and combined endpoint of death, stroke and MI were also lower in CABG group ($p = 0.03$). Complexity of CAD was scored in the trial (SYNTAX score) with low score (<22) including less complicated, 23–32 indicating intermediate, and more than 33 indicating complicated anatomy. At 12 months MACE was same for CABG and

TABLE 1: Fractional flow reserve-based intervention trials and outcomes

Study name	Year	Size	Trial design	Clinical presentation	FFR cut-off	Outcomes
DEFER	2001	325 patients at 14 medical centers	Prospective, randomized	Stable chest pain and an intermediate stenosis without objective evidence of ischemia	0.75	No benefit stenting a nonischemic stenosis
FAME	2009	1,005 patients at 20 medical centers	Prospective, randomized	Multivessel CAD	0.80	Routine measurement of FFR in patients with multivessel CAD who are undergoing PCI with drug-eluting stent significantly reduces MACE at 1 year
FAME 2	2012	888 patients at 28 medical centers	Prospective, randomized	Stable CAD and hemodynamically significant stenoses	0.80	FFR-guided PCI with drug-eluting stent + OMT vs. OMT alone decreased the rate of urgent revascularization. In FFR negative lesions, OMT alone resulted in excellent outcomes, regardless of the angiographic appearance of the stenoses
Muller et al.	2011	730 patients at 1 Belgium center	Observational, nonrandomized study	Angiographically intermediate isolated proximal LAD stenosis	0.80	Medical treatment is associated with favorable long-term clinical outcomes in angiographically equivocal lesions nonischemic by FFR
Mayo Registry	2013	7,358 patients at the Mayo Clinic	Retrospective registry	Patients undergoing PCI, excluding STEMI or cardiogenic shock	<0.75 → PCI 0.75–0.80 → operator discretion >0.8 → OMT	FFR-guided treatment strategy is associated with a favorable long-term outcome with decreased MACE
Van Belle et al. (R3F)	2014	1,075 patients at 20 centers in France	Prospective observational study	Angiographically ambiguous lesion	0.80	FFR during diagnostic angiography is safe and associated with reclassification of the revascularization decision in about half of the patients
RIPCORD	2014	200 patients at 10 centers in the United Kingdom	Prospective observational study	Stable angina	0.8	FFR has an important influence both on which coronary arteries have significant stenosis and on patient management
DANAMI-3-PRIMULTI	2015	627 patients at two centers in Europe	Prospective randomized controlled trial	Patients with STEMI and multivessel disease who had undergone primary PCI of an infarct-related coronary artery	0.80	Complete-staged revascularization during the index admission, guided by FFR reduces the risk of future events, driven by fewer repeat revascularizations
Compare-Acute	2017	885 at 24 centers in Europe and Asia	Prospective randomized controlled trial	Patients with STEMI and multivessel disease who had undergone primary PCI of an infarct-related coronary artery	0.80	FFR-guided complete revascularization of noninfarct-related arteries in the acute setting resulted in lower MACE, driven by decreased revascularization
IRIS-FFR	2017	5,846 patients	Prospective registry	Patients with at least one coronary lesion	0.75	FFR ≤0.75: The risk of MACE was significantly lower in revascularized lesions than in deferred lesions. Lesions with FFR ≥0.76, the risk of MACE was not significantly different between deferred and revascularized lesions

CAD, coronary artery disease; FFR, fractional flow reserve; IRIS, Interventional Cardiology Research Incooperation Society; LAD, left anterior descending; MACE: major adverse cardiac events; OMT: optimal medical therapy; PCI: percutaneous coronary intervention; STEMI: ST-elevation myocardial infarction.

TABLE 2: Indications for coronary angiography in patients with stable ischemic heart disease

Class	Indication	Level of evidence
I (indicated)	Patients with SIHD who have survived sudden cardiac death or potentially life-threatening ventricular arrhythmia should undergo coronary angiography to assess cardiac risk	B
	Patients with SIHD in whom symptoms and signs of heart failure develop should be evaluated to determine whether coronary angiography should be performed for risk assessment	B
	Coronary angiography is recommended for patients with SIHD whose clinical characteristics and results of noninvasive testing indicate a high likelihood of severe ischemic heart disease and when the benefits are deemed to exceed risk	C
II (good supportive evidence)	Coronary angiography is reasonable to further assess risk in patients with SIHD who have depressed LV function (EF <50%) and moderate-risk criteria on noninvasive testing with demonstrable ischemia	C
	Coronary angiography is reasonable to further assess risk in patients with SIHD and inconclusive prognostic information after noninvasive testing or in patients for whom noninvasive testing is contraindicated or inadequate	C
	Coronary angiography for risk assessment is reasonable for patients with SIHD who have unsatisfactory quality of life because of angina, have preserved LV function (EF >50%), and have intermediate-risk criteria on noninvasive testing	C

EV, ejection fraction; LV, left ventricle; SIHD, stable ischemic heart disease.

PCI for low SYNTAX score, but was higher in PCI group with intermediate or high score. At 3 years follow-up the mortality rate was greater in subjects with three-vessel CAD treated with DES than those with CABG. It seems reasonable to conclude that for complex and diffuse CAD, CABG scores over PCI but for uncomplicated or less complicated anatomy survival rate is same.

- *Percutaneous coronary intervention versus coronary artery bypass grafting for left main coronary artery disease:* In SYNTAX trial after excluding patients who underwent surgery because of complex disease, 705 patients with unprotected left main disease were randomized to PCI or CABG. Majority had low SYNTAX scores. At 1 year rates of all-cause death and MACE score were similar.²⁷ Repeat revascularization was more common in PCI group than in CABG (11.8% vs. 6.5%), but stroke was more common in CABG group (2.7% vs. 0.3%). At 5 years follow-up MACE rates did not differ for low or intermediate SYNTAX scores, but for high SYNTAX scores MACE was higher for PCI group (46.5% vs. 29.7%, p = 0.003). In PRECOMBAT (Premier of Randomized Comparison of Bypass Surgery Versus Angioplasty Using Sirolimus-Eluting Stent in Patients With Left Main Coronary Artery Disease) study of 600 patients composite endpoint of death, MI or stroke at 2 years was same (4.4% vs. 4.7%) for PCI versus CABG but target lesion revascularization was more often required in PCI group (9.0% vs. 4.2%).²⁸

The above randomized trials suggest that major clinical outcomes in selected patients with left main CAD are similar with CABG and PCI at 1–2 years follow-up but repeat revascularization rates are higher after PCI than after CABG

- *Percutaneous coronary intervention or coronary artery bypass grafting in diabetes mellitus:* A comprehensive meta analyses of 8 trials in patients with diabetes mellitus

and multivessel CAD establishes the superiority of CABG over PCI in this subset of patients. At 5 years or longest follow-up, patients with diabetes mellitus randomized to CABG, had lower all-cause mortality rate than those randomized to PCI with DES or bare metal stents (RR 0.67%; 95% CI: 0.52–0.86; p = 0.002).²⁹ Patients with diabetes should receive guideline indicated medical therapy and revascularization should be considered in those with symptoms impacting quality of life. Current indications for CABG and PCI are mentioned in table 3.

Based on above evidence flowchart 1 shows suggests algorithm for approach to revascularization to improve survival and flowchart 2 shows the algorithm for revascularization to improve symptoms.

CONCLUSION

Chronic stable angina or SIHD needs to be viewed as a syndrome where ischemia may result from pathology anywhere from epicardial stenosis to resistance vessels. Hence, if mechanism can be identified then selecting appropriate patients for revascularization would be possible. This is essential because despite multiple trials there is no evidence that strategy of initial revascularization especially routine PCI scores over medical therapy as far as hard cardiovascular outcomes are concerned. If at all there is evidence for survival benefit of patients it is for CABG where indicated. Compared to CABG, in select patients, PCI may offer similar outcomes at least in intermediate follow-up (around 5 years). Strategies for hemodynamic assessment like FFR and iFR may help in deciding which patients may have comparable results for PCI versus CABG as well as which patients can be continued on OMT.

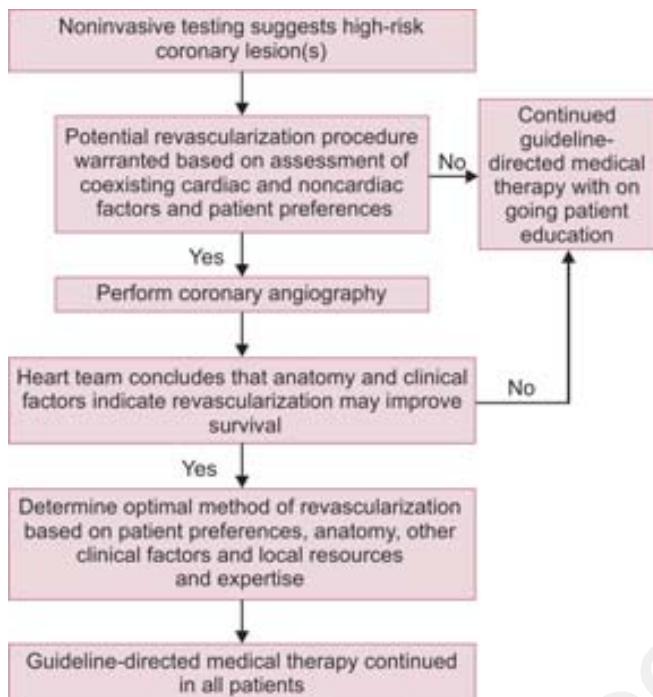

TABLE 3: Guidelines for coronary artery bypass grafting and percutaneous coronary intervention in stable ischemic heart disease^{30,31}

Anatomic setting	Class	Recommendation	Levels of evidence
Unprotected left main			
CABG	I		B
PCI	IIa	For SIHD when both of the following are present: • Anatomic conditions associated with a low-risk for PCI procedural complications and a high likelihood of a good long-term outcome • Clinical characteristics that predict a significantly increased risk for adverse surgical outcomes	B
	IIb	For SIHD when both of the following are present: • Anatomic conditions associated with a low to intermediate risk for PCI procedural complications and an intermediate to high likelihood of a good long-term outcome • Clinical characteristics that predict increased risk for adverse surgical outcomes (e.g., STS-predicted operative mortality >2%)	B
	III	For SIHD in patients (vs. performing CABG) with unfavorable anatomy for PCI and who are good candidates for CABG	B
Three-vessel coronary artery disease with or without proximal left anterior descending coronary artery disease			
CABG	I		B
PCI	IIa	It is reasonable to choose CABG over PCI in patients with complex three-vessel CAD (e.g., SYNTAX score 222) who are good candidates for CABG	B
	IIb		B

Revascularization in Diabetes: Rational Choices in 2018

Rajiv Agarwal

SUMMARY

The outcome of coronary revascularization in diabetic patients is undeniably worse than that in nondiabetics regardless of the modality chosen. Large randomized trials have looked at the choice between coronary artery bypass grafting (CABG) and percutaneous coronary intervention (PCI) in diabetic patients including BARI, BARI 2D, ARTS II, CARDia, VA-CARDS, and BEST besides the SYNTAX and FREEDOM trial. They all suggest that in stable multivessel disease with diabetes, CABG offers superior outcome as compared to PCI including approximately 30% mortality benefit with CABG. There is lower incidence of angina and repeat revascularization and also fewer hard endpoints like recurrent myocardial infarction (MI) and mortality with CABG. Stroke, however, occurs more frequently after CABG than with PCI. Coronary revascularization guidelines, therefore, recommend CABG over PCI for stable multivessel disease in diabetic patients as a class I recommendation.

The SYNTAX trial looked at anatomical complexity of coronary disease and suggested that in the low-risk tertile (SYNTAX score ≤22), diabetic multivessel disease patients did as well with PCI, even with the now obsolete Taxus stent, as with CABG.

The randomized trials do not represent the full spectrum of diabetic patients undergoing revascularization as often patients with weak hearts, repeat procedures and comorbidities are excluded. In many such patients in the real world, PCI may be chosen over CABG with a reasonable expectation of faster recovery and less procedure-related morbidity even at the cost of more incomplete revascularization. There is also a strong patient preference for less invasive treatment by PCI rather than CABG, provided results can be assured. Registry data also documents the marked preference for PCI over CABG even in multivessel diabetics in clinical practice despite better results with surgery. Hence, the continuing search to define the subsets, if any, of multivessel diabetic patients who can safely be offered PCI.

The results of PCI are continually improving with second-generation drug-eluting stents (DES) performing better than the first generation. In a network meta-analysis of diabetic patients, second-generation DES had equivalent outcome to CABG.

The heart team is useful in evolving consensus here. Diabetes alone cannot lead to a reflexive recommendation of CABG for revascularization. Decisions should be guided by data including accounting for both coronary anatomy (SYNTAX score) and clinical factors to predict mortality by SYNTAX-II. Recent data suggests that with modern techniques including the above and fractional flow reserve (FFR) guidance, PCI outcomes are better than historical controls and comparable to CABG even in the diabetic patient.

There is urgent need for a new randomized trial using contemporary techniques of PCI and CABG. We need to be forward looking but vigilant against hype.

INTRODUCTION

Approximately 20–30% of patients admitted with acute coronary syndromes (ACS) have diabetes mellitus (DM), mostly type 2 diabetes (T2DM).¹ Diabetes increases the risk of developing coronary artery disease (CAD) and has been called a CAD risk equivalent.² An individual with diabetes has the same coronary disease risk as a person with prior MI. The prognosis of a diabetic with MI is worse than that of a nondiabetic. This is especially true in long-standing diabetics and those on insulin therapy. Coronary atherosclerosis is more extensive in diabetic patients, with faster disease progression, more diffuse disease, more left main involvement and poorer outcomes with any revascularization treatment as compared to patients without diabetes.³ Diabetic patients have increased platelet reactivity and impaired responsiveness to clopidogrel which can be a problem following coronary stents.⁴ Diabetic patients also tend to have more restenosis after balloon angioplasty and bare metal stents than nondiabetics.^{5,6}

SURGERY OR PERCUTANEOUS CORONARY INTERVENTION

Coronary revascularization is a key component of the management of the patient with diabetes and is the focus of this paper. The outcome of coronary revascularization in diabetic patients is undeniably worse than that in nondiabetics regardless of the modality chosen. The more important question is how to revascularize these patients—mainly the choice between percutaneous coronary intervention (PCI) and coronary artery bypass grafting (CABG). A survival advantage at 5 years of CABG over PCI in diabetic patients was demonstrated as early as 1996 in a subgroup analysis of the diabetic patients in the Bypass Angioplasty Revascularization Investigation (BARI) trial.⁷ No such survival difference was seen in the overall trial. This superiority of CABG over PCI in diabetic patients was due to lower cardiac mortality, was confined to those surgical patients receiving at least one internal mammary artery graft⁸ and was maintained at 7 years and 10 years.^{9,10} Although this trial compared plain balloon angioplasty with CABG, yet the difference in outcomes has persisted till date despite the improvement in technology and techniques including the introduction of bare metal stents¹¹ and first-generation drug-eluting stents (DES).¹² Particularly noteworthy is the persisting mortality benefit with CABG as compared to PCI in diabetic patients in the large FREEDOM (Future REvascularization Evaluation in patients with Diabetes mellitus: Optimal management of Multivessel disease) trial.¹²

FREEDOM TRIAL

The FREEDOM trial of 2012 is the largest and most contemporary randomized controlled trial (RCT) which focused exclusively on diabetic patients. It showed superior outcomes with CABG than with PCI in all subgroups. All-cause death and also MI were significantly less with CABG than with PCI, while stroke rate and repeat revascularization were increased with CABG.

Guidelines

Coronary revascularization guidelines therefore recommend CABG over PCI for stable multivessel disease in diabetic patients as a class I recommendation.¹³⁻¹⁵ However, CABG in diabetics may be associated with considerable morbidity related to infections, sternal and leg wound problems, renal insufficiency, etc. Patients also increasingly prefer the rapid recovery, and less invasive nature of PCI.

OTHER RANDOMIZED TRIALS

Numerous randomized trials have been conducted on diabetic patients with stable CAD comparing the outcomes of PCI with CABG.^{8,12,16-24} The problem is in being able to compare similar patients who are representative of the whole group because, traditionally, patients with multivessel disease with less anatomical complexity have been offered PCI whereas patients with more complex disease including

diffuse disease and chronic total occlusions (CTOs) have been offered CABG.

One approach, which was used in the Bypass Angioplasty Revascularization Investigation 2 Diabetes (BARI-2D)¹⁶ trial of 2009, randomized diabetic patients with multivessel disease between early revascularization and intensive medical therapy with a nonrandomized assignment to a PCI or CABG stratum based on clinical and angiographic data. The CABG stratum had more extensive and complex disease. This trial failed to demonstrate a benefit of PCI over medical therapy and we shall discuss this later. The CABG stratum showed improvement in the composite endpoint of death or MI or stroke over medical therapy. BARI-2D, therefore, offers an indirect comparison of the results of CABG and PCI in disparate patient groups.

Reasons offered for better results with CABG range from an inherent advantage over PCI by virtue of bypassing mild nonculprit lesions to the presence of more complex disease in the CABG stratum, thereby allowing the emergence of an advantage of revascularization over medical therapy.¹⁷ CABG bypasses not just the critical lesion but also associated milder lesions which may progress in future. Indeed, after PCI with current stents that have low restenosis rates, repeat ischemic events happen more often at nontreated sites which had mild or no disease on initial angiogram.¹⁸ This suggests that CABG may have an inherent theoretical advantage over lesion specific treatment by PCI, especially in diabetic patient with multivessel disease.

Other randomized trials have directly compared PCI and CABG in patients deemed eligible for both procedures. While rigorous, this method also excludes many patients who are eligible for only one procedure. The large randomized trials include ARTS II, CARDIA, VA-CARDS, and BEST besides the SYNTAX (SYNergy between percutaneous coronary intervention with TAXus and cardiac surgery) and FREEDOM trial.^{19-25,12} They all suggest that in stable multivessel disease with diabetes, CABG offers superior outcome as compared to PCI including approximately 30% mortality benefit with CABG. This benefit is driven not only by lower incidence of angina and repeat revascularization but also fewer hard endpoints like recurrent MI and mortality. Stroke, however, occurs more frequently after CABG than with PCI. The difference between CABG and PCI may emerge only on longer term follow-up. Thus, in one meta-analysis there was no difference in the rates of MI and death at 1 year but at 5 years, CABG came out significantly ahead.²⁶ Other meta-analyses with varying criteria and even patient level analysis of data have also shown CABG to be superior.²⁷⁻²⁹ It may therefore be argued that even in the less complex patients where both procedures are possible, CABG is superior to PCI in diabetics.

SYNTAX Trial

The SYNTAX trial assessed the complexity of multivessel disease by angiography using an anatomical SYNTAX score and divided patients into low, intermediate and high risk tertiles.²³ Diabetics did worse overall than nondiabetics regardless of the method of revascularization. CABG perfor-

med better overall than PCI. However, in the low-risk tertile (SYNTAX score ≤ 22), the results of PCI and CABG were comparable both in the diabetic and nondiabetic subgroup at 1 year and 5 years.^{24,25} This was based on numerically lower rates of death, MI and cerebrovascular accident but significantly higher repeat revascularization with PCI than with CABG.

Thus, there exists a subgroup of diabetic multivessel disease patients with low anatomical complexity in whom PCI, even with the now obsolete Taxus stent, performs as well as CABG. The limitations of subgroup analysis are however well known and the equally large FREEDOM trial could not identify such a low risk group for PCI.¹²

INCOMPLETE REVASCULARIZATION

Anatomical, technical and clinical factors may lead to incomplete revascularization in patients with multivessel disease. This may be more so in PCI where some lesions may be left untreated due to CTOs, lesion complexity or even contrast load. In one large meta-analysis of multivessel disease, incomplete revascularization occurred in 56% of PCI versus 25% of CABG patients.³⁰ Incomplete revascularization was associated with an adverse impact on long-term survival, and MI with more repeat revascularization. In clinical practice, most physicians are unwilling to leave incomplete revascularization in a large viable left anterior descending (LAD) territory and this may impact choice of therapy.

SECOND-GENERATION DRUG-ELUTING STENTS

The results of the randomized trials may be outdated with the current improvement in technology from plain balloon angioplasty to bare metal stent to DES.³¹ Even the often quoted FREEDOM trial used first-generation DES. Contemporary second-generation DES have thinner struts, better geometry, better polymer and drugs than first-generation DES. This contributes to better initial outcomes, less restenosis, and less repeat procedures with second-generation DES as compared to first generation. In a network meta-analysis of diabetic patients, second-generation DES had equivalent outcome to CABG.³² However, RCTs directly comparing second-generation DES with CABG are needed to confirm that PCI has indeed caught up with surgery.

REAL WORLD SCENARIO

Beyond the need for better technology, it should also be remembered that the topline results of the randomized trials do not fully reflect clinical realities. The trials enroll selected patients and most often exclude patients with severe left ventricular dysfunction, left main disease, recent ACS, prior revascularization and significant comorbidities including renal failure. In many such patients in the real world, PCI may be chosen over CABG with a reasonable expectation of faster recovery and less procedure related morbidity even at the cost of more incomplete revascularization. There is also a strong patient preference for less invasive treatment by PCI

rather than CABG provided results can be assured. Hence, the continuing search to define the subsets, if any, of multivessel diabetic patients who can safely be offered PCI.

REGISTRY DATA

Real world practices are best assessed by registry data. In the BARI, those patients who refused randomization in the main trial were enrolled in a registry in which physicians chose the method of revascularization. Twice as many patients were offered PCI as compared to CABG based on clinical factors. PCI fared as well as CABG even in diabetics unlike the main trial out to 7 years. Thus with proper selection, PCI in diabetics may be as safe as surgery and more acceptable to patients and physicians.³³ These were, however, stable lower risk patients who were BARI eligible.

Another registry covering the province of British Columbia, Canada at the time of the FREEDOM trial found that 63% of diabetic patients undergoing revascularization were characterized as ACS rather than stable ischemic heart disease (SIHD).³⁴ Again, PCI was chosen twice as often as CABG. However, CABG patients in this report did significantly better than those offered PCI. Patients offered PCI were older and had more left ventricular dysfunction, which may have influenced the outcome. Thus, the real world preference for PCI is completely missed in the RCTs although CABG may be underutilized in practice.

Another nationwide registry from Sweden enrolled all type 1 diabetics who were offered multivessel revascularization over a 19-year period. It also highlighted the preference of PCI over CABG in multivessel diabetic patients in practice.³⁵ PCI patients were sicker with more advanced age, female gender, poorer renal function, more prior MI and stroke and other comorbidities and longer duration of diabetes than CABG patients. However, surgical patients had better long-term outcome partly due to imbalance in baseline factors. The preference for PCI over CABG increased markedly from the early to the late years of the study. This certainly reflects physician and patient preference for a less invasive procedure in sicker patients. Thus, in the real world, multivessel diabetic patients may be offered PCI rather than CABG at two ends of the spectrum, viz., either if they are thought to have less anatomical complexity or if they have high clinical risk.

RATIONAL CHOICE OF REVASCULARIZATION STRATEGY: EVOLVING A CONSENSUS

Is real world practice, which often chooses PCI over CABG in multivessel diabetics, rational or an example of therapeutic anarchy? Should we offer PCI over CABG to selected diabetic patients with multivessel disease despite higher incidence of incomplete revascularization? Does the lesion independent nature of CABG confer an irreducible advantage despite improvement in PCI treatment of individual lesions?

The heart team is useful in evolving consensus here but should not be deciding merely by competing expert opinions.

A randomized trial to capture the entire clinical spectrum and validate this approach is difficult. More science is needed.

The SYNTAX and FREEDOM trials are already outdated as they compared conventional PCI with first-generation DES. A rational choice of procedure must account for high clinical risk and use the best available technology.

SYNTAX-II Score and Trial

The anatomical SYNTAX score has been upgraded to the SYNTAX-II score by incorporating those clinical variables which impacted outcomes in the SYNTAX trial database and predicting 4-year mortality on this basis.³⁶ Factors like age, gender, renal function, ejection fraction, peripheral vascular disease and chronic obstructive pulmonary disease were found to impact outcomes. The performance of the SYNTAX-II score has been validated in multiple studies.³⁷ Interestingly, once the SYNTAX score was calculated, presence of diabetes no longer influenced the relative benefit of CABG and PCI. Thus, diabetes alone cannot lead to a reflexive recommendation of CABG for revascularization.

The recently published SYNTAX-II trial compared the outcomes of contemporary PCI with matched controls from SYNTAX trial in *de novo* three-vessel disease.³⁸ Overall, the heart team chose PCI in 454 out of 708 patients that were screened. Decision-making was guided by the SYNTAX-II score and the procedure was guided by FFR and intravascular ultrasound. With these advances, along with a heart team approach and contemporary strategies for CTOs, there was a 42% improvement in 1-year outcomes of PCI from SYNTAX-I to SYNTAX-II trial (MACCE 17.4 vs. 10.6%). This was driven by a significant decline in MI, definite stent thrombosis and repeat revascularization. SYNTAX-II patients with diabetes did as well as those without diabetes. Exploratory analysis also suggests that the 1-year outcome of contemporary PCI from SYNTAX-II matches that of a CABG subgroup from SYNTAX trial. These findings need to be confirmed over the longer term as differences in outcome might emerge at 5 years, but are potentially practice changing.

NEW RANDOMIZED TRIALS NEEDED

There is urgent need for a new randomized trial using contemporary techniques of PCI and CABG in order to better inform choice of revascularization strategy in the contemporary era in diabetics and even those without diabetes. Of course, technology keeps changing and outcome data takes time to accrue, so in each timeframe, we need to be forward looking but vigilant against hype.

COMPARISON WITH MEDICAL THERAPY

The second controversial area is the need to demonstrate superiority over medical therapy in SIHD patients in order to recommend revascularization. The negative results of the BARI-2D trial when comparing PCI and medical therapy in stable low risk patients are mentioned above.¹⁶ The Clinical Outcomes Utilizing Revascularization and Aggressive Drug

Evaluation (COURAGE) trial shows similar results.³⁹ A nuclear substudy of COURAGE suggests that patients with significant documented ischemia may derive benefit from revascularization, but this finding is controversial.⁴⁰ The more recent sham-controlled ORBITA trial looked at a low risk single vessel disease population with no left ventricular dysfunction and found no improvement in exercise capacity with PCI compared to medical therapy at 6 weeks.⁴¹ All these trials suffer from a high rate of subsequent revascularization in the medical arm. In ORBITA, once the randomized trial was over, fully 85% of patients in the medical arm underwent PCI, thus preventing longer follow-up and calling the conclusions into question.⁴² However, one may conclude that asymptomatic or even mildly symptomatic patients can be offered initial intensive medical management with revascularization reserved for significant symptoms. The still on-going International Study of Comparative Health Effectiveness with Medical and Invasive Approaches (ISCHEMIA) trial may offer further answers although it is already mired in controversy due to late modification of primary endpoint and the lack of sham controls.⁴³ Recent improvements in medical therapy including drugs like ranolazine, trimetazidine and ivabradine in addition to statins, angiotensin-converting enzyme inhibitors or angiotensin receptor blockers and beta-blockers need to be acknowledged. Newer antidiabetic drugs, including the SGLT2 inhibitors, offer the potential for further cardiovascular event reduction but are beyond the scope of this chapter.^{44,45} The impact, if any, on outcomes of medical therapy versus revascularization is unknown.

ACUTE CORONARY SYNDROMES

There is a paucity of randomized data on revascularization strategy in diabetic patients with ACS who turn out to have multivessel disease. This group constitutes the majority of patients undergoing revascularization in diabetes with a preference for PCI in clinical practice despite better outcomes in selected patients with CABG.³⁴ Culprit vessel intervention alone may be the favored strategy in unstable patients with multivessel intervention in the same sitting being reserved for cardiogenic shock and also simple lesions in stable patients.

TYPE AND DURATION OF DIABETES

Data is also limited on the influence of the type and duration of diabetes on the relative outcomes of PCI and CABG. The Swedish registry mentioned earlier suggests that CABG is superior to PCI in both type I and type II diabetes.³⁵ Insulin treated patients did worse than those on oral drugs in the FREEDOM trial, but this may be due to more advanced disease in patients taking insulin.⁴⁶ It may be noted that when patients were randomized between insulin provision and insulin sensitization in the BARI-2D study, there was no difference in outcome except more hypoglycemia with insulin.¹⁶

CONCLUSION

The heart team approach as adopted in many centers has gone a long way in improving the patient's access to information about both procedures. In such a scenario, patient preference will assume greater importance as the patient has to decide the importance he/she attaches to cost, invasiveness of approach, rapidity of recovery, and chance of repeat procedures, besides the data about lesser mortality but more stroke with CABG. An expanding group of lower risk patients may choose PCI over CABG even in presence of diabetes.

Pending the availability of more data, the heart team should recognize that revascularization decisions in diabetic multivessel disease are complex. Where there is equipoise and both procedures are anatomically feasible, the heart team should counsel patients accordingly. A formal calculation of SYNTAX score (upgraded to clinical SYNTAX-II) may be used in addition to expert opinion. Inclusion of functional data by FFR may further improve outcomes of PCI, and even reduce the number of lesions treated and stents used as is being studied in the FAME 3 (Fractional flow reserve versus Angiography for Multivessel Evaluation) trial.⁴⁶ The recent presentation of the SYNTAX-III revolution data using CT-derived FFR has shown a roadmap for further improvement of rational decision making even in surgical patients.^{47,48}

Enhanced External Counterpulsation: Current Status

Ashok Goyal

INTRODUCTION

Cardiovascular diseases particularly coronary artery disease (CAD) is currently a leading cause of death in India and is rapidly presenting as an epidemic, resulting in 23% of total and 32% of adult deaths in 2010–2013. Using more stringent criteria (clinical \pm Q waves), the prevalence varies from 1 to 2% in rural populations and 2–4% in urban populations.¹ Heart failure (HF) incidence has also reached epidemic proportions with 5.7 million patients in USA, 10 million in Europe, and 20 million in Asia, and is the most frequent cause of emergency visits and hospitalization in the elderly population, accounting for 5–10% of all hospital admissions and an estimated 50% mortality at 5 years.²

The CAD patients with refractory angina and HF have imposed a great challenge for their treatment due to: (1) high morbidity and mortality, (2) increased cost burden because of repeated emergency department (ED) visits or hospitalization, (3) high rate of stent restenosis or graft occlusion, and (4) high risk of repeat revascularization procedures.

Optimal medical therapy (OMT) and invasive revascularization, i.e., percutaneous coronary interventions (PCI: balloon angioplasty or stent implantation) and coronary artery bypass surgery (CABG), are the most widely used treatment modalities, but neither of these treatment modalities provide a complete cure of this progressive disease with its causative mechanisms still persisting even after treatment. Further, the role of standard revascularization procedures in chronic stable angina (CSA) is not well understood and still under investigation and debate. Furthermore, during or after revascularization procedures, myocardial infarction (MI) remains a common entity due to distal micro-thromboembolism leading to myonecrosis, coronary spasm, arrhythmias, or hypotension.³ Despite many advances in OMT and invasive revascularization procedures, a significant number of patients suffering from chronic refractory angina pectoris with or without underlying HF could not be successfully managed, and are left to suffer with

FIG. 1: Enhanced external counterpulsation machine. Consisting of a patient bed attached to an air compressor unit, computerized control panel, three sets of cuffs wrapped around the calves, thighs, and buttocks of the patient.

their symptoms of restricted activities to anticipate a reduced life expectancy.

Enhanced external counterpulsation (EECP) therapy with a different mode of action consists of a bed with attached air compressor and computerized control panel that involves the electrocardiography (ECG)-gated sequential inflation or deflation of three sets of cuffs wrapped around the lower extremities (i.e. calf, thigh, buttock), which produces hemodynamic effects similar to those of an intra-aortic balloon pump (IABP) (Fig. 1).

ENHANCED EXTERNAL COUNTERPULSION IN CORONARY ARTERY DISEASE AND HEART FAILURE TREATMENT

Enhanced external counterpulsation was carefully reviewed in the 2012—Stable Ischemic Heart Disease (SIHD) guideline,

but the comments received after the guideline's publication prompted a re-examination of the existing literature in 2014.⁴ The efficacy of EECP in treating SIHD has been evaluated in several randomized controlled trials (RCTs) and nonrandomized, observational, prospective trials and registry studies, which documented significant and long-term clinical benefit from EECP therapy in patients of CSA.

The MUST-EECP (Multicenter Study of Enhanced External Counterpulsation) was landmark prospective, blind study that randomly assigned 139 patients of CSA with positive exercise stress test. Patients were subjected to either full dose EECP or to sham (placebo) method with minimal pressures. The study showed a significant increase in exercise time post-EECP from baseline (426 ± 20 s to 470 ± 20 s, $p < 0.001$) versus the sham group without active counterpulsation (432 ± 22 s to 464 ± 22 s, $p < 0.03$) and significant improved time for more than or equal to 1 mm ST-segment depression on stress testing in the EECP group (337 ± 18 s to 379 ± 18 s, $p < 0.002$) compared with placebo (326 ± 21 s to 330 ± 20 s, $p < 0.74$). These effects were maintained 12 months after EECP treatment.⁵ Additional RCTs were published in 2009 by Buschmann et al.⁶ and in 2010 by Gloeker et al.⁷ comparing intracoronary and collateral blood flow rates by angiography in patients treated with EECP against those treated with sham procedure, and proved that collateral flow index increased significantly in the EECP-treated group compared with sham-treated group. Another small unblinded RCT published in 2011 by Bondesson et al.⁸ in patients with refractory angina—Canadian Cardiovascular Society (CCS) class III being randomized to EECP and no-EECP groups. Mean CCS angina class was significantly improved in EECP group but not in no-EECP group. However, data from RCTs on long-term outcomes are lacking.

International EECP Patient Registry (IEPR) enrolled 7,500 patients from more than 90 centers and their results have demonstrated the symptomatic clinical benefit by at least one functional angina class with improvement in exercise tolerance, myocardial perfusion, and antianginal drug requirement^{9,10} which might be maintained for up to 5 years in patients with favorable initial clinical response. About 86% of IEPR patients completed the 35-hour treatment, designated as EECP responders and the remaining as EECP nonresponders. At 5 years, major adverse cardiovascular events (death, acute MI, new or redo- CABG or PCI) were significantly lower among EECP responders (23%) compared to nonresponders (86%). EECP responders also have significant post-therapy improvement in perfusion defects on radionuclide stress tests performed to the same cardiac work load and double product.¹¹⁻¹³

Percutaneous coronary interventions candidates suitable for and treated with EECP had 1-year major event rates comparable to patients receiving elective PCI. These results suggested that EECP, a noninvasive procedure, could be used as a first-line treatment keeping invasive revascularization reserved for EECP failures, or in high-risk patients with SIHD.¹⁴ However, it warrants a need of a randomized controlled study to ascertain the efficacy of EECP combined

with drug therapy as a first-line treatment in select patients with SIHD.

Soren et al.^{15,16} have evaluated the safety and efficacy of EECP therapy in patients with refractory angina and severe left ventricular dysfunction [ejection fraction (EF) $<35\%$] and found a significant and persistent reduction in angina severity: 72% improved from severe angina to no or mild angina and 52% stopped using nitroglycerin with significantly decreased ED visits and hospitalizations.

However, many studies on EECP therapy were not double blind, and lack good control groups because of technical and ethical limitations.

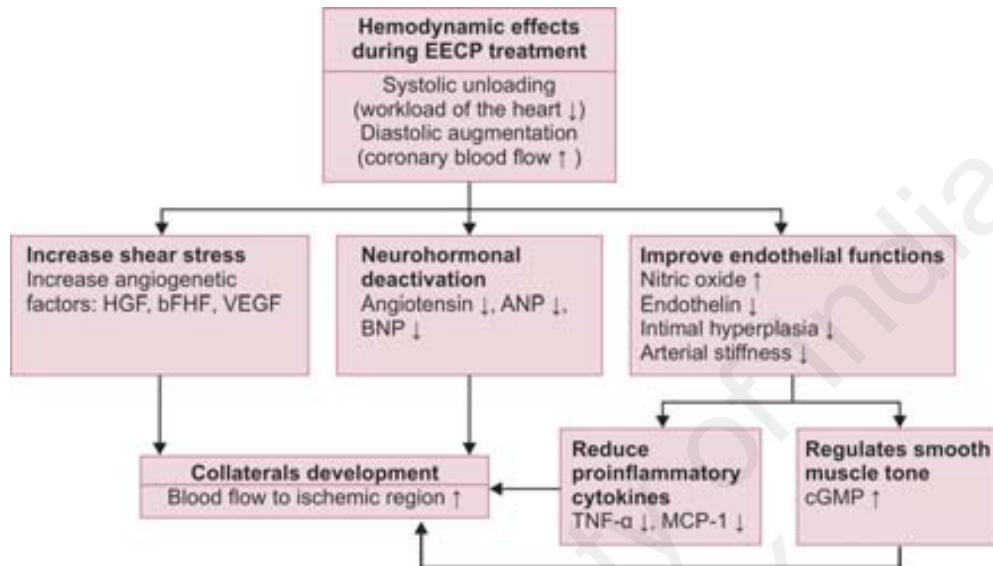

MECHANISM OF ACTION

Despite favorable findings, the mechanism(s) for the clinical effectiveness of EECP in CAD and HF patients remains largely unknown. Recent (2016) systemic review and meta-analysis of the available literature (5 RCTs and 1 prospective studies between 1992 and 2007) focused on the effect of EECP on the measurement of myocardial perfusion, and concluded that the standard EECP therapy (35 1-hour sessions) significantly increased myocardial perfusion and left ventricular function in CAD patients [pooled weighted mean differences (WMD) = statistical index: -0.19 ; 95% confidence interval (CI): -0.38 to 0.00 ; $p = 0.049$ with no significant publication bias—Begg's $p = 0.091$; Egger's $p = 0.282$.]¹⁷ However, EECP is expected to work through several pathways affecting each other (Flowchart 1).

The hemodynamic effects of EECP has been assessed through both noninvasive and invasive techniques and found to be similar to those of IABP for diastolic augmentation and systemic vascular resistance. However, the right atrial pressure, pulmonary capillary wedge pressure, and cardiac index increased during EECP in contrast to IABP, suggesting that EECP increases venous return, raises cardiac preload, and increases cardiac output. Further, in contrast to IABP, the EECP therapy is thought to provide permanent effects on the heart, because the resulting increase in coronary artery perfusion pressure may enhance coronary collateral development or increase flow through existing collaterals^{18,19} (Fig. 2).

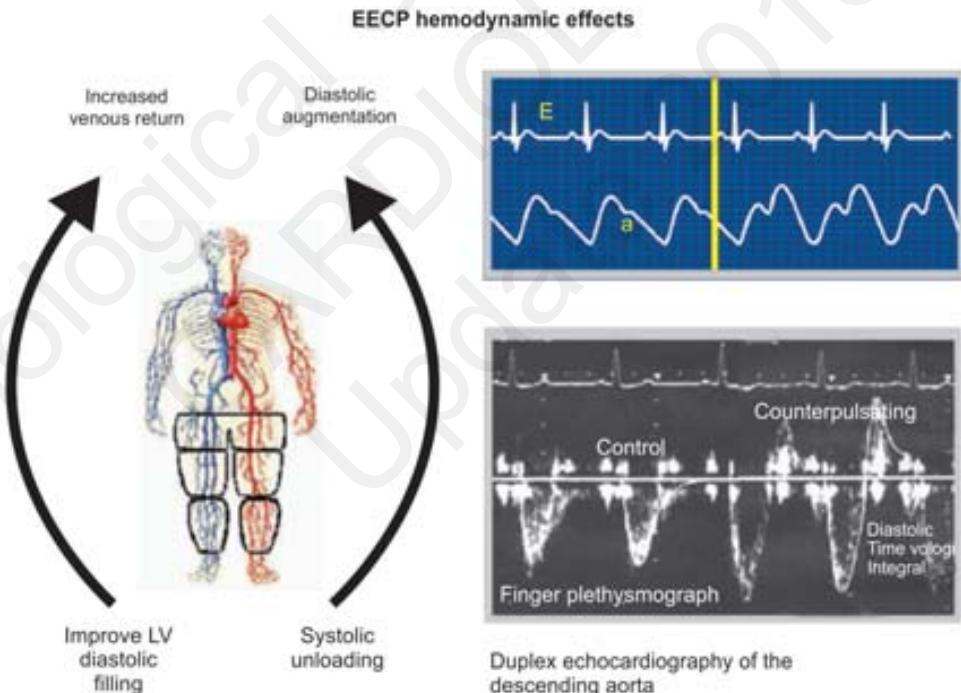

Endothelium plays an integral part in vascular homeostasis, and its dysfunction leads to decreased nitric oxide—a potent vasodilator, antiproliferative, anti-inflammatory molecule, and increased endothelin-1—a potent vasoconstrictor, mitogenic, proinflammatory molecule. Prospective and randomized controlled studies^{20,21} predicted EECP in CAD patients, through its sheer stress, leads to a significant increase in plasma nitric oxide levels and decrease in plasma endothelin-1 levels. These studies showed significant increase in flow-mediated dilatation of peripheral arteries, and thereby improving coronary blood flow in EECP treated patients.

Braith et al.²¹ in their randomized controlled study in 42 symptomatic CAD patients (28 by active-EECP and 14 by sham EECP) showed EECP treatment-mediated significant reduction in proinflammatory cytokines, vascular cell

ANP, atrial natriuretic peptide; bFHF, basic fibroblast growth factor; BNP, brain-type natriuretic peptide; cGMP, cyclic guanosine monophosphate; HGF, hepatocyte growth factor; MCP-1, monocyte chemotactic protein-1; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

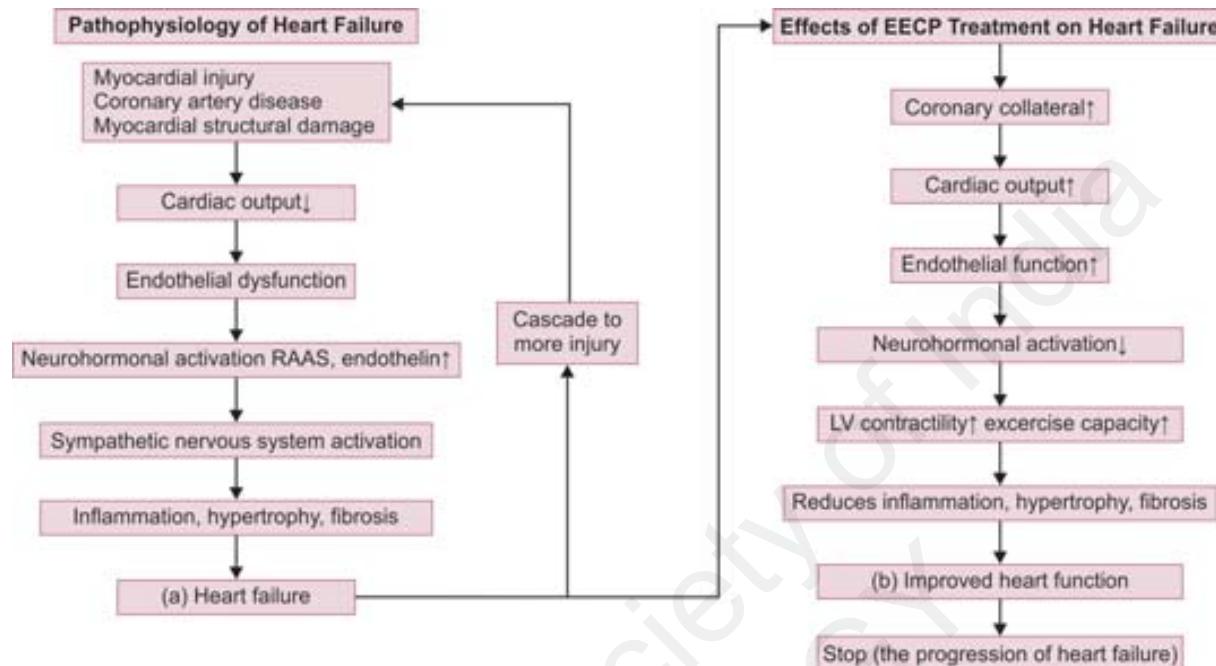

FLOWCHART 1: Mechanisms of enhanced external counterpulsation (EECP) therapy. Possible mechanisms responsible for the clinical benefit associated with EECP therapy. Acute hemodynamic and neurohormonal changes, prolonged stimulus to increase sheer stress which promotes endothelial function improvement is thought to promote myocardial collateralization via opening of latent conduits, arteriogenesis, and angiogenesis.

EECP, enhanced external counterpulsation; LV, left ventricular.

FIG. 2: Acute hemodynamic effects of enhanced external counterpulsation therapy. Right upper corner: Showing the ECG tracing and finger plethysmogram. As soon as the device turned on (yellow line) diastolic augmentation starts. Right lower corner: Showing the diastolic augmentation by echocardiography. E (ECG), electrocardiogram; a, aortic notch.

LV, left ventricular; RAAS, renin-angiotensin-aldosterone system.

FLOWCHART 2: Enhanced external counterpulsation (EECP) in heart failure. (a) Pathophysiology of heart failure starting with some form of injury to the heart muscle and cascading down to heart failure and leading back to more myocardial injury; (b) EECP stops the path back to more myocardial injury and reduces the negative remodelling effects of heart failure, thereby improving heart function.

Vascular shear stress is a known stimulus for angiogenesis leading to coronary collateral development and recruitment by increasing vascular endothelial growth factors (VEGFs), fibroblast growth factors, and platelet-derived growth factors. EECP treatment in CAD patients through its shear stress effects has shown to increase plasma levels of these growth factors.²²

As illustrated the pathophysiology of HF in flowchart 2, HF is not a single organ disease but a systemic disease. HF usually starts with some form of injury to the myocardium, reducing the ability of the heart to effectively eject blood, decreasing the cardiac output, leading to endothelial dysfunction and activating the neurohormonal [Renin-Angiotensin-Aldosterone System (RAAS) and endothelin] and sympathetic nervous system, which in turn leads to myocardial hypertrophy, fibrosis, inflammatory injury, and further atherosclerosis. This chain reaction continues and cascades to worsening of HF.

Enhanced external counterpulsation is a treatment methodology that deals with every aspect of the deteriorating effects leading to HF. There is ample scientific evidence that EECP promotes coronary collateral circulation providing more blood supply to ischemic regions of the heart to improve cardiac output. The improved cardiac function increases blood flow velocity, and the sheer stress on the endothelium promotes the release of circulating endothelial progenitor cells and improve endothelial function. This in turn reduces neurohormonal or sympathetic activation, inflammatory reaction, arterial wall stiffness, intimal hyperplasia, myocardial hypertrophy and fibrosis, thereby lowering vascular resistance and decelerating the deteriorating effects so as to stop the progression of HF.

INDICATIONS AND CONTRAINDICATIONS

United States Food and Drug Administration (US FDA) has approved EECP therapy for: (1) refractory angina pectoris not responding to OMT or not amenable to invasive revascularization procedures, and (2) congestive HF. The following group of patients of angina or angina equivalent with or without HF may be benefitted from EECP therapy (Table 1).

TABLE 1: Indications and contraindications of enhanced external counterpulsation in patients of coronary artery disease and heart failure

Indications	Contraindications
Abnormal coronary artery anatomy	Aortic insufficiency
Restenosis of stents or grafts	Arrhythmias
Noncardiac morbid conditions	Severe uncontrolled hypertension
Unwillingness for invasive revascularization	Deep vein thrombosis
Stable heart failure	Aortic aneurysm
LV dysfunction—moderate-to-severe	Recent cardiac catheterization
–	Coagulopathy prothrombin time—INR >2.5
–	Pregnancy

INR, international normalized ratio; LV, left ventricular.

- Coronary anatomy unsuitable for invasive revascularization, e.g., diffuses atherosclerosis or congenital anomalies
- Restenosis of stents or grafts after invasive revascularization and redo revascularization is not possible
- Advanced comorbid conditions of noncardiac origin (lungs, liver, and kidney) or advanced age that increases the risk of invasive revascularization procedures.
- On OMT, not willing for additional invasive revascularization procedures
- Stable HF (NYHA II and III)
- Left ventricular dysfunction (EF <35%) due to cardiomyopathy—ischemic or idiopathic.

Enhanced external counterpulsation therapy may be somewhat uncomfortable due to the high pressure sequential compressions of the cuffs as it can cause skin abrasions, ecchymoses, bruises, paresthesias, or leg or waist pains. It is not recommended in the following conditions (Table 1):

- Aortic insufficiency (moderate to severe)—as the regurgitation would prevent diastolic augmentation
- Arrhythmias like atrial flutter or fibrillation and ventricular premature contractions (if frequent)—as these may interfere with EECP system triggering
- Hypertension (BP > 180/110 mm Hg)—as the augmented diastolic pressure may exceed safe limits
- Deep vein thrombosis (DVT) is an absolute contraindication—as it may cause pulmonary thromboembolism (PTE)
- Aortic aneurysm (>4 mm) or dissection—as diastolic pressure augmentation may be detrimental
- Cardiac catheterization from femoral route (2 weeks)—as there may be risk of bleeding from the site of arterial puncture
- Coagulopathy (prothrombin time—international normalized ratio >2.5)—as it may cause bruises in the legs
- Pregnancy—as the effects of EECP therapy on the fetus have not been studied.

ENHANCED EXTERNAL COUNTERPULSION IN EXTRACARDIAC DISEASES

Several research publications have revealed the potential uses of EECP in the treatment of various extracardiac disease like cardiac syndrome X (nonobstructive CAD),²³ ischemic strokes,^{24–26} erectile dysfunction,^{27,28} and hepatorenal syndrome.²⁹ New studies do explore the role of EECP therapy in primary and secondary prevention of CAD in persons who are prone to have CAD due to the presence of multiple risk factors like diabetes, hypertension, obesity, dyslipidemia, and tobacco user.

CONCLUSION

Several clinical trials^{30–32} in last two decades have suggested that EECP is truly and rather only noninvasive, efficacious, safe, cost-effective, and OPD-based therapy in improving

angina pectoris, long-term left ventricular functions, exercise capacity and quality of life in CAD and HF patients that have failed to respond adequately to OMT, PCI, or CABG. Its positive clinical response rate is averaging 70–80% and sustained up to 5 years or more, and also complements the invasive revascularization.

It has been approved by US FDA for the management of refractory angina—chronic stable (class IIb—level of evidence B) and congestive HF. However, due to large and quality scientific data now available, and as per the description of the rating or evidence levels defined by American College of Cardiology and American Heart Association guidelines, it is believed that EECP has earned a Class IIa treatment recommendation with level of evidence A.³³ More randomized controlled research is needed for more confirmatory mechanism of action and long-term effects of EECP therapy. Recent studies, may provide an array of hope to ascertain the efficacy of EECP—a truly noninvasive treatment combined with drug therapy, as a first-line treatment in selected patients with CAD with or without HF, keeping invasive revascularization reserved for EECP failures, or high-risk patients.

Cardiac Rehabilitation: The Road Less Travelled

Satyendra Tewari, Raj Pratap Singh

INTRODUCTION

Cardiac rehabilitation (CR) is defined as comprehensive long-term programs involving medical evaluation, prescribed exercise, cardiac risk factor modification, education, and counseling, designed to limit the physiological and psychological effect of cardiac illness, reduce the risk of sudden death (approximately 10%) or reinfarction, control cardiac symptoms, and enhance the psychological and vocational

status of the individual patient.¹ CR is a process where cardiac patient in partnership with a multidisciplinary team is encouraged and supported to achieve and maintain optimal physical and psychosocial health.² CR is an umbrella term that covers various facets of a holistic and comprehensive cardiac care and encompasses all measures used to help people with heart disease to return to active life and prevent recurrence of events (Fig. 1).

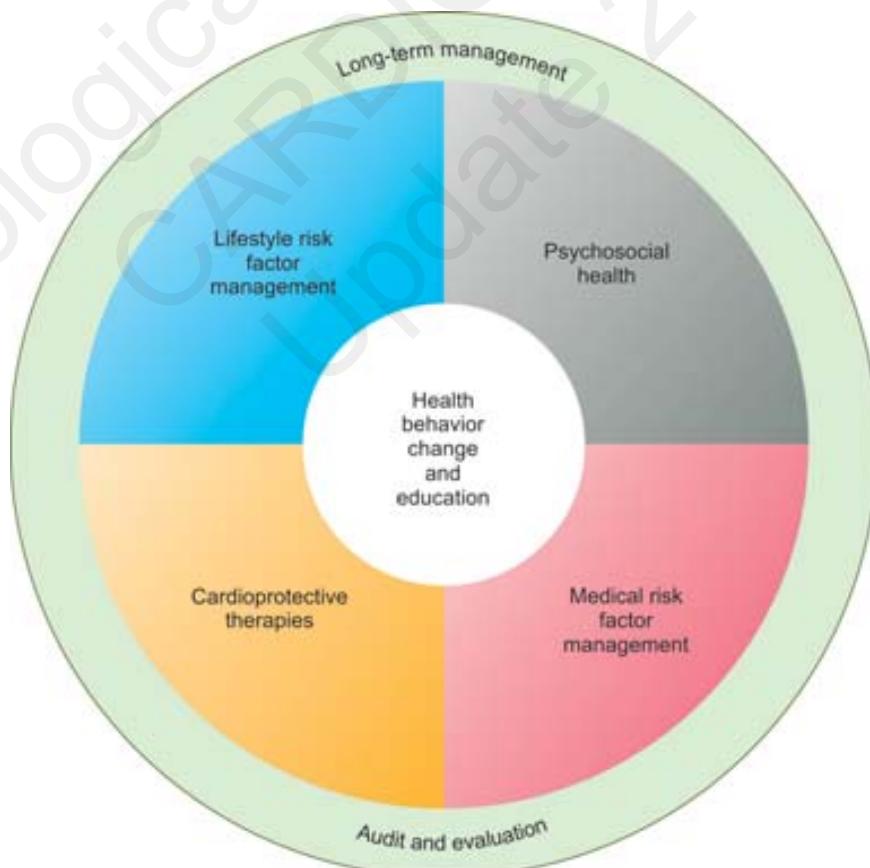

FIG. 1: Comprehensive approach to cardiac rehabilitation.³

Cardiac rehabilitation has been studied in multiple randomized controlled trials (RCTs), observational and cohort studies.⁴ These as well as multiple meta-analysis and systematic reviews have shown that structured CR leads to decreased mortality,⁵ morbidity, myocardial infarction and hospital admissions,⁶ early mobility and return to work and routine activity, improvement in quality of life, physical fitness and psychosocial wellbeing, and decreased symptoms of depression.^{5,7-10} Despite such robust evidence of multitude of benefits proper CR is available only to minority of patients and it remains a road less travelled. The American Heart Association (AHA) scientific statement on exercise and acute CV events noted that risk of major cardiovascular event is one event in 60,000–80,000 hours of supervised exercise.^{11,12}

The goal of CR is to enable cardiac patients to lead a fulfilling life by maximizing their physical, psychological, and social functioning. This is achieved by:

- Introducing and encouraging behavior that minimize the risk of further cardiac events
- Facilitating and shortening the period of recovery after an acute cardiac event
- Promoting strategies for achieving recommended goals for prevention of cardiovascular disease (CVD)
- Developing and maintaining skills for long-term behavior change and self-management
- Promoting appropriate use of health and community services
- Improving compliance with treatment and exercise advised

INDICATIONS OF CARDIAC REHABILITATION

- Acute coronary syndrome [ST-elevation myocardial infarction (STEMI) or non-STEMI or unstable angina]
- Chronic stable angina
- Compensated heart failure
- Postcoronary angioplasty
- Postpacemaker, intracardiac defibrillator implantation
- Postcardiac surgery like coronary artery bypass grafting or valvular surgery
- Left ventricular assist device therapy
- Heart or other organ transplant
- Patients at high risk of cardiac events, e.g., diabetes, hyperlipidemia, and hypertension
- Peripheral vascular disease.

From the given list of indications it is clear that there can be varied conditions requiring CR and patient with each one of them may differ. Thus there is a heterogeneity and hence the rehabilitation program has to be tailored according to the need of patient (one size does not fit all). It is also important to understand that in order to implement CR correctly one needs to have a multidisciplinary team involving the specialist (cardiologist), trained nursing staff, people specially trained for providing out of hospital education and nutrition and exercise advice with support from family members and local physician. It is of utmost importance that the CR services meet

the need of patient and family members of patient should be encouraged to participate in CR program.

Traditionally four phases of CR have been described:^{13,14}

- *Phase 1:* (Inpatient) Usually lasts during the duration of hospitalization. It consists of a gradual, progressive exercise and education program and improves patient's understanding of disease and preventive efforts to slow the progression of disease
- *Phase 2:* (Postdischarge) Graded physical activity and behavior modification aimed at weight loss, healthy eating, smoking cessation, and other factors to reduce disease risk
- *Phase 3:* (Outpatient exercise program) Lasts 6–12 months. Consists of supervised exercise programs that can be performed at home or in a community service facility with continuous emphasis on risk factor reduction
- *Phase 4:* Indefinite duration maintenance phase.

INPATIENT CARDIAC REHABILITATION

In current era the hospitalization durations continue to decrease therefore there is often not sufficient time for to address all aspects of CR. Nevertheless CR should begin soon after admission. Inpatient CR consists of providing information, reassurance and counseling, mobilization guidelines, appropriate discharge planning, and referral to outpatient CR, and primary care physician in a clear simple understandable form. Patient and family should be informed regarding nature of disease, prognosis, prospective treatment, importance of medications and compliance, resumption of physical activity, modification of risk factors, and psychosocial issues. The aim of mobilization program is a progressive increase in physical activity and can start as early as first day. It should balance the risks of premature activity with the deleterious effects of bed rest. Early mobilization improves self-confidence. The protocols vary according to hospital practices and age, frailty, presence of comorbidity, and current medical condition. For example, after coronary angioplasty mobilization may be achieved in a single days whereas in patient of heart failure it may be much slower.

A six-stage progression of mobilization has been developed:¹⁵

1. Go to toilet and shower in wheel chair, sit in chair for meals, do arm and leg exercises. Supported by ward staff in these processes
2. Shower in a wheelchair while remaining seated, do arm and leg exercises, walk slowly for 1–2 minutes twice a day
3. Patient to shower on their own while seated on the wheelchair, walk to the toilet as necessary. Walk slowly for 2–3 minutes twice a day
4. Walk at an easy pace for 3–4 minutes twice a day. In addition, patient may walk around room as much as they like
5. Walk for 4–5 minutes twice a day. Climb one flight of stairs with the supervision of the nurse or physiotherapist
6. Walk for up to 10 minutes twice a day. Climb two flights of stairs with the supervision of the nurse or physiotherapist.

The progression through these stages varies according to patient status. Close watch for symptoms should be kept and brought immediately to notice of treating physician. Every patient should also be seen by a clinical nutritionist or dietitian, anthropometric measurements made, and full risk profile recorded. At discharge the patient and family should be counseled regarding medications, compliance, symptoms of deterioration, and importance of continuing CR. Patient should be provided with information about local community resources and patient support group. A communication to local physician and if possible CR coordinator or physiotherapist should be made for continuing supervised exercise and rehabilitation in postdischarge period.

Postdischarge Period

May vary from 2 to 6 weeks. Patient contact can be made by home visits or telephone by rehabilitation team. Patient has clear instructions on his or her individualized exercise prescription. Initially walking on level ground is prescribed. Initially, the intensity of exercise is maintained at about 4 metabolic equivalents (METs) and heart rate should not exceed 20 beats/minutes above their resting heart rate. If tolerated well then walking distance is progressively increased to 3–5 km. Patient should be followed up in outpatient department (OPD) for symptoms and assessment of anthropometry and behavioral therapy regarding lifestyle changes and risk factor modifications. Also the food diaries should be given to patients to complete at home.

Outpatient Cardiac Rehabilitation

Structure outpatient CR is aimed at developing a lifelong approach for cardiovascular prevention. Usually last up to 1-year after discharge. Patient can exercise at home or CR facilities without monitoring but with supervised and structured exercise programs. Low to moderate intensity exercises corresponding to 60–75% of maximum heart rate initially followed by addition of resistance exercises if appropriate is the norm. Aerobic exercises like jogging, cycling, rowing, and treadmill are preferred. A warm up of 15 minutes followed by exercise session for 30–35 minutes followed by cooldown of 10 minutes is reasonably good.¹⁶ Food diaries should be collected and reviewed with areas for improvement highlighted. Patients can attend nutrition talks if available. The patients should be counseled regarding continuing preventive measures (e.g., reduce weight, decrease salt, stop smoking, control hypertension, etc.) and supportive things like mindful meditation. Various scales can be used to analyze the performance of patient and improvement of symptoms, e.g., six-minute Walk Test, Seattle Angina Questionnaire, Minnesota Living with Heart Failure, Special Activity Questionnaire, Depression, Anxiety, and Stress Scale, and Borg Scale for Perceived Exertion.

Maintenance Phase

This phase continues lifelong. Patient continues to exercise unsupervised and continues dietary and lifestyle modification

with periodic OPD visits at local or specialty centre. Continuing ongoing preventive measures is an integral part of CR and should continue indefinitely.

It is clear that CR requires a coordinated effort of lots of people like patient, family members, treating cardiologist, nutritionist, nurse, physiotherapist, local physician, etc. It becomes difficult for busy centers. Therefore in developed countries there is a concept of CR teams and there is a person designated as rehabilitation coordinator who coordinates a team of various professionals in providing CR services. At some places there are specific CR centers providing professional exercise, nutritional and psychosocial services under single roof. Despite proven role and robust evidence participation in CR programs is poor with average of 20–50% in developed countries. The situation in developing countries is abysmal where CR remains the road not travelled.

BARRIERS TO CARDIAC REHABILITATION IN INDIA

- Lack of any structured and coordinated CR program at most of centers
- Overburdened tertiary center hospitals
- Poor referral for CR
- Physician inertia; few physicians or cardiologist endorse and effectively counsel regarding the need of proper CR
- Poor patient adherence, leading to low enrolment and high dropout rate
- Multiple morbidities, leading to poor functional capacity
- Poor exercise habits
- Patient compliance with medication and abstinence from tobacco is poor
- Problems with transport and geographical barriers
- Poor social support
- Lack of leave from work to attend center-based sessions
- Lack of availability of nutritionist and physiotherapist trained for CR
- *Geographical constraints:* Availability of services is poor in many geographical areas and transportation to urban centers cost time and money. CR otherwise is also best provided locally.

What can be done to improve the situation? As treating cardiologists the onus lies on us to put things on right track. Cardiologist and his team should counsel regarding the disease, its nature, prognosis, importance of preventive measures, exercise, and compliance with medications. In hospital dietary advice and exercise counseling also helps. It is important to dissipate information and educate medical, paramedical staff as well as patient and relatives regarding the concept and benefits of CR. Local physician is at an advantage to provide CR services as he is more accessible to the patient and able to see and monitor his progress frequently. The habit of referring the patient back to local general practitioner should be encouraged because since CVD are a major burden to society government should take steps to set up CR services and promote the concept of prevention (both primary and secondary).

Cardiac rehabilitation is thus an amalgamation of various efforts that one can do to promote and preserve cardiovascular health. In view of current epidemic of CVD it needs to be emphasized and adopted widely. We may be practicing it in some form or other things need to be put together to make a coordinated effort so that CR no more remains a road less travelled.

Acute Coronary Syndromes

Why Seek Vulnerable Coronary Plaques?

Amir Ahmadi, Michael Valentine, Rick Chazal, Jagat Narula

WHAT IS A VULNERABLE PLAQUE?

The plaques associated with acute coronary events including sudden death, myocardial infarction and unstable angina in a majority of cases result from acute coronary thrombosis secondary to plaque rupture.¹ In about a fourth of cases eroded surface of the plaques leads to thrombotic occlusion of the coronary lumen. Whereas the latter occurs predominantly in young smoking women, the common garden variety of the plaque rupture-related acute events are associated with abundance of coronary risk factors and more likely to occur in older men and postmenopausal women.

The ruptured plaques carry distinct histopathological characteristics. These plaques reveal large plaque burden owing to huge necrotic core that is associated with substantial extraluminal growth (or positive remodeling). The expansive growth of the plaque is limited by the maximal stretch capability of the medial smooth muscle cell layer and at that time the plaque growth results in rapid strangulation of the luminal patency. Due to the significant inflammatory component and hence heightened cytokine milieu and collagenolysis and elastolysis, these plaques are left with attenuated fibrous caps, usually <55 µm in

thickness. Thin fibrous caps are amenable to high shear stress due to hemodynamic perturbances and disrupt to expose thrombogenic, tissue factor-rich necrotic cores to lumen. These characteristic plaque features [or high-risk plaque (HRP) features] could be seen with plaque rupture regardless of the degree of luminal stenosis. The angina-producing stable plaques, on the other hand do not usually carry large plaque burden or necrotic core, and are more likely to be constrictively (negatively) remodeled due to collagen/fibrous excess, even though they may be luminally critically occlusive.

It has been tacitly believed that the plaques with these definitive HRP features (i.e., large plaque and necrotic core burden, positive remodeling and thin inflamed fibrous caps) if still have the intact fibrous caps, should be considered vulnerable to rupture. The pathological studies have demonstrated that the lipid-rich plaques carrying fibrous caps of thinner than 85 µm are pathognomonic of vulnerable plaques. It is therefore important to identify vulnerable plaques with the expectation that the acute events could be prevented. Such a thinking could be of paramount clinical value because a simple relief of luminal stenosis does not prevent acute events (Fig. 1).

FIG. 1: Histopathologic characteristics A, Plaque rupture; B, High-risk plaque; C, Stable coronary lesion.

HOW IS VULNERABLE PLAQUE IDENTIFIED?

The intracoronary imaging strategies including intravascular ultrasound (IVUS) and optical coherence tomography (OCT) have confirmed the histopathological characteristics of vulnerable plaques *in vivo*. Whereas IVUS has demonstrated the presence of large plaque burden, echoluent necrotic core, and positive remodeling, the OCT has successfully mapped the fibrous cap thickness *in vivo*. However, the noninvasive imaging with computed tomography angiography (CTA) offers the most convenient basis of identification of the HRP characteristics (Fig. 2). These features in the CTA terminology have been called adverse plaque characteristics (APCs) owing to their association with poor prognostic outcomes.²⁻⁴ Two CTA plaque characteristics have demonstrated the best association with clinical outcomes up to 10 years of follow-up. These two features include the existence of low-attenuation plaques with less than 30 Hounsfield unit density (LAP, <30 HU) which represents IVUS-verified necrotic core and positive remodeling (PR, >110%); by presence of these characteristic such plaques have been referred to as 2-feature-positive plaques (2-FPP) and are found to be associated with lesions responsible for acute coronary events; 22.5% of 2-FPP resulted in an acute event over a 2-year follow-up. On the other hand, 2-feature-negative plaques (2-FNP) were

associated with benign outcomes with less than 0.5% of them resulting in acute events. Multiple other features have been suggested as the APC including circumferential necrotic cores (napkin-ring sign) and spotty calcification. The positive predictive value of HRP characteristics is increased based on the magnitude and number of HRP features and dynamicity of the HRP (see below).

THE QUANTITATIVE EXTENT OF HIGH-RISK FEATURES

The larger the necrotic core volume and the more expansive the positive remodeling, higher is the likelihood of rupture of the high-risk plaque.³ The eventful HRP demonstrated two-fold greater expansive remodeling compared to the HRP that did not produce acute coronary events; eventful HRP demonstrated 126% remodeling against 113% remodeling of uneventful HRP. The LAP volume was 20 mm³ in eventful plaques compared to 1.1 mm³ in the HRP which did not result in acute coronary events. Napkin rings are circumferential large necrotic cores and although infrequent they are closely associated with future events. Further, not only that the quantitatively greater APCs are associated with the events, greater the APC sooner occurs the event. It is therefore expected that larger data would allow us to define more accurate quantitative thresholds for identifying HRP likely to result in major adverse coronary events.

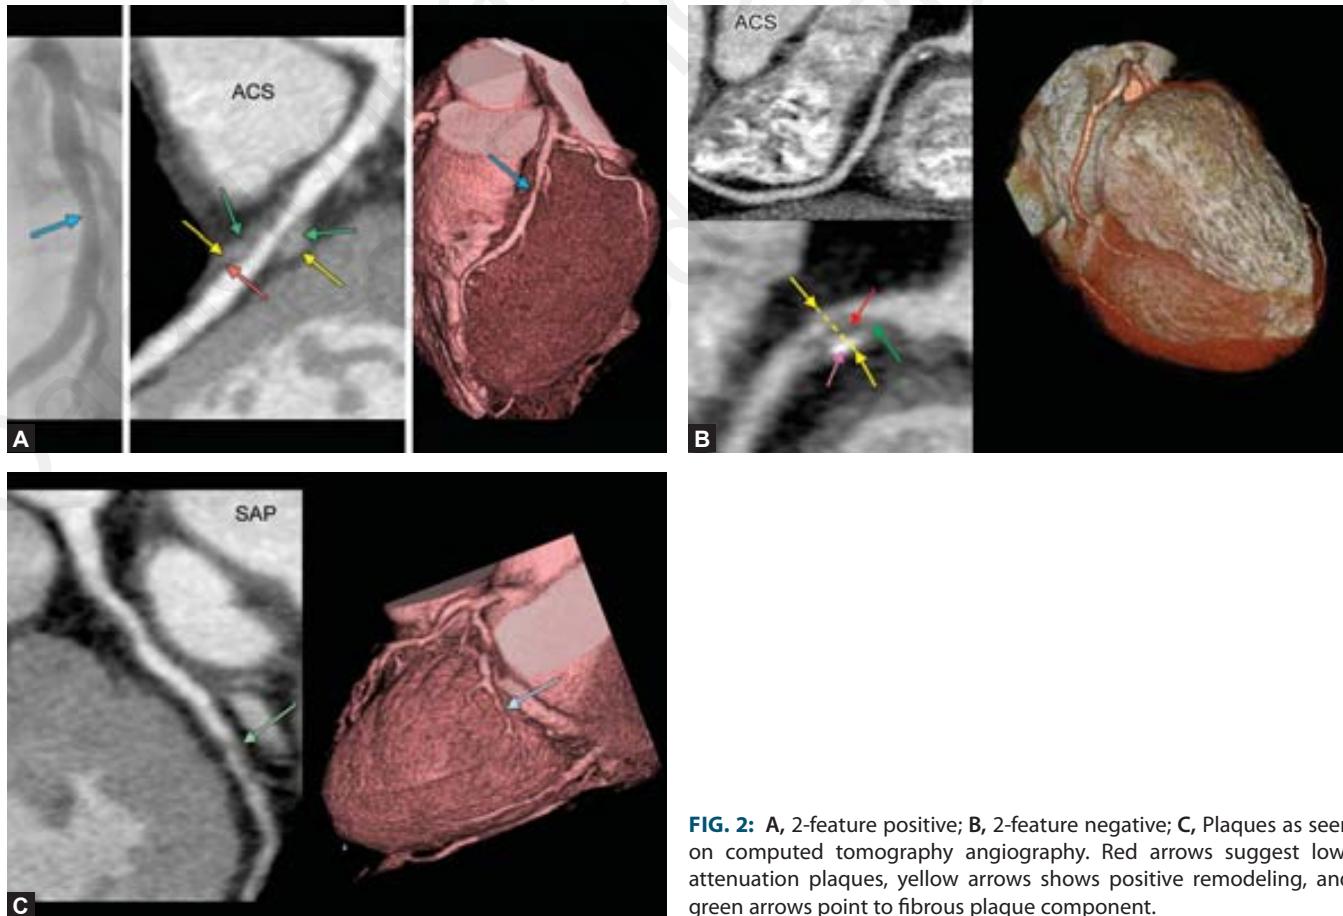

FIG. 2: A, 2-feature positive; B, 2-feature negative; C, Plaques as seen on computed tomography angiography. Red arrows suggest low-attenuation plaques, yellow arrows show positive remodeling, and green arrows point to fibrous plaque component.

THE NUMBER OF ADVERSE PLAQUE CHARACTERISTICS

Similar to quantitatively greater APC dose, it has been proposed that the greater number of APCs may contribute to improve positive predictive value of plaque characteristics. Recent CTA studies have revealed progressively superior outcome prediction with addition of increasing number of APCs. Similarly, the landmark PROSPECT (Providing Regional Observations to Study Predictors of Events in the Coronary Tree) study revealed higher plaque burden, IVUS-verified thin fibrous cap and more severe luminal obstruction as the three important determinants of adverse outcomes over 3.4 years in nonculprit vessels in 697 patients undergoing primary percutaneous coronary interventions.⁵ Whereas, the absence of all three APCs had a high negative predictive value with only 0.3% adverse events, one, two, and three features showed vessel-specific adverse events in 4.8%, 10.5%, and 18.2% instances. Even though there is increasingly superior positive predictive value for the increasing number of APCs, the number of patients with greater number of APCs becomes significantly smaller.

THE EVIDENCE OF PLAQUE PROGRESSION

Although, it has been tacitly believed that only minimally obstructive HRP are associated with adverse outcomes, a review of those studies suggest that the previous angiograms of the fateful patients were far removed from the index event

between 6 and 18 months and information about the plaque behavior in the interim was not available. Those studies which had the angiograms done incidentally within 3–6 months of the fateful events revealed significantly luminal stenotic coronary lesions.⁶ Similar data were available from the PROSPECT study⁵ which demonstrated almost doubling of the luminal stenosis in the culprit HRP over the follow-up of 3.5 years. In the pathological analysis of almost 300 plaques, it was demonstrated that 95% of the plaques that resulted in an acute event demonstrated more than 50% cross-sectional vascular area involvement. Therefore, it is becoming increasingly clear that the plaques must progress or enlarge (often causing significant luminal occlusion) before they are ready to rupture and result in an acute event. This phenomenon was observed in serial computed tomography (CT) angiograms of a large number of patients wherein the plaque progression⁴ was the most important determinant of adverse outcome (Fig. 3). We have also observed that a few plaques that are able to result in an event in spite of relatively mild luminal stenosis harbor huge necrotic cores and could contribute to the hemodynamic turbulence in the luminal flow.⁷

CONCLUSION

The CT angiographic features of the HRP are well established. It is our considered opinion that all CT angiograms should always be reported with comprehensive plaque characterization and where possible, fractional flow reserve. A greater

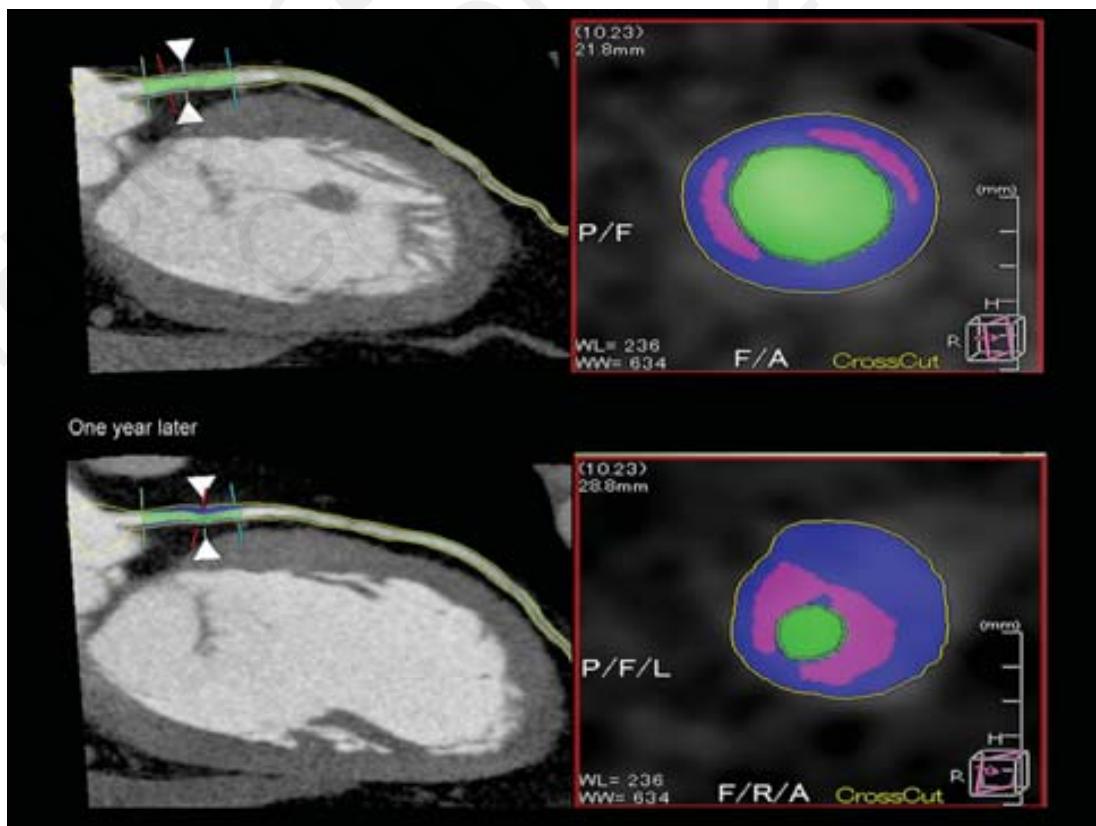

FIG. 3: Serial computed tomography angiography performed at 1-year interval, demonstrates progression of low-attenuation plaques. Patient developed acute coronary event a few weeks after the second scan.

magnitude of HRP features, large number of APCs and plaque progression over time are associated with greater likelihood of major adverse cardiac events. It has also become evident that large lipid rich plaques may be as strong a determinant of abnormal fractional flow reserve as luminal stenosis.

Protecting Heart from Ischemia-Reperfusion Injury: Current Understanding

Jabir Abdulkutty, Jimmy George

INTRODUCTION

Ischemic heart disease is the leading cause of death worldwide.¹ In patients with myocardial infarction (MI), the treatment of choice for reducing acute myocardial ischemic injury and limiting MI size is timely and effective myocardial reperfusion using either thrombolytic therapy or primary percutaneous coronary intervention (PPCI).¹⁻³ However, the process of reperfusion can itself induce cardiomyocyte death, known as myocardial reperfusion injury, for which there is still no effective therapy. Therefore, novel therapeutic strategies are required to protect the heart against ischemia or reperfusion injury, preserve myocardial function, prevent heart failure, and improve clinical outcomes in patients with ischemic heart disease.⁴

Myocardial infarction is usually caused by narrowing of the coronary artery due buildup of an atheromatous plaque and its subsequent rupture. Reperfusion is mandatory to salvage the ischemic myocardium; however this is accompanied by considerable changes in the mitochondrial permeability transition pore (mPTP) opening, generation of reactive oxygen species (ROS), bioavailability of nitric oxide (NO), intracellular distribution of Ca^{2+} and Na^+ , and pH. Paradoxically, reperfusion itself can actually cause cardiomyocyte death and subsequent irreversible myocardial injury, a phenomenon termed “ischemia reperfusion injury (IRI)”.^{5,6}

The absence of nutrients and oxygen in the myocardium leads to a series of changes within the myocardium. The oxidative phosphorylation, leading to mitochondrial membrane depolarization, adenosine triphosphate (ATP) depletion, and inhibition of myocardial contractile function is largely affected with the lack of oxygen supply.⁷ This process is fastened by the breakdown of all available ATP, as the F1F0-ATPase functions in reverse to maintain the mitochondrial membrane potential, resulting in hydrolysis of ATP and an increase in mitochondrial inorganic phosphate. Cellular metabolism switches to anaerobic glycolysis, in the

absence of oxygen resulting in the lactate accumulation, which reduces intracellular pH less than 7.0. Activation of the Na^+-H^+ ion exchanger occurs with intracellular accumulation of protons, which removes protons from the cell in exchange for Na^+ entry. The reduction of ATP during ischemia halts function of the $3\text{Na}^+-2\text{K}^+$ ATPase, thereby increasing the intracellular Na^+ overload. In response, the reverse activation of the $2\text{Na}^+-\text{Ca}^{2+}$ ion exchanger results in intracellular Ca^{2+} overloading as the cell tries to remove Na^+ .^{8,9}

Myocardial ischemic conditioning is referred to an intervention that protects the heart from ischemia or reperfusion injury. This conditioning may be provided before (preconditioning), during (perconditioning) or after the prolonged ischemic insult (postconditioning).⁸

The term “reperfusion injury” has been used for many decades to describe those events associated with reperfusion, some may be transient, (e.g., ventricular arrhythmias, myocardial stunning, and so on) and others permanent, (e.g., death induced by reperfusion, known as lethal reperfusion injury).⁹

MEDIATORS OF MYOCARDIAL REPERFUSION INJURY

Oxidative Stress

There is a burst of oxidative stress during the initial phase of myocardial reperfusion. This oxidative stress imparts myocardial injury and cardiomyocyte death. Therefore, antioxidant therapy was considered for prevention of such injury. However, studies have reported mixed results with antioxidant therapy in prevention of myocardial reperfusion injury.⁸

Intracellular Calcium Overload

We have already mentioned about the Ca^{2+} overload occurring at the time of acute myocardial ischemia. This is exacerbated

during myocardial reperfusion due to disruption of the plasma membrane, damage to the sarcoplasmic reticulum, and mitochondrial re-energization. Re-energization allows the entry of Ca^{2+} into the mitochondria via the Ca^{2+} uniporter due to the recovery of the mitochondrial membrane potential. The entry of Ca^{2+} induces the opening of the mPTP. Literature shows that pharmacologic antagonists of the sarcolemmal Ca^{2+} channel or the mitochondrial Ca^{2+} uniporter administered at the onset of myocardial reperfusion may reduce MI size by up to 50%.¹⁰

The Rapid Restoration of Physiological pH at the Time of Reperfusion

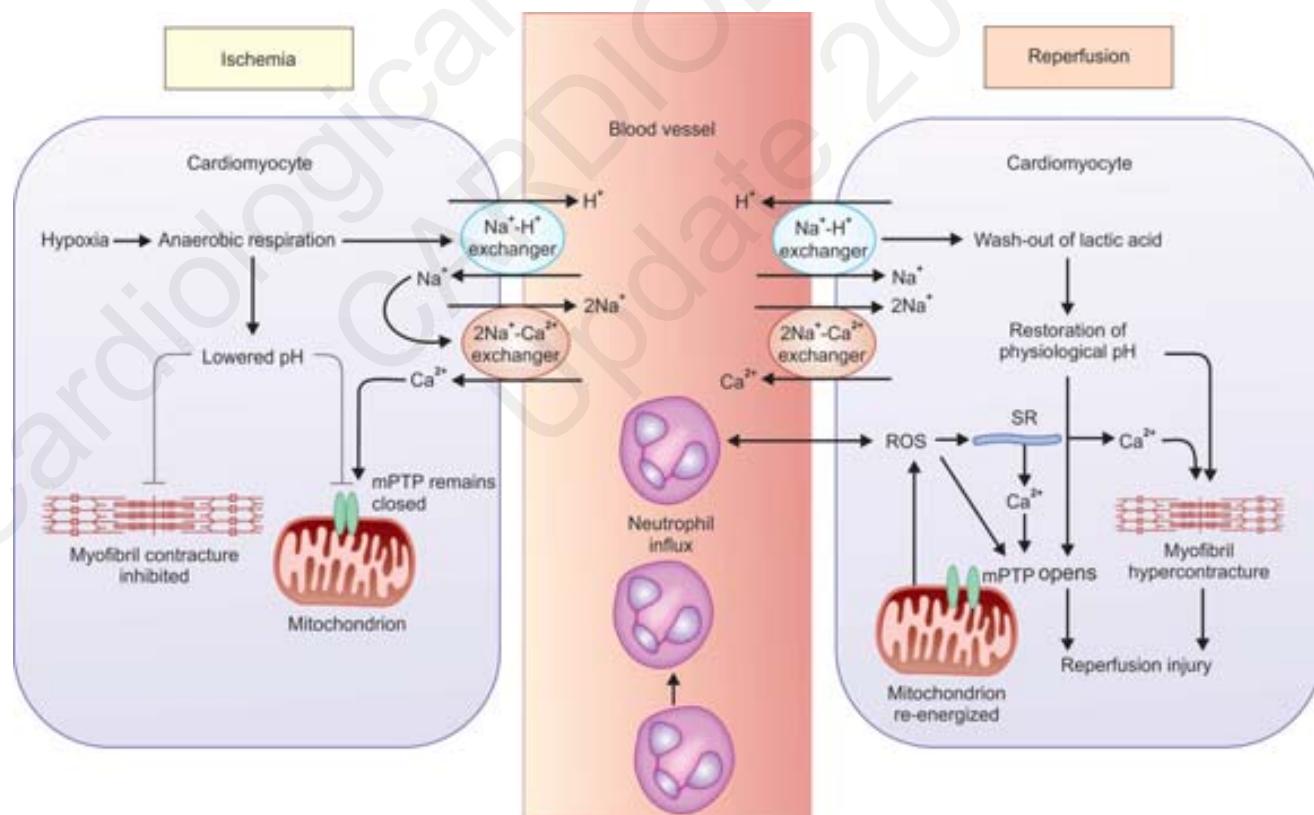

The intracellular pH which decreased to less than 7.0 during acute myocardial ischemia is restored to physiological pH during reperfusion by the activation of the Na^+-H^+ exchanger as well as the $\text{Na}^+-\text{HCO}_3^-$ symporter and by the washout of lactate. This pH shift contributes to mPTP opening and cardiomyocyte rigor hypercontracture in the early phase of reperfusion. Therefore, myocardial reperfusion injury may be reduced by the slow normalization of physiologic pH at the time of myocardial reperfusion. This may be achieved via the pharmacologic inhibition of the Na^+-H^+ exchanger or by slowing the process of myocardial reperfusion.^{11,12}

The Mitochondrial Permeability Transition Pore: An Important Target for Cardioprotection

Many of the above proponents of myocardial reperfusion injury appear to converge on the mPTP. The opening of mPTP, a nonselective channel of the inner mitochondrial membrane, causes depolarization of mitochondrial membrane and uncoupling of oxidative phosphorylation. This leads to ATP depletion and cell death. It has been shown that the mPTP is closed during acute ischemia. The mPTP opens during reperfusion in response to mitochondrial Ca^{2+} and phosphate overload, oxidative stress and relative ATP depletion, and rapid pH correction. Small and large animal MI models have shown that prevention of mPTP opening by mPTP inhibitors such as cyclosporin A at the onset of myocardial reperfusion reduce MI size by 40–50% (Fig. 1).¹¹

Inflammation: Guilty Mediator or Innocent Bystander

The contributory role of inflammatory response accompanying an acute MI in the pathogenesis of reperfusion injury is largely unclear. Different strategies aimed at reducing inflammation during reperfusion have shown significant

mPTP, mitochondrial permeability transition pore; ROS, reactive oxygen species; SR, sarcoplasmic reticulum.

FIG. 1: Schematic illustrating the main proponents of acute myocardial infarction.

reduction in MI size in experimental studies. But these results could not be reciprocated in clinical studies.^{13,14}

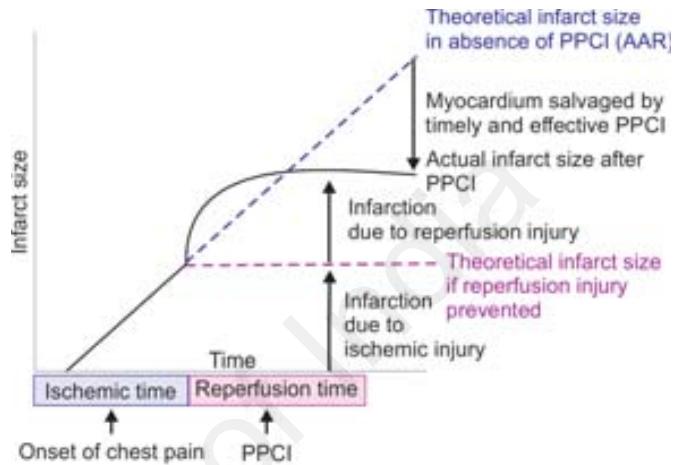

THERAPIES TO REDUCE ISCHEMIC INJURY

There were four landmark studies that changed the course of ST-elevation myocardial infarction (STEMI) treatment and led to the development of strategies to reduce ischemic injury. These studies along with their findings are listed below:

- The demonstration of a spatial progression of necrosis during an infarction—Reimer et al.,⁴ subjected anesthetized dogs to coronary occlusion of varying duration. They reported the progression of a wave front of myocardial necrosis from the central subendocardial layers with severe ischemia, to the less ischemic lateral boundaries and the subepicardium
- The demonstration of the reduced infarct size with reperfusion—Maroko et al., and Ginks et al.,¹⁵ demonstrated that the myocardial can be salvaged by reperfusion within 3 hours after coronary occlusion (“time is muscle”)
- The demonstration that coronary thrombosis is present in most cases of ongoing STEMI by DeWood et al.
- The administration of intracoronary thrombolytics (streptokinase) by Chazov et al. and later, in a larger group of patients, by Rentrop et al.^{4,15}

REPERFUSION BY PRIMARY PERCUTANEOUS CORONARY INTERVENTION, THROMBOLYSIS, OR BOTH¹⁶⁻¹⁹

Reperfusion is considered to be the most effective therapy for the management of ischemic injury during STEMI. Pharmacological, mechanical, and combined reperfusion techniques have evolved over the years, and their efficacy has been greatly advanced by the development of adjunctive therapies. The use of lytic agents in placebo-controlled trials was crucial in the elucidation of the benefits of sustained reperfusion. The GISSI-1 trial was the first large-scale trial that demonstrated a substantial reduction in mortality by reperfusion with intravenous administration of thrombolytic agents.¹⁶ During the early days, PCI for STEMI (primary angioplasty) was described as a rescue intervention in cases with unsuccessful thrombolysis and as an adjunctive therapy to thrombolysis. Angiogram was performed to evaluate the coronary anatomy and residual stenosis. It was only in 1983 that the use of primary angioplasty as an alternative to thrombolysis was acknowledged. Many studies comparing PCI and thrombolysis successfully demonstrated that timely PCI by an experienced team is superior to in-hospital thrombolytic therapy. Newer guidelines propose the use of thrombolytic therapy in patients who cannot get timely PCI. The planned PCI can be delayed until 3–24 hours after lytic administration. This approach differs from the facilitated approach, in which PCI is performed as soon

AAR, area at risk; PPCI, primary percutaneous coronary intervention.

FIG. 2: Illustrates the individual contributions of acute myocardial ischemic injury and myocardial reperfusion injury to final myocardial infarction (MI) size (expressed in arbitrary units) in ST-elevation MI patients up to 24 hours following primary percutaneous coronary intervention.

as the patient arrives at the PCI center.^{17,20,21} The STREAM (Strategic Reperfusion Early After Myocardial Infarction) trial showed that prehospital administration of the thrombolytic tenecteplase in patients who could not get PCI within 1 hour resulted in rates similar to standard primary PCI for the composite end points of death, shock, congestive heart failure, or reinfarction at 30 days. One-year mortality rates in both groups were almost identical (Fig. 2).²²

OTHER THERAPIES TO REDUCE ISCHEMIC INJURY

The mechanisms by which ongoing ischemic cascade that can be attempted slowing have been on investigation for long. Several randomized trials about various drugs have been tested, i.e., able to reduce oxygen consumption have. Among them, β -blockers are mainly studied in many STEMI trials, and there is no conclusive evidence of reduction in infarct size was noted, bringing the cardioprotective potential of β -blockers in STEMI into question. Majority of trials on β -blockers were done on nonreperfusion patients. Metoprolol compared with others have found to be having greater capacity in decreasing reperfusion injury.

Hypothermia has been well-established in reducing progression of ischemic damage in animal models of STEMI, but its clinical application of hypothermia has been limited. CHILL-MI (Rapid Endovascular Catheter Core Cooling combined with cold saline as an Adjunct to Percutaneous Coronary Intervention for the Treatment of Acute Myocardial Infarction) trial included patients scheduled for PCI. The subjects were randomly divided into two groups, i.e., standard care or a rapid cooling protocol (infusion of cold saline plus endovascular cooling device). A measured by cardiovascular magnetic resonance (CMR), hypothermia did not reduce infarct size, despite achievement of the target temperature.²³

Nonpharmacological Interventions to Reduce Reperfusion Injury²⁴

In nonpharmacological interventions the first major development was “ischemic preconditioning” described by Murry et al.²⁵ who, in 1986, reported that performing short duration cycles of ischemia and reperfusion before a prolonged coronary artery occlusion with reperfusion could considerably reduce final infarct size in dogs. Given that total ischemic time was unaltered by this intervention, this study suggested that there was more to limiting infarct size than a shorter duration of ischemia.^{24,25}

The second breakthrough was the description of “ischemic postconditioning” by Zhao et al. in 2003. They showed that performing short duration episodes of ischemia and reperfusion immediately after reflow following prolonged ischemia could decrease the final infarct size in dogs by 30–40%. This effect was more unexpected than preconditioning, because the intervention was applied after reflow. Therefore, it has no connection to the duration of ischemia or any associated event and must be related to the prevention of events occurring after reperfusion.^{26,27}

PHARMACOLOGICAL INTERVENTIONS TO REDUCE REPERFUSION INJURY

Cyclosporine-A

Cyclosporine-A has its mode of action as a postconditioning agent. It acts by inhibiting the opening of the mPTP channel. Piot et al. in his study of 58 patients randomized to receive a single bolus of cyclosporine-A or placebo immediately before PCI. There was significant increase in the area of reperfusion as observed.²⁸

Metoprolol

Beta-blockers have been tested in various STEMI trials in 70s and 80s with no concrete cardioprotective effect. But majority of these trials were before the reperfusion era. Preclinical data from the pig model of infarction demonstrated that intravenous (IV) metoprolol very significantly reduces infarct size when administered before reperfusion.²⁹ The reduction in reperfusion injury rather than of reduced myocardial oxygen consumption, the mechanism responsible for this infarct-limiting effect is proposed to be related to a reduction in reperfusion injury due to the effect of metoprolol on circulating cells (neutrophils or platelets) rather than cardiomyocytes. This preclinical evidence led to the METOCARD-CNIC (Effect of Metoprolol in Cardioprotection during an Acute Myocardial Infarction) trial. The trial included 270 anterior STEMI patients undergoing PCI who were randomly divided into two groups, i.e., early IV metoprolol or control before reperfusion. Infarcts, measured by CMR, were significantly smaller in the IV metoprolol group, six-month CMR follow-up of more than 200 patients showed that the IV metoprolol group had a fewer proportion of lower left ventricular (LV) ejection. The encouraging results from the METOCARD-CNIC trial appear to contradict findings from the much larger COMMIT

(ClOpidogrel and Metoprolol in Myocardial Infarction Trial). In this trial, STEMI patients undergoing thrombolysis were randomized to early IV metoprolol followed by oral metoprolol or matching placebo. The COMMIT showed significantly reduced rates of reinfarction and ventricular fibrillation in response to early IV metoprolol, but there was no infarct size reduction and had an excess cardiogenic shock, resulting in a net neutral effect on mortality.³⁰

Glucose Modulators

Sodi-Pallares had proposed use of glucose to protect cardiomyocytes from energy depletion during MI.³⁰ Combine administration of glucose-insulin-potassium (GIK) during ongoing MI has been tested in several trials. The IMMEDIATE (Immediate Myocardial Metabolic Enhancement during Initial Assessment and Treatment in Emergency Care) trial included patients with suspected acute coronary. The subjects were randomized to GIK or placebo groups during transfer to the hospital. In the subgroup of patients presenting with STEMI, GIK significantly reduced CMR-evaluated infarct size. Lonborg et al. randomized 172 STEMI patients to receive IV injection of the glucagon-like peptide-1 (GLP-1) analog exenatide or placebo. Myocardial salvage on CMR was significantly higher in the exenatide group.³¹

Abciximab

Glycoprotein IIb or IIIa inhibitors reduce thrombotic events by their potent effect on platelets and platelet leukocyte aggregates implicated in ischemia-reperfusion (I/R) injury. The INFUSE-AMI (Intracoronary Abciximab and Aspiration Thrombectomy in Patients with Large Anterior Myocardial Infarction) trial recruited 452 anterior wall STEMI patients undergoing PCI to test the effect of abciximab and/or thrombectomy on infarct size, as evaluated by CMR. Thrombus aspiration had no effect on infarct size, but intra-coronary administration of abciximab significantly reduced infarct size.^{32,33}

Risk Stratification in Unstable Angina/NSTEMI: A Current Approach

Anoop Jain, CB Meena, Sahil Sareen

INTRODUCTION

Ischemic heart disease (IHD) may manifest clinically as either chronic stable angina or an acute coronary syndrome (ACS).¹ The spectrum of ACS includes ST-segment elevation myocardial infarction (STEMI), and the non-ST elevation acute coronary syndrome (NSTE-ACS). The latter consists of non-STEMI (NSTEMI) and unstable angina (UA), which have indistinguishable clinical presentations at the initial evaluation.

Several features help to differentiate ACS from chronic stable angina, including (1) sudden onset of symptoms at rest (or with minimal exertion) that lasts at least 10 minutes unless treated promptly; (2) severe pain, pressure, or discomfort in the chest; and (3) an accelerating pattern of angina that develops more frequently, with greater severity, or that awakens the patient from sleep. The 12-lead electrocardiogram (ECG) and markers of myocardial necrosis are essential tools in distinguishing between the three types of ACS. Patients with typical symptoms without persistent (>20 min continuously) ST-segment elevation in at least two contiguous electrocardiographic leads, but with elevation of myocardial biomarkers more than 99th percentile of normal, are classified as having NSTEMI. Patients without typical symptoms and serial negative markers of myocardial necrosis are classified as having UA, a diagnosis that carries a better prognosis.

EPIDEMIOLOGY

Cardiovascular diseases (CVDs) have now become the leading cause of mortality in India.² A quarter of all mortality is attributable to CVD. Ischemic heart disease and stroke are the predominant causes and are responsible for more than 80% of CVD deaths. The Global Burden of Disease Study estimate of age-standardized CVD death rate of 272 per 100,000 population in India is higher than the global average of 235 per 100,000 population.

Some aspects of the CVD epidemic in India are particular causes of concern, including its accelerated buildup, the early age of disease onset in the population, and the high case fatality rate.²

The fraction of ACS attributed to NSTEMI continues to increase, while that for STEMI is declining, for several reasons: (1) wider use of preventive measures, such as aspirin, statins, and smoking cessation; (2) aging of the population, with greater prevalence of diabetes and chronic kidney disease (CKD) and lower rates of smoking; and (3) broader use of troponin assays with higher sensitivity for myocardial necrosis, which shifts the diagnosis from UA to NSTEMI.³

PATHOPHYSIOLOGY

The pathogenesis of NSTE-ACS involves four processes operating singly or in various combinations: (1) disruption of an unstable atheromatous plaque, which may be driven at least in part by inflammation;⁴ (2) coronary arterial vasoconstriction; (3) gradual intraluminal narrowing of an epicardial coronary artery caused by progressive atherosclerosis or restenosis after stenting; and (4) oxygen supply-demand mismatch (Fig. 1).⁴

Activation of the coagulation cascade and platelets play central roles in the formation of thrombus following plaque disruption.

CLINICAL AND RISK ASSESSMENT

Initial risk assessment is made clinically, based on the history, risk factors for coronary artery disease, clinical assessment (including the heart rate and blood pressure).^{5,6}

The ECG is recommended by the clinical guidelines as a first-line test that should be performed immediately. The ECG has good specificity (97%), but poor sensitivity (28%) in ACS.⁷ This assessment is of pivotal importance since cardiac biomarkers are usually unavailable initially. The most common abnormalities on the 12-lead ECG are

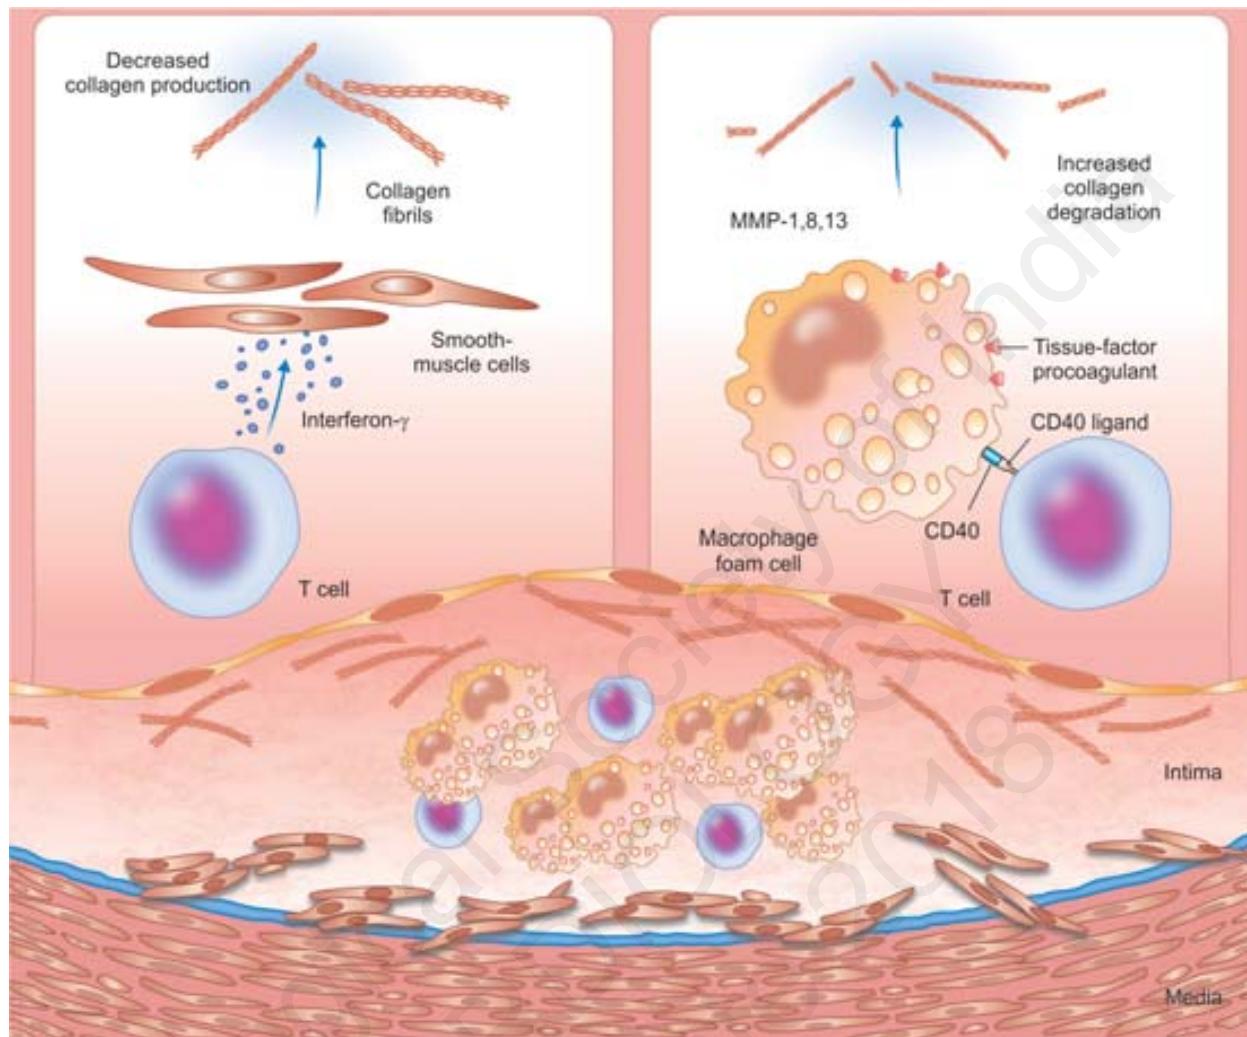

FIG. 1: Inflammatory pathways involved in rupture and thrombosis in coronary arteries: An atherosomatous plaque is shown at the bottom of the figure depicting a central lipid core containing macrophage foam cells (in yellow) and T cells (in blue). Arterial smooth muscle cells (red) are the source of arterial collagen (triple helical structures). T cells are activated and produce cytokines, which inhibit the production of the new, interstitial collagen. T cells may also activate macrophages in the intima by expressing CD40 ligand. This inflammatory signaling causes overproduction of matrix metalloproteinases, which catalyze the initial rate-limiting step in collagen breakdown (top right). These consequences of inflammatory cascade contribute to the instability of the plaque's fibrous cap.

ST-segment depression and T wave inversion, which are more likely to be present while the patient is symptomatic. Greater degrees of ST-segment depression predict poorer outcomes. Deep (>0.2 mV) T wave inversions are compatible with, but not necessarily diagnostic of, NSTEMI, whereas isolated T wave inversions of lesser magnitude are not particularly helpful given their low specificity. More than half of patients with definite NSTEMI may have normal or nondiagnostic ECGs.

Cardiac-specific troponins I (cTnI) and T (cTnT) are the biomarkers of choice to identify myocardial necrosis, thus distinguishing between NSTEMI and UA. Since the sensitivities of different troponin assays in clinical practice vary, the consensus recommendation is to define MI by an elevation in cTnI or cTnT more than 99th percentile of the normal range of the specific assay used⁸ with a typical

temporal rise and fall occurring in a patient with a clinical presentation consistent with ACS. As high-sensitivity troponin (hsTn) assays⁸ that can detect ultralow concentrations of troponin in approximately 90% of healthy individuals become increasingly available, consideration of the clinical context of a troponin elevation will become even more important in avoiding misdiagnosis and improper triage in management of patients. Several other biomarkers may be useful to determine prognosis and help guide care. Of these, the natriuretic peptides [i.e. brain natriuretic peptide (BNP) and N-terminal pro-BNP] have been most widely used in patients with NSTEMI. Similarly, C-reactive protein (CRP), a marker of inflammation, is elevated following NSTEMI, and the degree of elevation correlates with long-term cardiovascular (CV) outcomes. Other promising novel biomarkers in diagnosis of ACS include chemokine ligand-5

and ligand-18,⁹ interleukin-6,¹⁰ heart-type fatty acid-binding protein,¹¹ pentraxin,¹² midregional proadrenomedullin,¹³ and copeptin.¹³

The combination of hs-cTn and novel biomarkers has also been investigated. In a prospective observational study of 478 patients, the combination of hs-cTn and copeptin demonstrated significantly higher sensitivity to identify NSTE-ACS than a repeat hs-cTn.¹⁴

NONINVASIVE TESTING

Noninvasive testing in patients with established or suspected NSTE-ACS plays a number of important roles: (1) establishing the presence (or absence) of significant CHD; (2) diagnosing CHD as the cause of cTn elevation in patients who may have other explanations; (3) evaluating the extent of residual ischemia after initiation of medical therapy, helping to guide future management; (4) localizing the territory of ischemia before revascularization in a patient with multivessel disease; and (5) assessing left ventricular (LV) function.

Symptom-limited or pharmacologic stress testing appear to be safe after at least 24 hours of stabilization without symptoms of active ischemia or other signs of hemodynamic or electrical instability. For most patients, electrocardiographic exercise stress testing is recommended if the ECG at rest lacks significant baseline abnormalities. If significant baseline ECG abnormalities are present, stress perfusion or echocardiographic imaging should be performed before and immediately after exercise.

Echocardiography is useful in the assessment of LV systolic and diastolic function and can also identify left atrial dilation, functional mitral regurgitation, tricuspid annular plane systolic excursion, diastolic dysfunction, and ventricular mechanical dyssynchrony. Speckle tracking echocardiography can predict patients of NSTE-ACS with acute coronary occlusion who may benefit from an early revascularization strategy.¹⁵

Coronary CT angiography (CCTA) has been proposed as a modality to improve the early management of NSTE-ACS patients. In a large study involving 1,000 patients at nine hospitals in the United States, CCTA facilitated the exclusion of a diagnosis of ACS, increasing discharge from the emergency department and reducing length of stay.¹⁶ Three large randomized trials have shown that CCTA compared to standard evaluation expedites the triage of patients presenting with chest discomfort in the ED, thereby shortening length of stay.¹⁶⁻¹⁸ The appropriate indications according to a study¹⁹ include an ECG which is negative or indeterminate for myocardial ischemia, low-intermediate pretest likelihood by risk stratification tools, a TIMI risk score of 0-2 (low risk) or a HEART score less than 3, more than or equal to 1 negative troponin value, including point-of-care assays and equivocal or inadequate previous functional testing during index ED or within previous 6 months. It is also appropriate for evaluation of cardiac mass (suspected tumor or thrombus, or of a pericardial condition (pericardial mass, constrictive pericarditis, or complications of cardiac surgery). Evaluation of pulmonary vein anatomy prior to invasive radiofrequency

ablation for atrial fibrillation can also be done via a coronary CT. Noninvasive coronary vein mapping prior to placement of biventricular pacemaker and noninvasive coronary arterial mapping, including internal mammary artery prior to repeat cardiac surgical revascularization are also appropriately assessed by CCTA, although for this intra- and extracardiac structural and functional assessment, cardiac magnetic resonance (CMR) is found to be better.

Cardiac magnetic resonance imaging (CMRI) using a rapid-scan protocol can provide precise measurements of ventricular volumes and function, evaluate ventricular wall edema, identify areas of infarcted versus hibernating myocardium, establish the presence of myocardial perfusion, quantify wall motion, and identify myocardium at risk in patients with NSTE-ACS.²⁰

Cardiac magnetic resonance imaging can be used in evaluation of CAD with an intermediate pre-test probability of CAD and in cases where ECG is uninterpretable or exercise test is equivocal or uninterpretable. Evaluation of coronaries especially in new onset failure can be done by CMR.

STRATIFICATION OF RISK

An estimate of the absolute individual patient risk of NSTE-ACS is important in clinical management and when assessing the treatment strategies because different patients have different risks. The potential for risk reduction by an appropriate intervention broadly depends upon the absolute risk itself and is directly proportional to it. A single risk variable may not provide a reliable assessment of risk. In practice, there has been a tendency to use this single factor like a cardiac marker for patient risk stratification, for example, serum troponin. This may not be accurate enough alone for predicting the absolute risk specially when used in a qualitative manner.

For example, when compared to a well-validated risk scoring system (GRACE21), that uses multiple risk factors, a large proportion of troponin positive patients had low to medium risks and vice versa (Fig. 2).²¹

Therefore, a number of risk scoring systems have been developed to predict short- and medium-term outcome in patients with acute coronary syndromes. Fourteen observational studies²¹⁻³⁴ were identified that assessed the utility of various risk scores.

TIMI Risk Score

A 7-point score for patients with acute coronary syndromes derived by summing the presence of each of these factors (1 point for each) (Table 1):²²

- Age more than 64 years
- More than three coronary risk factors
- Prior coronary angiographic coronary obstruction
- ST-segment deviation
- More than two angina events within 24 hours
- Use of aspirin within 7 days
- Elevated levels of cardiac biomarkers (e.g., troponin).

FIG. 2: Bar chart describes the distribution of (left axis) troponin positive (red bars) and troponin negative (yellow bars) patients according to category of GRACE risk score (ranging from 51 to 226) among 27,406 patients with non-ST elevation acute coronary syndrome in the GRACE registry. The blue curve (right axis) depicts the observed hospital mortality rates.

TABLE 1: TIMI risk score

TIMI score	14-day adverse cardiac event rate (%)
0/1	4.7
2	8.3
3	13.2
4	19.9
5	26.2
6/7	40.9

TABLE 2: GRACE risk score

GRACE score	Risk category	In-hospital deaths (%)	Postdischarge to 6 months (% of deaths)
<109	Low risk	<1	<3
109–140	Intermediate risk	1–3	3–8
>140	High risk	>3	>8

GRACE Risk Score

According to some studies, the GRACE risk score provides the most accurate stratification of risk both on admission and at discharge (Table 2).^{35,36}

Variables used in the GRACE 2.0 risk calculation include age, systolic blood pressure, pulse rate, serum creatinine, Killip class at presentation, cardiac arrest at admission, elevated cardiac biomarkers and ST deviation. If the Killip class or serum creatinine values are not available, a modified score can be calculated by adding renal failure and use of diuretics, respectively.

One of the limitations of the GRACE score is its non-adoption in daily practice probably due to lack of awareness by medical and nursing staff, a lack of access to the on-line website, and lack of time in a busy department since the creatinine and troponin blood results are required before the score can be completed.

PURSUIT Risk Score

The PURSUIT risk score for death at 30 days was derived from the RCT of the same name (N = 9461; NSTE-ACS).²⁹ It includes variables like age, sex, (Canadian Cardiovascular Society (CCS)-class in previous 6 weeks, heart rate, systolic blood pressure (SBP), rales, and ST-segment depression at presentation.

Other risk scores include PREDICT, AMIS, EMMACE, SRI (simple risk score), and comparative studies have been undertaken to compare these aforementioned risk scores against one another. In the MINAP database (N = 100,686), the PURSUIT, GRACE, SRI, and EMMACE risk scores showed similarly high discrimination in predicting the likelihood of death.³⁰

GRACE Risk Score versus PURSUIT Risk Score

Two studies of populations with non ST-segment elevation ACS showed no significant difference in discriminatory performance between the GRACE and PURSUIT risk scores for predicting in-hospital and one year mortality.^{23–28} Similarly, GRACE and PURSUIT risk scores have been found to have a better discrimination for 1 year mortality than TIMI risk score.²⁸

The various risk models reviewed use different components to make up their systems, and none is clearly superior, although PURSUIT, GRACE, and PREDICT seem to have better discrimination than TIMI for mortality.

Bleeding Risk

Various pharmacological agents (such as antithrombin and antiplatelet drugs) and coronary revascularization [either percutaneous coronary intervention (PCI) or coronary artery bypass graft (CABG) surgery] are known to be associated with some treatment hazards (particularly bleeding complications), which for the individual patient must be balanced against any potential treatment benefits.

Major bleeding events are associated with increased mortality in NSTE-ACS.^{37,38} The can rapid risk stratification of unstable angina patients suppress adverse outcomes with early implementation of the ACC/AHA guidelines (CRUSADE) bleeding risk score was developed from a cohort of 71,277 NSTE-ACS patients (derivation cohort) and further validated in a cohort of 17,857 patients (validation cohort) from the same registry.³⁹ The CRUSADE bleeding risk score considered baseline patient characteristics (i.e., female gender, history of diabetes, history of peripheral vascular disease or stroke), admission clinical variables (i.e., heart rate, systolic blood pressure, signs of heart failure) and admission laboratory values (i.e., hematocrit, calculated creatinine clearance) to estimate the patient's likelihood of an in-hospital major bleeding event.

The acute catheterization and urgent intervention triage strategy (ACUITY) bleeding risk score was derived from a pooled cohort of 17,421 patients with ACS (both NSTE-ACS and STEMI) recruited in the ACUITY and harmonizing outcomes with revascularization and stents in acute myocardial infarction (HORIZONS-AMI) trials.³⁷

CRUSADE and ACUITY scores have reasonable predictive value for major bleeding in ACS patients undergoing coronary angiography, with CRUSADE found to be the most discriminatory.⁴⁰ However, in patients medically treated or on oral anticoagulants, the predictive value of these scores is not established.

MANAGEMENT (BOX 1)

General Measures

After the initial evaluation and a directed history with physical examination is done, an ECG should be performed within 10 minutes of arrival. Blood specimens for cTn or, if possible, hsTn assay should be obtained and a second assay can be performed after 3–6 hours of the first test. Patients with

BOX 1 Management of non-ST elevation acute coronary syndrome

- General measures
- Anti-ischemic therapy
- Antithrombotic therapy
- Intervention
- Rehabilitation

elevated cTn or new ST-segment abnormalities or deemed to be at moderate or high risk based on a validated risk score should be admitted to a specialized cardiovascular intensive care unit (ICU). Patients with UA but without elevated cTn and ischemic electrocardiographic changes should be admitted to a monitored bed, preferably in a CV step-down unit.¹ In these settings, continuous electrocardiographic monitoring with telemetry should be present. Patients should be placed on bed rest and inhaled oxygen provided to patients with arterial oxygen saturation (SaO_2) less than 90% and those with HF and pulmonary rales.

Anti-ischemic Therapy

Rationale

Beta-blockers

Beta-adrenergic receptor blockers decrease heart rate, blood pressure, and contractility, resulting in a reduction in myocardial oxygen demand. These effects are primarily the result of competitive antagonism of the β_1 cardiomyocyte receptors. The evidence supporting their clinical benefit is largely derived from earlier studies in patients with acute MI before the current era of reperfusion therapy for STEMI. The findings have been extrapolated to include patients with UA and NSTEMI (Table 3).⁴¹

Nitrates

Therapy with nitrates exerts beneficial effects by decreasing preload and LV end-diastolic volume, thereby reducing myocardial oxygen demand. Nitrates also dilate both normal and diseased coronary arteries, an action that potentially increases both antegrade and collateral coronary blood flow. Typically, nitrates are used in patients with ACS who have hypertension or HF and in those with continued angina.

Calcium Channel Blockers (CCBs)

CCBs may cause vasodilation, reduce heart rate, or decrease myocardial contractility. Because these effects occur to a variable extent with the various CCBs, there is not a class effect. The American College of Cardiology/American Heart

TABLE 3: Class of drugs and their role in NSTE-ACS

Class of drug	Role in NSTE-ACS
Beta blockers	Decreased mortality
Nitrates	No benefit on mortality
Calcium channel blockers	No clear benefit on mortality or reinfarction
Nicorandil	Decreases arrhythmias and transient ischemia
Trimetazidine	Decreases short-term mortality
Ranolazine	Decreases recurrent ischemia and arrhythmias
Cyclosporine (inhibitor of mitochondrial permeability transition pore)	Reduces infarct size in small studies ⁴²

NSTE-ACS, non-ST elevation acute coronary syndrome.

TABLE 4: Antiplatelet and anticoagulation treatment summary for non-ST elevation acute coronary syndrome

Initial treatment
DAPT and anticoagulant therapy:
1. Aspirin (COR I, LOE A)
2. P2Y12 inhibitor, clopidogrel or ticagrelor (COR I, LOE B)
3. Anticoagulant: Enoxaparin (COR I, LOE B) or fondaparinux (COR I, LOE B) or bivalirudin (for invasive strategy, COR I, LOE B)
4. Can consider GP IIb/IIIa receptor inhibitors in high-risk patients stratified to early invasive strategy (Eptifibatide or tirofiban; COR IIb, LOE B)
During hospitalization
Medically treated patients:
1. Aspirin (COR I, LOE A)
2. P2Y12 inhibitor, either ticagrelor or clopidogrel (COR I, LOE B)
3. Anticoagulant: Enoxaparin (COR I, LOE B) or UFH (COR I, LOE B) or fondaparinux (COR I, LOE B)
PCI-treated patients:
1. Aspirin (COR I, LOE A)
2. P2Y12 inhibitor, clopidogrel, ticagrelor or prasugrel (COR I, LOE B)
3. Anticoagulant: Enoxaparin (COR I, LOE B) or UFH (COR I, LOE B) or fondaparinux (COR I, LOE B) or bivalirudin
4. Can consider GPIIb/IIIa receptor inhibitors in high-risk patients not adequately pretreated with clopidogrel (COR I, LOE A) or in high-risk patients adequately pre-treated with clopidogrel (COR IIa, LOE B)
Long-term treatment
Medically treated patients:
1. Aspirin indefinitely (COR I, LOE A)
2. P2Y12 inhibitor, clopidogrel or ticagrelor for up to 12 months (COR I, LOE B)
PCI-treated patients:
1. Aspirin indefinitely (COR I, LOE A)
2. P2Y12 inhibitor clopidogrel or ticagrelor or prasugrel for at least 12 months (COR I, LOE B)

Association (ACC/AHA) UA/NSTEMI guidelines recommend that for patients with continuing or frequent ischemia in whom a β -blocker cannot be given, a nondihydropyridine CCB should be administered (COR I, LOE B) in the absence of clinically significant LV dysfunction or other contraindications. It is reasonable to give a nondihydropyridine CCB (COR IIa, LOE C) to patients with recurrent ischemia after β -blockers and nitrates have been fully used.

Other Agents

Trimetazidine is also a piperazine derivative that shifts myocardial metabolism from fatty acid oxidation to more oxygen-efficient glucose oxidation pathways, thus reducing ischemia without measurable changes in the heart rate-blood pressure product. Nicorandil is a drug that activates ATP-sensitive K^+ channels and dilates peripheral and coronary arterioles. This K^+ channel function is also postulated to induce cardiac protection via an ischemic preconditioning-like effect. Cardiac ischemia is associated with alterations in intracellular sodium and calcium concentrations, leading to arrhythmias, decreased contractility, and myocyte death. Ranolazine preserves intracellular ATP levels, improves myocardial function, and limits the extent of ischemic myocardial necrosis. Its role in patients with ACS is less well defined than its demonstrated usefulness in some patients with chronic stable angina.

Antithrombotic Therapy

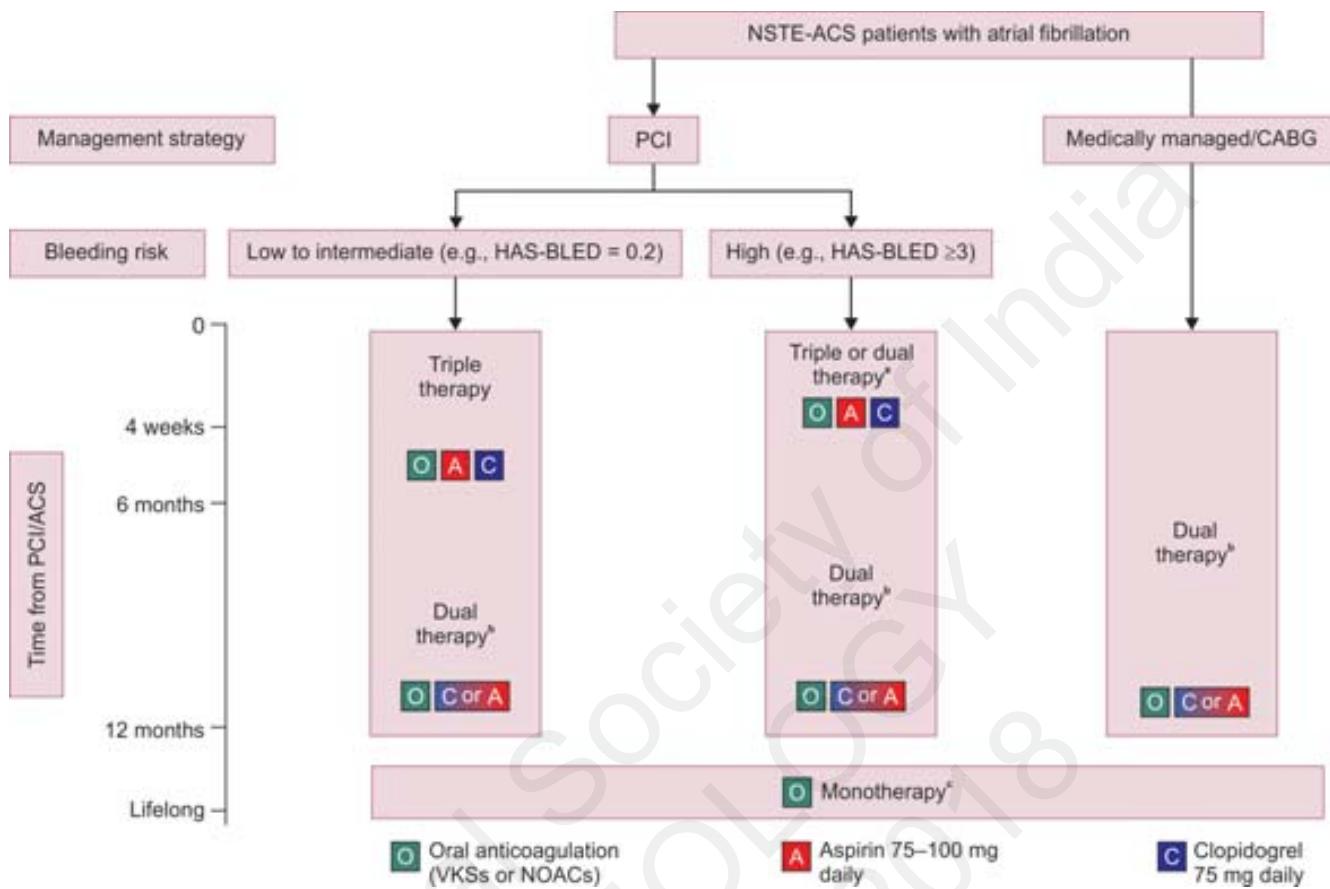

Antiplatelet and anticoagulation treatment summary for NSTEMI according to 2014 AHA/ACC guidelines is as shown in table 4.

About 10% of patients who are admitted with NSTEMI require long-term treatment with oral anticoagulants for various reasons, such as atrial fibrillation, prior venous thromboembolism, and mechanical heart valves.⁴³ The combination of antiplatelet and anticoagulant treatment, either as dual or as triple therapy, increases the bleeding risk three- to fourfold as compared to warfarin monotherapy.⁴³ In patients with NSTEMI receiving DAPT who had been receiving prior oral anticoagulation, it is reasonable to transition to a parenteral anticoagulant at or shortly after presentation (i.e., once therapeutic anticoagulation has waned). If immediate angiography is required, radial access is the preferred choice because it may reduce the risk of access site bleeding. After the procedure, the duration of triple therapy should be minimized.

In one study⁴⁴ participants with atrial fibrillation undergoing PCI with placement of stents, who were administered either low-dose rivaroxaban plus a P2Y12 inhibitor for 12 months or very-low-dose rivaroxaban plus DAPT for 1, 6, or 12 months were associated with a lower rate of clinically significant bleeding than was standard therapy with a vitamin K antagonist plus DAPT for 1, 6, or 12 months. The three groups had similar efficacy rate.

Predictive value of the HAS-BLED (Hypertension, Abnormal renal/liver function, Stroke, Bleeding history or predisposition, Labile international normalized ratio, Elderly, Drugs or alcohol use) score for clinical outcomes has been investigated in patients with and without atrial fibrillation⁴⁵ (Flowchart 1).

The HAS-BLED scoring system is similar to the GRACE and CRUSADE systems but better than TIMI system to

PCI, percutaneous coronary intervention; CABG, coronary artery bypass graft.

FLOWCHART 1: Antithrombotic strategies in patients with non-ST elevation acute coronary syndrome (NSTE-ACS) and nonvalvular atrial fibrillation (AF).

predict long-term survival outcomes in patients with NSTEMI without atrial fibrillation.⁴⁵ However, HAS-BLED score is easier to calculate than GRACE and CRUSADE scores.

Intervention: Invasive versus Conservative Management

Approach

An early invasive strategy, in the absence of contraindication, is recommended in patients with NSTE-ACS who have ST-segment changes and/or positive troponin assay on admission, or in whom these high-risk features develop over the subsequent 24 hours. Other high-risk indicators, such as recurrent ischemia or evidence of congestive heart failure, also indicate an early invasive strategy.^{1,46} An early invasive strategy is also advised in patients with NSTE-ACS previously treated with CABG.¹ and in patients who have had NSTE-ACS within 6 months of a previous PCI and in whom restenosis may be the cause.⁴⁶ Indications for an initial conservative strategy include patients with life-threatening comorbid conditions or in whom the risks outweigh the potential benefits, and in low-risk patients without recurrent symptoms.^{1,46}

Comparison: Invasive versus Conservative

In the meta-analysis performed by Milasinovic et al. (2015),⁴⁷ the early invasive patients received intervention between 0.5 hours and 24 hours from hospital admission and the delayed invasive patients received intervention between 20.5 hours and 86 hours from hospital admission. From the large study population used, they were able to conclude that an earlier invasive strategy was associated with lower rates of recurrent ischemia at 6 months (4.1% compared with 7.5%).

Angiographic success (TIMI epicardial grade 2 or 3 flow) can be achieved in a large majority (95%) of patients with NSTE-ACS who undergo PCI, even in those considered to be at high risk.⁴⁸ However, the development of intraprocedural complications, such as transient or sustained loss of a side branch, abrupt closure, distal embolization, or development of the no-reflow phenomenon, may entail a four- to fivefold increase in the risk for ischemic complications and death over the next 30 days.⁴⁸ Although use of drug-eluting stents (DESs) reduces the risk for restenosis, there is a risk for late stent thrombosis following DES implantation, especially when DAPT (i.e., ASA and P2Y12 inhibitor) is discontinued. This serious complication can be reduced in the long-term in

BOX 2 Risk criteria in patients with NSTEMI**Very-high-risk criteria**

- Hemodynamic instability or cardiogenic shock
- Recurrent or ongoing chest discomfort refractory to optimal medical therapy
- Life-threatening arrhythmias or cardiac arrest
- Mechanical complications of MI
- Acute heart failure
- Recurrent dynamic ST-T wave changes, particularly with intermittent ST-elevation

High-risk criteria

- Rise and fall in cardiac troponin in compatible with MI
- Dynamic ST-T wave changes without symptoms (silent)
- Elevated TIMI (>4) or GRACE (>140) risk score

Intermediate-risk criteria

- Diabetes mellitus
- Renal insufficiency (eGFR <60 mL/min/173 m²)
- LVEF <40% or congestive heart failure
- Early post-MI angina
- Prior CABG
- TIMI (2–3) or GRACE (109–140) risk score

Low-risk criteria

- None of the characteristics mentioned above

CABG, coronary artery bypass graft; eGFR, estimated glomerular filtration rate; NSTEMI, non-ST elevation acute coronary syndrome; MI, myocardial infarction; PCI, percutaneous coronary intervention.

patients with DESs, by continuing DAPT beyond 12 months after stenting.⁴⁸

Both North American and European guidelines recommend using a “heart team” approach to guide decisions regarding revascularization that includes input from interventional cardiologists and cardiothoracic surgeon in patients with LMA and complex CAD. Factors that favor CABG include multiple and complex coronary lesions, presence of DM, LV systolic dysfunction, and DAPT intolerance. Factors favoring PCI include high risk of operative mortality, prior thoracotomy, and advanced CKD.¹

Table 2 and box 2 shows the management of NSTEMI⁴⁹ patients according to risk stratification.

Rehabilitation

Non-ST elevation-ACS is a heterogeneous syndrome, not a specific disease. Subgroups of patients who respond to specific therapies should be identified. Specifically, there is considerable variation in the responses to antiplatelet agents and anticoagulants, in terms of both efficacy and safety. Efforts should be elevated to identify predictors of responses to these agents.

The time of discharge is important to let the patient know the importance of continuance of the antiplatelet agents and to teach the patient regarding the modifiable risk factors and the impact they have on the disease process.

The management strategies often depend on risk assessment, available facilities and financial constraints. An analysis of data from Indian ACS registries⁵⁰ highlight the problems related to accessibility of health care, literacy, and economic status on management outcomes. NSTEMI patients are older, have more risk factors and present late. The utilization of evidence based medication is less.

Inadequate access to health care, difficulty in transportation and poor socioeconomic background are impediments to the care of patients in rural areas. In urban centers, out of pocket expenses remain challenging for patients.

hs-cTroponin in Acute Coronary Syndrome: Current Status

Amal K Banerjee

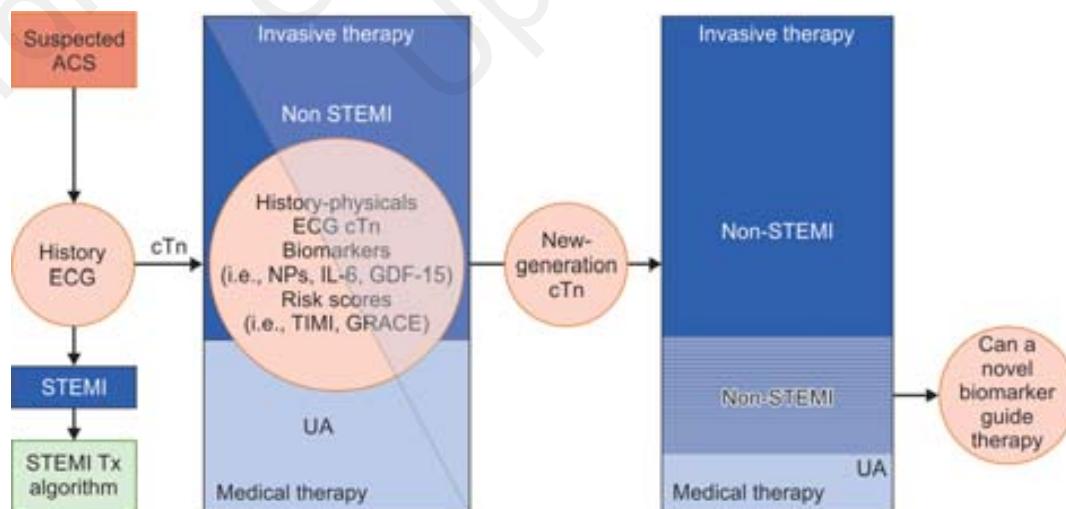

INTRODUCTION

Chest pain is one of the most common reasons for presentation to hospitals worldwide. Despite the majority of patients not having acute coronary syndrome (ACS), hospital admission for observation and serial cardiac troponin (cTn) testing is required in many patients to identify those with and without myocardial injury.

The field of ACS is rapidly changing. Besides new drugs, the evolution is mainly driven by the introduction of novel biomarkers in an effort to respond to the partly unmet need for better diagnosis, prognostication, and management of patients. Novel biomarkers may improve diagnostic accuracy, identify subgroups of patients who may benefit from a specific therapeutic modality in the acute phase, and reveal pathophysiological insights that need to be addressed by long-term medical treatment. In this context, the new-generation cTn assays provide considerably more sensitive

and timely diagnosis of ACS.¹ The highly sensitive new-generation cTn assays modify the classification of patients with non-ST-segment elevation acute coronary syndrome (NSTE-ACS) by increasing the percentage of cases with NSTE myocardial infarction (MI) and limiting that of unstable angina (UA) (Fig. 1).² As a result, this reclassification² creates a need for novel prognostication models that would identify high-, moderate-, and low-risk patients and thus guide our treatment decisions. In particular, the long-term benefit of an invasive approach in the subgroup of patients who are reclassified from UA to NSTE myocardial infarction has not yet been proven by large randomized trials. Whether this need is addressed by novel biomarkers remains to be seen.

Despite uneasiness among clinicians about the increasing sensitivity of assays for cTn, it is rare that clinical algorithms for laboratory-based tests have as much data to guide decision making as do high-sensitivity assays for

ACS, acute coronary syndrome(s); cTn, cardiac troponin; ECG, electrocardiogram; NP, natriuretic peptides; STEMI, ST-segment elevation myocardial infarction; Tx, therapy; UA, unstable angina.

FIG. 1: The role of highly sensitive new-generation cTn in the diagnosis and risk stratification of patients with ACS.

cTn for diagnosis (rule-in) or exclusion (rule-out) of MI. Rather, the proliferation of research evaluating variations in such algorithms in the emergency department (ED) has the potential to overwhelm clinicians with options. Of the emerging applications for hsTn, the rapid rule-out of MI in the ED is the application most likely to be embraced by clinicians.³ This application most directly leverages the superior analytic and clinical sensitivity of hsTn assays as an advantage by translation into a robust negative predictive value (NPV) for MI.

CLINICAL PERSPECTIVE

Recently, high-sensitivity cardiac troponin (hs-cTn) assays have been implemented into routine clinical care in Europe, Canada, Australia, New Zealand, and other countries. These assays overcome some of the limitations of conventional cTn assays, particularly the sensitivity deficit at presentation.^{4,5} hs-cTn assays provide higher early diagnostic accuracy for acute myocardial infarction (AMI) when compared with conventional cTn assays.^{6,7} However, their clinical introduction has also been associated with challenges, particularly the interpretation of mild elevations.

CLINICAL PRACTICE GUIDELINES

The most recent European Society of Cardiology (ESC) guidelines for the management of ACSs in patients presenting without persistent ST-segment elevation⁸ proposed a new algorithm using high-sensitivity troponin: a 1-hour rule-in and rule-out algorithm.

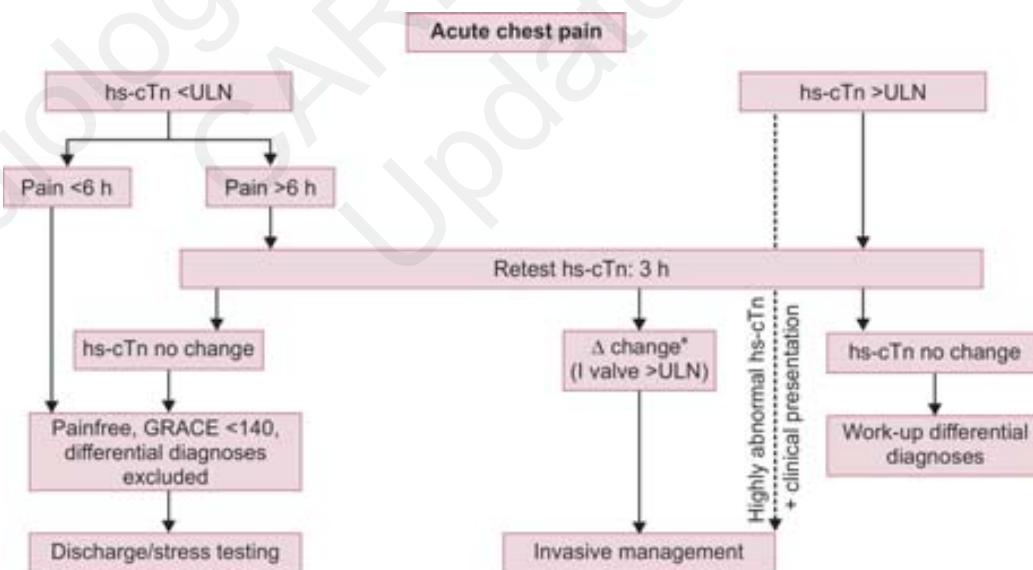

Rule-in and Rule-out Algorithms in ESC 2015 Guidelines on Management of ACS⁸

Due to the higher sensitivity and diagnostic accuracy for the detection of acute MI at presentation, the time interval to the second cTn assessment can be shortened with the use of high-sensitivity assays. This may reduce substantially the delay to diagnosis, translating into shorter stays in the emergency department and lower costs.⁸

It is recommended to use the 0-hour/3-hour algorithm (Flowchart 1).⁸ As an alternative, 0-hour/1-hour assessments are recommended when hs-cTn assays with a validated algorithm are available (Flowchart 2).⁸ The 0-hour/1-hour algorithms rely on two concepts: first, hs-cTn is a continuous variable and the probability of MI increases with increasing hs-cTn values;⁹ second, early absolute changes of the levels within 1-hour can be used as surrogates for absolute changes over 3-hour or 6-hour and provide incremental diagnostic value to the cTn assessment at presentation. The cut-off levels within the 0-hour/1-hour algorithm are assay specific.⁸⁻¹⁰

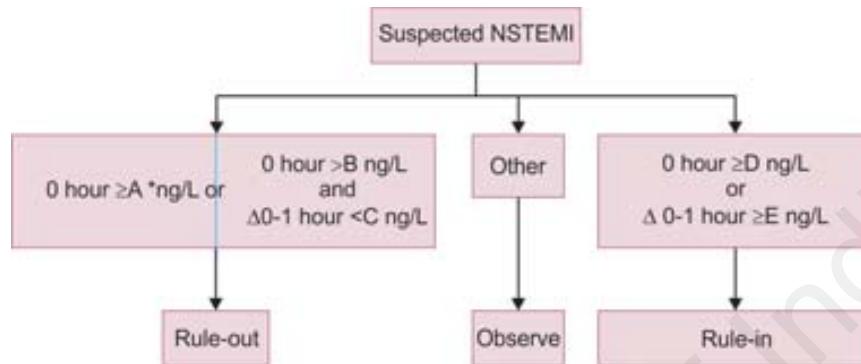

Characteristics of 0-hour/3-hour and 0-hour/1-hour Algorithms⁸

"The negative predictive value for MI in patients assigned to rule-out exceeded 98% in several large validation cohorts.⁹⁻¹³ Used in conjunction with clinical and ECG findings, the 0-hour/1-hour algorithm may allow the identification of candidates for early discharge and outpatient management. The positive predictive value for MI in those patients meeting the rule-in criteria was 75–80%.^{1,9,11,13} Most of the rule-in

GRACE, Global Registry of Acute Coronary Events score; hs-cTn, high-sensitivity cardiac troponin; ULN, upper limit of normal, or 99th percentile of healthy controls; ^aΔ, change, dependent on assay. Highly abnormal hsTn defines values beyond 5-fold the upper limit of normal.

hs-cTnT, high-sensitivity cardiac troponin T; hs-cTnI, high-sensitivity cardiac troponin I; NSTEMI, non-ST-elevation myocardial infarction.

FLOWCHART 2: 0-hour/1-hour rule-in and rule-out algorithms using high-sensitivity cardiac troponins (hs-cTn) assays in patients presenting with suspected non-ST-elevation myocardial infarction (NSTEMI) to the emergency department. 0-hour and 1-hour refer to the time from first blood test. NSTEMI can be ruled-out already at presentation, if the hs-cTn concentration is very low. NSTEMI can also be ruled out by the combination of low baseline levels and the lack of a relevant increase within 1-hour. Patients have a high likelihood for NSTEMI if the hs-cTn concentration at presentation is at least moderately elevated or hs-cTn concentrations show a clear rise within the 1st hour. Cut-off levels are assay-specific. Cut-off levels for other hs-cTn assays are in development.

patients with diagnoses other than MI did have conditions that usually require inpatient coronary angiography for accurate diagnosis, including takotsubo cardiomyopathy and myocarditis.^{9,13,14} Patients who do not qualify for rule-out or rule-in represent a heterogeneous group that may require further investigations, if no alternative explanation for the cTn elevation is identified. A large proportion of these patients may require a further hs-cTn assessment (e.g., at 3-hour). For rapid rule-out, alternative approaches to the 0-hour/1-hour or 0-hour/3-hour algorithms have been adequately validated and may be considered. A 2-h rule-out protocol combining the Thrombolysis in Myocardial Infarction (TIMI) risk score with ECG and hs-cTn at presentation allowed a safe rule-out in up to 40% of patients.¹⁵

"When using any algorithm, three main caveats should be considered—(1) algorithms should only be used in conjunction with all available clinical information, including detailed assessment of chest pain characteristics and ECG; (2) in patients presenting very early (e.g., within 1 hour from chest pain onset), the second cTn level should be obtained at 3-hour, due to the time dependency of troponin release; (3) as late increases in cTn have been described in approximately 1% of patients, serial cTn testing should be pursued if the clinical suspicion remains high or whenever the patient develops recurrent chest pain.¹⁶ High-sensitivity cTn assays also maintain high diagnostic accuracy in patients with renal dysfunction. To ensure the best possible clinical use, assay-specific optimal cut-off levels, which are higher in patients with renal dysfunction, should be used."¹⁷

RISK ASSESSMENT AND OUTCOMES

Beyond diagnostic utility, cTn levels add prognostic information in terms of short- and long-term mortality to clinical and ECG variables. While hs-cTn T and I seem to have comparable diagnostic accuracy, high-sensitivity cardiac troponin T (hs-cTnT) has greater prognostic accuracy.¹⁸ The higher the high-sensitivity troponin levels at presentation, the greater the risk of death.⁹

Sometimes Earlier may not be Better

The ESC guidelines 15 algorithm opened a wide debate regarding its efficacy and safety. Allan S Jaffe et al. from the Mayo Clinic in Rochester, Minnesota, USA challenge this notion.¹⁹ They argue that, although these algorithms may represent an advance in the early diagnosis of chest pain patients, the ESC guidelines may have overlooked some gaps in the evidence for these approaches that could inadvertently disadvantage patients.

The hs-cTn 0-hour/1-hour algorithm, they said, proposed in the ESC guidelines on the management of NSTEMI might allow a rapid rule in and rule out of a large proportion of patients with suspected NSTEMI. A critical question is: Should the 1-hour algorithm for rule-in and rule-out of AMI be used universally? This approach might substantially speed up the triage of patients with suspected NSTEMI. Yet, some concern has recently been raised on this universal application regardless of symptom duration, overall clinical risk, and sex.

Guideline mandated diagnostic assessments should be applicable to all possible patients within a given disease state. To accomplish this goal, the 1-hour algorithm would have required a more extensive database than the one used.⁸ The studies relied on included large numbers of low risk patients presenting early after onset of symptoms but lacked substantial numbers of early patients with AMI. This group is critical to study to be sure that these patients manifest elevations even early after AMI so they can be distinguished from those without AMI. The largest number of AMIs in the studies evaluating the approach was 443 with only 106 patients presenting in less than or equal to 3-hour after onset.²⁰ How many presented in less than 2-hour is unclear. "Thus, we have insufficient knowledge about how the algorithm works in patients early after AMI".¹⁹

It is likely that some components of the 1-hour algorithm will work well. It may be that low hs-cTn values at presentation is a good way to exclude AMI, not because they are sensitive at detecting myocardial injury but because the risk factors associated with ischemic heart disease cause increases in hs-cTn within the normal range so baseline values are not apt to be low. Thus, low values define a low-risk group.²⁰ "However, we are less confident about some of the other recommendations such as utilizing a solitary fixed cut off for diagnosis of AMI and the application of this approach too all patients with possible AMI including those with renal failure, acute illness, the elderly and those who present early. Until these issues are clarified clinicians should take an extra caution in the interest of safe patient care".¹⁹

Marco Roffi from the Hôpitaux Universitaire in Geneva, Switzerland, contradicting Jaffe et al. mention that the 2015 ESC guidelines propose two hs-cTn-based diagnostic algorithms for patients presenting with acute chest pain and/or suspected AMI to the emergency department. By including the new hs-cTn 0-hour/1-hour algorithm, the novel ESC guidelines have tried to balance diagnostic accuracy and speed carefully and guide physicians toward the best possible clinical use of high-sensitivity cardiac troponins.

Two Large Multicenter Studies Seem to Confirm the Effectiveness and Safety of the Algorithm Proposed by ESC

In one study in 2,222 patients, Pickering et al.²¹ found that the 0-hour/1-hour algorithm using hs-cTnT allowed to safely rule out about 50% of patients who had a prevalence of MI less than 0.5. Similar results were obtained using hs-cTnI.²¹ This study has also shown that the sensitivity of the 0-hour/1-hour high-sensitivity troponin T and high-sensitivity troponin I algorithms was not as high as reported in the derivation studies referenced in the ESC guidelines. The study has further suggested, that the ESC guidelines 0-hour/1-hour algorithm should only be implemented with safeguards, including robust clinical risk assessment, the assessment will likely reduce the proportions of patients who will be eligible for this rapid rule-out algorithm and the use of the rule-in algorithm to rapidly transit emergency patients

to the cardiology services will depend on local acceptance of moderate positive predictive values.

In the other study in 2,828 patients, Boeddinghaus et al.²² found very similar results using hs-cTnI. Furthermore during 2-year follow-up mortality in ruled out patients was about 2% only. The key advantage of the 1-hour algorithm and the 0-hour/1-hour algorithm is that they also provide detailed guidance for the rule-in of AMI. On the other hand, the need for two measurements is a logistic disadvantage in comparison with the single-measurement strategies. Because of its stringent and robust methodology, this study also provided accurate estimates for the real sensitivity and NPV of the respective strategies.²²

Impact of High-Sensitivity Cardiac Troponin on Use of Coronary Angiography, Cardiac Stress Testing, and Time to Discharge in Suspected Acute Myocardial Infarction

In a very important clinical study,²³ Raphael Twerenbold et al. have shown that hs-cTn assays provide higher diagnostic accuracy for AMI as compared with conventional assays. They have also concern that use of hs-cTnT may also result in an increased use of unnecessary coronary angiographies due to their ability to detect cardiomyocyte injury in conditions other than AMI. The authors therefore evaluated the impact of the clinical introduction of hs-cTnT assays on the use of coronary angiography, stress testing, and time to discharge in 2,544 patients presenting to the emergency department with symptoms suggestive of an ACS. The patients were derived from a multicenter study either before (i.e., in 1,455 patients) or after (i.e., in 1,089 patients) the introduction of hs-cTnT assays. AMI was the clinical discharge diagnosis in 14% before and in 10% after the introduction of hs-cTnT assays; while at 9%, UA was less often the clinical discharge diagnosis than with conventional assays, where it was 14%. The rate of coronary angiography was similar before and after the introduction of hs-cTnT assays, as was the percentage of coronary angiographies showing no stenosis. In contrast, the use of stress testing was substantially reduced from 29 to 19% with high-sensitivity assays. In outpatients, the median time to discharge decreased by 79 minutes with high-sensitivity assays, and total costs decreased by 20%.

The authors conclude that the introduction of hs-cTn assays does not lead to an increased or inappropriate use of coronary angiography, but is associated with an improved rule-out process and thereby reduces the need for stress testing and time to discharge.²³

CONCLUSION

Though conventional troponin (cTn) methods are of substantial importance and have changed the landscape of modern cardiology, the relatively high imprecision of many cTn assays (especially at very low analyte concentrations) leaves them unable to resolve small differences in biomarker values. In turn, this results in lower sensitivity for detecting

small amounts of myocardial necrosis, such as that seen in patients at first contact, or resolve small changes in closely spaced serial samples. In this regard, several hours must often pass before a definitive rise in cTn might occur; this troponin blind interval is a major concern with cTn methods, slowing down triage, and creating apprehension and clinical delays.

Developed in response to calls for increased assay precision at low troponin concentration,²⁴ hsTn assays appear to overcome many limitations of cTn. In several clinical trials such as the Advantageous Predictors of Acute Coronary Syndrome Evaluation (APACE) study,¹ it was found hsTn testing allowed for more rapid identification or exclusion of AMI when compared with cTn. Based on these and other data,²⁵ hsTn testing is now accepted and in use in several countries, with strategies incorporating rapid hsTn testing protocols (based on a 0–3-hour approach or a 0–1-hour approach), even incorporated in European clinical practice guidelines.⁸ Finally, it is worth mentioning that this is a rapidly moving field and further research is needed to understand the clinical utility and cost-effectiveness of this approach to risk stratification.

Managing Acute Coronary Syndrome in Renal Dysfunction

Parayoru K Asokan, Kailash K Goyal

INTRODUCTION

Presence of renal dysfunction in patients with acute coronary syndrome (ACS) is common and is associated with both short- and long-term poor prognosis.^{1,2} The National Cardiovascular Data Registry Acute Coronary Treatment and Intervention Outcomes Network (NCDR-ACTION) registry showed that 42.9% of patients with non-ST-elevation myocardial infarction (NSTEMI) and 30.5% of patients with STEMI have chronic kidney disease (CKD), and defined as a glomerular filtration rate (GFR) less than 60 mL/min/1.73 m².³ Despite a high prevalence, patients with CKD are often excluded from ACS clinical trials,^{4,5} which results in lack of data and insufficient treatment for this high-risk population. Further, the fear of complications such as bleeding and contrast-induced nephropathy (CIN) deters an interventional cardiologist from using invasive diagnostic and revascularization procedures in these patients contributing to poor outcomes. In this review, we aim to highlight the unique features and briefly summarize the available evidence associated with managing ACS in patients with renal dysfunction.

PATHOPHYSIOLOGY

Several studies have shown a higher burden of multivessel disease, longer stenoses, more severe calcification, and chronic occluded lesions compared with the general population.⁶⁻⁸ Moreover, atherosclerotic plaque composition assessed with intravascular ultrasound (IVUS) demonstrated greater necrotic core and dense calcium with less fibrous tissue in CKD, suggesting that renal dysfunction not only results in greater plaque burden, but also alters coronary atherosclerotic plaque composition to a less stable phenotype.⁹ This accelerated disease may be due to the presence of risk factors such as chronic inflammation, chronic oxidative stress, changes in nitric oxide availability, chronic phosphate retention, secondary hyperparathyroidism, and elevated levels of fibroblast growth factor 23.¹⁰⁻¹² Patients with

CKD have also been shown to have an accelerated infarct expansion in association with enhanced inflammation and oxidative stress, as compared with non-CKD patients.

DIAGNOSIS OF ACUTE CORONARY SYNDROME IN PATIENTS WITH RENAL DYSFUNCTION

The clinical presentation of ACS in patients with CKD is markedly different from that of patients without CKD. Data from the SWEDEHEART Registry (Swedish Web System for Enhancement and Development of Evidence-based Care in Heart Disease Evaluated According to Recommended Therapies) showed that the incidence of chest pain and typical electrocardiogram (ECG) findings decrease with worsening renal function and presentation with heart failure increases.¹³ The diagnostic value of baseline ECG is often limited by nonspecific changes due to left ventricular hypertrophy and electrolyte disturbances. To complicate things further, troponin levels may remain chronically elevated and are less specific for the diagnosis of ACS in patients with renal dysfunction. However, increase in troponin levels 2-3 times the upper limit of normal with a rise and fall pattern likely indicates myocardial infarction.

MANAGEMENT

Anticoagulant Therapy

Heparin is the standard management in patients with ACS and the two preparations available are unfractionated heparin (UFH) and low-molecular weight heparin (LMWH). Primary route of UFH elimination is via the reticuloendothelial system (RES) and hence a dose modification is not required in patients with renal dysfunction. Enoxaparin (most commonly used LMWH), on the other hand, is cleared primarily by renal mechanism. A substudy of the EXTRACT (Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Treatment)-TIMI 25 trial showed that

with every 30 mL/minute decrease in creatinine clearance (CrCl), the risk of major and minor bleeding increased by 50%¹⁴ suggesting that dosage adjustment is needed in these patients to minimize the bleeding risk. The current US Food and Drug Administration-approved dose for enoxaparin in ACS patients with CrCl less than 30 mL/minute/1.73 m² is 1 mg/kg subcutaneously every 24 hours. Table 1 shows the dose modification needed for various drugs used in ACS for patients with renal dysfunction.

Fondaparinux is an indirect factor Xa inhibitor and recommended as the preferred anticoagulant in UA/NSTEMI patients being managed with a conservative strategy who have an increased risk of bleeding. In a subanalysis of OASIS-5 (Fifth Organization to Assess Strategies in Acute Coronary Syndrome) trial,¹⁵ fondaparinux was associated with low rates of bleeding compared to enoxaparin across all quartiles of renal dysfunction. Hence, it may be preferred over enoxaparin in patients with CrCl between 30 mL/minute and 59 mL/minute/1.73 m² but should be avoided, if CrCl less than 30 mL/minute/1.73 m², as it is excreted unchanged through renal mechanism.

TABLE 1: Dose modification of various drugs in patients with acute coronary syndrome and renal dysfunction

Drug	Route of elimination	Effect of renal dysfunction on dose	Remarks
Unfractionated heparin	RES	None	Preferred over LMWH in patients with renal dysfunction
LMWH	Renal (40%)	Dose should be reduced by half in patients with CrCl <30 mL/min/1.73 m ²	Increased risk of bleeding in patients with CKD
Fondaparinux	Renal	Avoid if CrCl <30 mL/min/1.73 m ²	May be preferred over enoxaparin in patients with GFR between 30 and 59 mL/min/1.73 m ²
Aspirin	Renal	None	Should be used in patients with CKD presenting with ACS
Clopidogrel	Renal (50%), feces (50%)	None	Should be considered in CKD patients presenting with ACS
Prasugrel	Renal (60–70%)	None	Should be considered in CKD patients not requiring dialysis
Ticagrelor	Biliary	None	Should be considered in CKD patients not requiring dialysis
Abciximab	RES	None	Increased risk of bleeding in patients with CKD
Eptifibatide	Renal (50%)	Dose should be reduced by half in patients with CrCl <30 mL/min/1.73 m ²	Increased risk of bleeding in patients with CKD
Tirofiban	Renal (40–70%)	Dose should be reduced by half in patients with CrCl < 30 mL/min/1.73 m ² . Contraindicated in patients on dialysis	Increased risk of bleeding in patients with CKD
Statins	Hepatic	None	Should be considered in CKD patients presenting with ACS
Beta-blockers:			Should be used in CKD patients presenting with ACS
• Propranolol	Hepatic	None	
• Metoprolol	Hepatic	None	
• Carvedilol	Hepatic	None	
• Atenolol	Renal	Should be modified according to creatinine clearance	

ACS, acute coronary syndrome; CKD, chronic kidney disease; CrCl, creatinine clearance; LMWH, low-molecular weight heparin; RE; reticuloendothelial system; GFR, glomerular filtration rate.

Antiplatelets

Aspirin

McCullough et al.¹⁶ showed that aspirin reduced in-hospital mortality by 64.3–80% across all quartiles of CrCl in patients with CKD and ACS. In a study by Yan et al.¹⁷ aspirin was associated with improved 1-year survival to a similar extent among those with normal and impaired renal function. Similarly, in a meta-analysis of 287 randomized trials,¹⁸ antiplatelet therapy produced a 41% proportional reduction in serious vascular events and no significant increase in extracranial bleeds in patients undergoing hemodialysis. Thus, the available data suggest that aspirin therapy is safe as well as effective in ACS patients with renal dysfunction and should be used to reduce the risk of death and vascular events.

Dual Antiplatelet Therapy

Dual antiplatelet therapy (DAPT) with aspirin and an additional agent (clopidogrel, ticagrelor, or prasugrel) are used routinely in patients with ACS. Observed rates

of bleeding have been higher with clopidogrel than with placebo in CKD patients, but several studies such as CURE,¹⁹ CREDO,²⁰ or CLARITY-TIMI 28²¹ showed that there was no significant interaction based on renal function and no significant increase in risk with the use of clopidogrel in ACS patients with CKD. Similarly, the efficacy associated with prasugrel compared with clopidogrel and the efficacy and safety associated with ticagrelor compared with clopidogrel were evident in patients with and without CKD, and the data suggest these agents should be considered in CKD patients who are not considered to be at high risk of bleeding.

Glycoprotein IIb/IIIa Inhibitors

Abciximab is cleared via the RES, and there is no current recommendation for dose adjustment for patients with CKD. Eptifibatide and tirofiban are dependent on renal clearance for elimination and hence a dose adjustment is required. Frilling et al.²² compared the efficacy of abciximab in normal and CKD patients. Patients in either group had similar clinical outcomes. The CKD patients had more episodes of major bleeding but similar episodes of minor bleeding and thrombocytopenia. Several other studies using glycoprotein (GP) IIb/IIIa receptor antagonists in CKD patients with ACS showed a reduction in ischemic events and a variable increase in the risk of bleeding events. So, the currently available data suggest that these agents can be used cautiously with proper dose modification.

Statins

Statins have proved to be effective in preventing cardiovascular events in the general population, however, randomized trials of statin therapy in patients with CKD yielded mixed results. Studies like AURORA²³ and ALERT,²⁴ which mostly included dialysis-dependent patients showed no benefit of statin therapy. However, the Study of Heart and Renal Protection trial (SHARP) randomized patients with CKD (both on dialysis and not on dialysis) to 20 mg simvastatin plus 10 mg ezetimibe or placebo and showed a benefit of simvastatin plus ezetimibe therapy on the risk of the primary composite endpoint of first major atherosclerotic event.²⁵ Similarly, a meta-analysis of randomized trials showed that statin use for primary prevention consistently lowers the risk of death and major cardiovascular events by 20% in patients with CKD and not on dialysis.²⁶ So, data show a consistent benefit with regard to a reduction in cardiovascular events with statin therapy in CKD patients who present with ACS and support the routine use of statins in this population.

Beta-blocker Therapy

The β-blockers are recommended for all patients with ACS unless contraindicated. Metoprolol, propranolol, and carvedilol are all extensively hepatically metabolized and do not require dose adjustments in renal impairment. Atenolol is renally eliminated and requires dose adjustment in those with renal impairment. An observational study showed that

β-blocker use was associated with a 40% relative reduction in mortality among those undergoing dialysis and a 56% relative reduction among those without end-stage renal disease (ESRD)²⁷ and so should be considered in all patients presenting with ACS.

Angiotensin Blockade

Angiotensin-converting enzyme (ACE) inhibitors/angiotensin receptor blockers (ARBs) are recommended by current guidelines to be initiated and continued indefinitely in all patients with ACS and a left ventricular ejection fraction (LVEF) less than 40% and also for those with hypertension, diabetes mellitus (DM), and CKD unless contraindicated. The most common concerns with ACE inhibitors or ARBs, however, include perceived worsening renal function and hyperkalemia. There is no absolute level of serum creatinine (SCr) that precludes the use of these agents; however, caution is warranted, if the SCr exceeds 2.5 mg/dL, and these can be used as long as the SCr does not increase beyond this point and the serum potassium remains less than 5.5 mEq/L.

Aldosterone Receptor Antagonists

Aldosterone antagonists such as spironolactone and eplerenone are recommended for post-myocardial infarction (MI) patients who are receiving therapeutic doses of an ACE inhibitor and a β-blocker, have a LVEF less than 40%, and have either DM or heart failure. But there are concerns regarding the increased risk of life-threatening hyperkalemia attributable to aldosterone antagonists, particularly when combined with angiotensin blockade. Therefore, the American College of Cardiology/American Heart Association guidelines recommend against using aldosterone blockade, if significant renal dysfunction (SCr >2.5 mg/dL in men and >2.0 mg/dL in women) or hyperkalemia (serum potassium >5.0 mEq/L) coexists.²⁸

Fibrinolytic Therapy

The commercially available thrombolytics (alteplase, reteplase, tenecteplase, and streptokinase) do not require dose adjustment for CKD. Several observational studies have evaluated the association of CKD with outcomes and the treatment effect of fibrinolytic therapy in STEMI patients. Data from these studies showed increasing rates of intracranial hemorrhage with worsening renal function. Despite this, fibrinolytic therapy should be considered as a treatment strategy for CKD patients presenting with STEMI when primary percutaneous coronary intervention (PCI) is not available. However, given the increased rates of intracranial hemorrhage observed with worsening renal function, careful consideration of the benefits, and risk of fibrinolytic therapy in this population are required.

Percutaneous Coronary Intervention

Primary PCI, whenever available, should be the treatment of choice in patients with STEMI as the cardiovascular risk is

greater than the risk of requiring renal replacement therapy (RRT) in most of the patients. Sadeghi et al.²⁹ evaluated the potential impact of renal insufficiency in patients undergoing primary PCI in the Controlled Abciximab and Device Investigation to Lower Late Angioplasty Complications (CADILLAC) trial. In patients with estimated glomerular filtration rate (eGFR) less than 60, procedural success rates were lower (87.2% vs. 92%, $p = 0.01$), and was associated with 9-fold greater mortality at 1 month and a fivefold increase in mortality at 1-year. Further, in a single-center retrospective study,³⁰ the 30-day and 6-month mortality were reduced from 22 to 3.6% ($p < 0.03$) and from 25.4 to 7.1% ($p < 0.05$) among renal dysfunction patients who underwent PCI during hospitalization. This suggests that mild-to-moderate renal insufficiency in the setting of STEMI is associated with increased mortality but an early PCI may be beneficial among such patients.

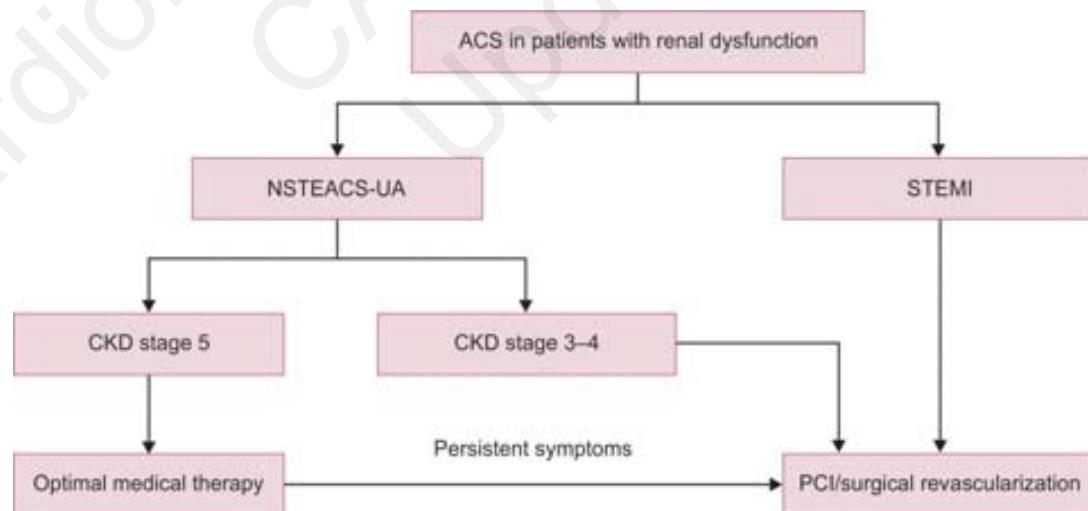

Renal dysfunction is a strong independent predictor of mortality in patients with NSTE-ACS. In a study by Keeley et al.,³¹ there was a reduction in 6-month mortality in patients with CKD stage 3 and 4 and NSTE-ACS with early revascularization. The SWEDEHEART study, however, suggested that an early invasive strategy was harmful for CKD five patients with NSTE-ACS and should be tried to be managed with optimal medical therapy. A detailed algorithm regarding management of ACS in patients with renal dysfunction is shown in flowchart 1.

Contrast-induced Nephropathy

Contrast-induced nephropathy, also known as contrast-induced acute kidney injury (CI-AKI), is an iatrogenic renal injury that follows intravascular administration of radiopaque contrast media (ROCM) in susceptible individuals. The most widely used definition is the increase in SCr more than or

equal to 0.5 mg/dL or 25% increase of SCr from the baseline value at 48 hours after CM administration. Serum cystatin C levels have also been evaluated as an early marker of CI-AKI. In a study by Briguori et al.³² performed on CKD patients undergoing percutaneous transluminal coronary angioplasty (PTCA), increase of cystatin C levels more than or equal to 10% at 24 hours after the procedure was found to reliably predict the patients with high risk of CI-AKI. Pre-existent stage-3 CKD, defined as an eGFR less than 60 mL/min/1.73 m², is the most commonly identified risk factor for CIN and all the measures to prevent CIN should be taken meticulously in such patients. The most commonly used measures to prevent CIN are:

- Use minimum amount of CM
- Avoid concomitant use of other nephrotoxic drugs
- Hydrate the patient with isotonic saline and/or sodium bicarbonate before and after the procedure
- *N-acetylcysteine (NAC)*: Although the strength of the evidence is low, NAC is a well tolerated and inexpensive drug and it has a relatively good profile of adverse effects. Thus, in 2012, Kidney Disease: Improving Global Outcomes (KDIGO) guidelines suggested NAC for patients with high risk of CI-AKI.³³ There is no consensus on the dose of the NAC, however, it is usually used at a dose of 600–1,200 mg orally twice daily
- *Prefer isoosmolar contrast media (IOCM) or hypoosmolar contrast media (LOCM) over hyperosmolar CM*: In a meta-analysis,³⁴ a mild decrease in the risk of CI-AKI was found with iodixanol (IOCM) when compared to iohexol (LOCM), however, no difference was found between the groups in terms of risk of RRT, cardiovascular outcomes, or death. Therefore, KDIGO guidelines do not make a recommendation about the preference of IOCM or LOCM due to lack of reliable evidence³³

NSTEACS-UA, non-ST elevation acute coronary syndromes-unstable angina; PCI, percutaneous coronary intervention; STEMI, ST-elevation myocardial infarction.

FLOWCHART 1: Algorithm for management of acute coronary syndrome (ACS) in patients with chronic kidney disease (CKD).

- **Remote ischemic preconditioning (RIP):** It is based on a hypothesis that a transient ischemia of an organ may protect against an ischemic injury of another distant organ. This is mostly induced by arm ischemia performed by inflation of blood pressure cuffs during or before the procedure. Few studies have shown that RIP decreases the risk of CI-AKI.^{35,36} However, further randomized clinical trials are needed
- **Prophylactic hemodialysis/hemofiltration:** Prophylactic hemodialysis (HD)/hemofiltration (HF) has not been found to be protective against CI-AKI. In a meta-analysis, no beneficial effect of these treatment modalities was found against CI-AKI.³⁷ Furthermore, HD was found to increase the risk of CI-AKI. Thus, prophylactic renal replacement treatment is not recommended.

CONCLUSION

Presence of renal dysfunction should not prevent an ACS patient from receiving standard guideline-directed therapy. Patients with CKD can receive antithrombotic therapy, DAPT, standard medical therapy, as well as coronary revascularization therapy but with an increased risk of bleeding. These patients have poor prognosis compared to those without renal dysfunction, however, adherence to guideline-based therapy appears to be associated with improved short- and long-term mortality.

ST-Segment Elevation Myocardial Infarction

Burden and Outcome of STEMI in India

Santanu Guha, Avik Karak

PREAMBLE

Mr AB, a 45-year-old farmer, residing at a remote village area of Bengal, presented to a small rural hospital in a small town of Midnapore, India, at 11:30 PM with severe chest pain. The hospital was a 10-bed facility with a small emergency room. The entire staff consisted of just three nurses and a junior doctor. The duty nurse recorded an electrocardiogram (ECG) and sent it to the doctor's house through a ward boy, situated 15 minutes away. The doctor diagnosed an anterior ST-segment elevation myocardial infarction (STEMI). However, he wanted to consult with the senior doctor to confirm the diagnosis before starting streptokinase (SK). However, he decided to go to the hospital to see the patient as he was having ongoing pain. He advised the relatives to shift the patient to a higher medical center in the closest city located 120 km away—a 3-hour journey. They decided to wait until next morning to organize funds to arrange for the transfer. The patient started to deteriorate and became hypotensive from early morning before the contemplated transfer and succumbed at 6.30 AM, before the transportation to the city hospital or the senior doctor could confirm the diagnosis. This is not an isolated case history. The names may be different but progressively younger men and women are dying every day of acute myocardial infarction (AMI) without proper medical attention. With the turn of the century, cardiovascular diseases (CVDs) have become the leading cause of mortality in India.¹ Approximately, 3–4% of Indians in rural areas and 8–10% in urban areas have coronary artery disease (CAD). Indians are more likely to develop CAD at younger ages during an individual's productive years resulting in loss of potentially productive years of life in India.^{2,3}

BURDEN OF CARDIOVASCULAR DISEASES IN INDIA

Cardiovascular disease is the leading cause of death in India accounting for approximately 21% of deaths in the year

2010, with 10% of deaths due to CAD. The Global Burden of Disease study estimated an age-standardized CVD death rate is 272 per 100,000 in Indian population in comparison to the global average of 235 per 100,000 population. The World Health Organization (WHO) estimated that India would lose \$237 billion from the loss of productivity and spending on health care over a 10-year period (2005–2010) with the current burden of CVD.⁴ There are no nationally representative surveillance data on the prevalence of CVD and the secular trends of CVD mortality in India at present. However, three large prospective studies from India recently have suggested a higher proportion of mortality attributable to CVD (30–42%) and an age-standardized CVD mortality rate of 255–525 per 100,000 population in men and 225–299 per 100,000 population in women in comparison with the Global Burden of Disease Study (2010).^{5–7} Ischemic heart disease (IHD) and cerebrovascular accident (CVA) constitutes the majority of CVD mortality in India (83%), with IHD being predominant (Fig. 1).⁸ The years of life lost

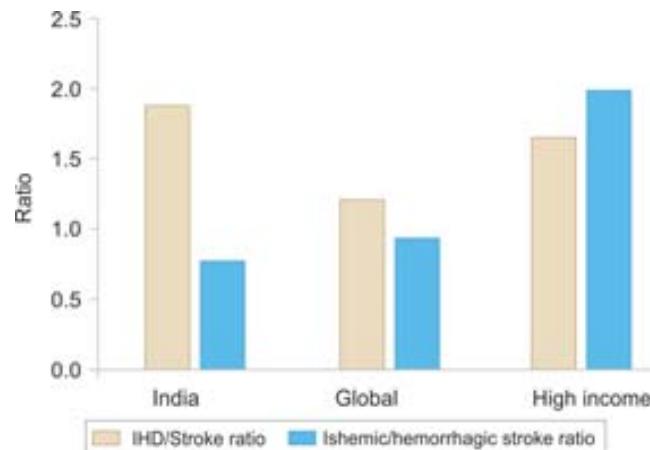

FIG. 1: Ischemic heart disease to stroke ratio and ischemic to hemorrhagic stroke ratio in India in comparison with global data.⁸

attributable to CVD in India increased by 59% from 1990 to 2010 (23.2–37 million).⁹ Several small cross-sectional studies performed in different parts of the country suggested a rapid increase in the IHD burden over the past few decades.^{10–32} The prevalence of IHD has increased by almost sevenfolds to approximately 14% in 2013 from a meager 2% in 1960 with a higher margin of increase in the rural areas where the prevalence has quadrupled (1.7–7.4%).^{10–22,31,32} The higher case fatality of acute coronary syndrome (ACS) could also result in the underestimation of prevalence among Indians.³³

BURDEN OF CARDIOVASCULAR DISEASE RISK FACTORS

It is estimated that, currently approximately 275 million individuals aged more than 15 years consume tobacco in India.³⁴ The rate of fruit and vegetables consumption is low in India. The National Family Health Survey-3 (NFHS-3), covering 156,316 individuals in India, reported that half of the population in its survey consumed zero to one serving of fruit in a week.³⁵ Time-series data on nutrient intake captured from the National Sample Survey Organization surveys indicate that, Indians' fat intake increased from 24 to 36 g/day and from 36 to 50 g/day in rural and urban individuals, respectively from 1972 to 2000.³⁶ The Indian Council of Medical Research-India Diabetes (ICMR-INDIAB) study is a large cross-sectional survey which assessed physical activity using the global physical activity questionnaire in 14,227 individuals aged more than or equal to 20 years showed that one of every two were considered physically inactive and less than 10% of the studied population engaged in recreational physical activity.³⁷ The prevalence of hypertension in Indian adults is in the tune of 30% (34% in urban areas and 28% in rural areas).³⁸ The average blood pressure has increased in the past two decades in India whereas in most Western nations it has declined.³⁹ Prospective Urban and Rural Epidemiology (PURE) study (83% of the participants being from India) showed that low educational status is associated with lower rates of awareness, treatment, and control of hypertension.⁴⁰ Urban areas of India has seen a doubling in the prevalence of diabetes mellitus (DM) in the past 20 years, from 9 to 17%, whereas it has nearly quadrupled, from 2 to 9% in the rural areas.⁴¹ There has been a rapid rise in the mean levels of total cholesterol, low-density lipoprotein (LDL) cholesterol, non-high-density lipoprotein (non-HDL) cholesterol, and triglycerides (TG) as shown in serial epidemiological studies.⁴² Low-HDL cholesterol was the most common abnormality.⁴³ Long-term material deprivation, unhealthy living conditions, and high levels of stress are other factors that also appear to contribute to excess CVD risk among socially deprived groups in India.^{44,45}

DETERMINANTS OF CARDIOVASCULAR DISEASE IN INDIANS

There are significant variations between various CVD risk factors within different regions. Southern states of India have

a higher prevalence of DM whereas hypertension appears to be higher in the North-eastern states.⁴⁶ The social determinants play an important role in the heterogeneity apart from the cultural diversities and variations in the economic development. Suboptimal social characteristics such as low educational, occupational, and socioeconomic status (SES) were associated with a clustering of more than or equal to three CV risk factors and a higher Framingham risk score in a cross-sectional study of CV risk factors in Jaipur.^{47,48} Social determinants play a major role in determining outcomes after a CVD event as shown in the CREATE (Clinical Trial of Reviparin and Metabolic Modulation in Acute Myocardial Infarction Treatment Evaluation) registry where the outcomes after ACS were worse in lower-SES individuals.³

EPIDEMIOLOGY OF STEMI IN INDIA

About 30 million individuals in India have CAD.³² With 381.5 per 100,000 CVD deaths in India, India ranked higher than Britain, US, and China in the WHO report in 2004.⁴ The fact that the mean age of occurrence of STEMI in Indians is 5–10 years lower than Western population was supported by a study done in Karnataka.⁴⁹ Abnormal lipids, smoking, hypertension, diabetes, abdominal obesity, psychosocial factors, low fruit and vegetable consumption, and lack of physical activity were the eight coronary risk factors as identified by the INTERHEART-South Asia study which accounted for 89% of the cases of all AMI in Indians. The INTERHEART study also revealed that Indians who developed STEMI had lower LDL and HDL cholesterol levels than others in the study. Apolipoprotein B/apolipoprotein A1 (ApoB/ApoA1) showed the strongest association with the risk of AMI in Indians.⁵⁰ This shows that Indians deserve a separate consensus in the management of ACS as there are many unknown factors at play. We can extrapolate data and latest trends from the few but significant registries like the CREATE registry, Kerala ACS registry, OASIS-2, DEMAT registry, North East (NE) registry and Himachal Pradesh registry for STEMI patients in India.^{3,33,51–54}

Presentation of ACS Patients as STEMI

The CREATE registry showed that STEMI accounted for 60% of ACS, while in Kerala ACS registry STEMI constituted only 40% which is slightly higher than that seen in many international registries. The Kerala ACS registry of the patients presenting a similar proportion of men as with the other Indian ACS registries which was higher when compared with the National Cardiovascular Data Registry in the US, Euro Heart Survey ACS II registry in Europe and Global Registry of Acute Coronary Events (GRACE) registry.^{55–57}

Case Fatality Rates in India

In-hospital mortality rate for STEMI in the Kerala ACS registry (8.2%) and CREATE registry (8.6%) were similar but were higher than GRACE (7%) and Euro Heart Survey ACS II (6%).^{3,54,56,57}

Delayed Presentation Time

In India various registries have shown trends of late presentation which hampers timely intervention which influences the prognosis and outcome of the STEMI patients.

Reperfusion Strategies are Underutilized

Thrombolytic therapy and primary percutaneous coronary intervention (PCI) are two commonly used reperfusion strategies. Kerala ACS registry reported a lower rate of utilization of thrombolysis in comparison to CREATE as well as GRACE registry.^{3,57} Thrombolysis was used in 41% of STEMI patients but when used, was generally prompt with less than one-third patients exceeding the door to needle times of more than 30 minutes. Approximately, half of the patients presenting with the diagnosis of STEMI received some form of reperfusion [thrombolysis, PCI or coronary artery bypass grafting (CABG)]. Primary PCI in STEMI, the gold standard of treatment, is available to a very small proportion of STEMI patients in India.

Inappropriate diagnosis and thrombolysis was one of the most worrisome factors in the management of STEMI as shown in the Kerala ACS registry⁵⁴ where 19% of non-STEMI (NSTEMI) and 10% of unstable angina (UA) patients also received thrombolysis and this was more common in the rural, non-teaching, and low volume centers. This percentage was much higher than that reported in the Western population (2.5–5%).⁵⁸

Practice Pattern and Guideline Adherence

Secondary analysis of the Kerala ACS registry showed that optimal in-hospital and discharge medical care defined as receiving dual antiplatelet therapy (DAPT), β -blockers, statin, and parenteral anticoagulation (in-hospital only), were given in 40% and 46% of admissions, respectively. Patients receiving optimal in-hospital medical care had 21% lower rate of in-hospital major adverse cardiac events (MACE). The CREATE registry³ reported a lower use of β -blockers and statins and a higher use of angiotensin-converting enzyme inhibitors/angiotensin II receptor blockers (ACEIs/ARBs) when compared with the Kerala ACS Registry⁵⁴ with an unfortunately even lower postdischarge rates of optimal medical care. The PURE registry reported that less than half of patients with prevalent CVD take more than or equal to one medication for secondary prevention.⁴⁰

Gender Differences in Presentation and Management

Kerala ACS registry (5,825 women out of 25,748 ACS patients) showed that women at presentation were approximately five years older than men with moderately higher rates of previous MI. Gender differences in the outcome of death or in the composite outcome of death, reinfarction, stroke, heart failure (HF), and cardiogenic shock were not statistically significant even after adjustment for possible confounding factors. The DEMAT registry (1,565 ACS patients from ten tertiary care centers in India) also corroborated that after adjustment for

age, education, history of CAD, STEMI presentation, and reperfusion of any type, there was no evidence of increased risk of death at 30 days among women, nor was there any difference between death, rehospitalization, and cardiac arrest at 30 days in comparison to men.⁵¹

The Economic Impact in India

Out of pocket expenditure (OOPE) amounts to up to nine times of the total household expenditures, depending on the SES and type of treatment availed, imposing a large financial burden on families. The high OOPE and catastrophic health expenditure (CHE) have been reported elsewhere due to CVD-related hospitalizations (including ACS) where India (Kerala) had the highest 15-month OOPE and more than 80% of the low- and middle-income groups and more than 60% of the high-income group experienced CHE.⁵⁹

Onset of Cardiovascular Disease and High Fatality

The INTERHEART study (across 52 countries) reported the occurrence of MI at an early age among patients from South Asia at a median age of 52 years in comparison with 62 years in the European origin cohort.² Gupta et al.,⁶⁰ in their study of age-specific trends in CV risk factors among the adolescent and young demonstrated that CV risk factors increase exponentially with age after Indians reach the 30–39-year age group. More severe manifestations of CVD and higher fatality rates are an additional cause of concern.⁴⁰ In the PURE study, the incidence of major CV events and mortality among individuals of low-income countries (96% from South Asia, of whom 83% were from India) was higher than in middle- and high-income countries, despite having a lower conventional CVD risk factor burden.⁴⁰

OUTCOME OF STEMI

Patients in India who have ACS have a higher rate of STEMI than do patients in developed countries. Various studies in the Indian subcontinent have studied the outcomes of STEMI in India. The following section focuses on the various studies with attention to the outcomes of STEMI patients in India.

Iseuzo et al.⁶¹ carried out a cross-sectional retrospective analysis of 1,468 ACS patients in Chennai. The time from onset of symptoms to presentation ranged from 5 to 120 minutes (median 5 h, mode 24 h) in patients with STEMI. The median time from onset of symptoms to hospitalization was 360 minutes, with 50 minutes from hospital to thrombolysis in the CREATE registry [which enrolled 20,937 patients, of which 12,405 (60.6%) had STEMI]. Medical therapy including antiplatelet drugs; ACEI/ARB were prescribed more in STEMI than in NSTEMI. About 58.5% of patients with STEMI received thrombolysis predominantly with SK (96.3%). Fewer patients with STEMI than those with NSTEMI or UA were given β -blockers; statins. Coronary angiography (CAG) was performed in 80.6% of patients in the study by Iseuzo et al. The CAG rate was higher in the STEMI group than NSTEMI/UA group which was statistically significant. Single vessel disease

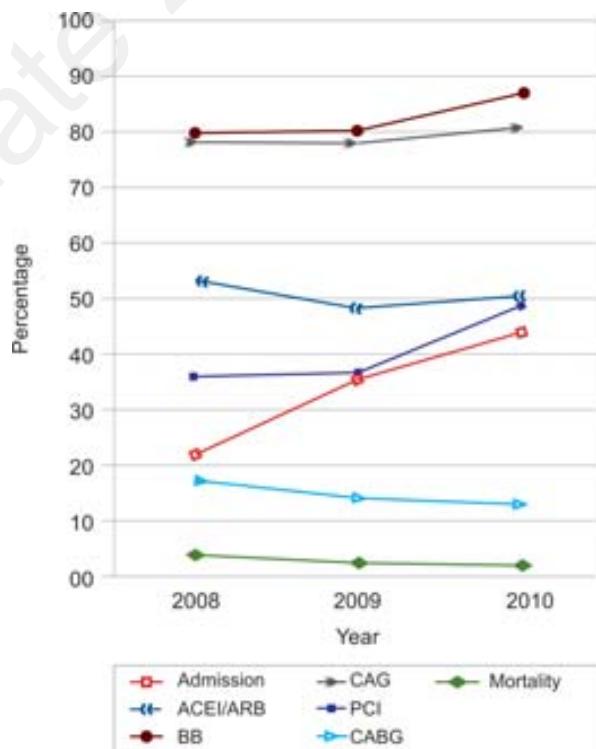

was more frequent in the STEMI group than the other group. About 20.3% of patients were thrombolyzed (streptokinase in 94.0%), while 53.3% and 10.3% had primary PCI and CABG, respectively in the STEMI group. About 16.1% of STEMI patients had sole medical therapy. Importantly, the rate of utilization of some form of reperfusion therapy was higher in the current than previous reports from India.^{3,62} Patients who had PCI were significantly younger than those who had only medical treatment in both the studies. Though CAG rate was higher in males than females, there were no statistically significant gender differences in the rates of PCI and CABG. Among the complications arrhythmias (3.7%), resuscitated cardiac arrest (1.8%) and intracardiac thrombus (1.5%) were the predominant ones. Seven days, 30 days, 6 months, and 1-year mortality rates were 0.4%, 0.7%, 2.0%, and 2.5%, respectively with total of 37 casualties reported in 1 year. Mortality increased with increasing age group and at higher risk stratification which was not statistically significant. At 1 year of follow up, reinfarction, resuscitated cardiac arrest and major bleeding were seen in 59/1,463 (4.0%), 26/1,468 (1.8%), 16/1,468 (1.1%), and 5/1,171 (0.4%) of the patients, respectively. Composite MACE comprising deaths, MI, stroke, cardiac arrest and bleeding at 1 year occurred in 9.7% of the study population. The deceased were predominantly the elderly and had renal dysfunction (higher serum creatinine) and severe left ventricular (LV) dysfunction. In the CREATE registry death, reinfarction, and stroke occurred in 8.6%, 2.3%, and 0.7% of STEMI patients, respectively at 30 days in comparison to NSTEMI or UA patients where death, reinfarction, and stroke occurred in 3.7%, 1.2%, and 0.3% patients, respectively. SES influenced the key treatments: more rich patients were given thrombolytics, β-blockers, statins, ACEIs/ARBs, PCI, and CABG surgery than poor patients. These differences resulted in a significant 2.7% absolute higher 30-day mortality in the poorest group when compared to the richest group, though rates of reinfarction or stroke were similar. Adjustment for treatments between the different strata of SES (but not risk factors and baseline characteristics) eliminated the differences in mortality between the rich and the poor, suggesting that better treatment of established CAD offers an opportunity to improve outcome of STEMI patients across the varied SES distribution in India. Higher number of poor patients might have died before reaching hospital resulting in under estimation of the actual mortality. It can be hypothesized that mortality can be reduced, if all patients, across all SES spectrum, had access to similar health care facilities, reached hospital rapidly, and received similar treatments.⁶³

In Kerala ACS registry data from 25,748 consecutive ACS admissions were collected from 125 hospitals from May 2007 to May 2009 the unadjusted in-hospital mortality rate was 8.2% in STEMI patients, compared with substantially lower rates in NSTEMI (1.8%) and UA (0.9%) patients. STEMI patients had a higher nonfatal MACE (stroke, reinfarction, HF, or cardiogenic shock) rates. STEMI patients had a higher risk of in-hospital death and in-hospital MACE when compared to patients with UA. Delayed presentation significantly affected the outcome of the STEMI patients as demonstrated by the fact that symptom-to-door time of more than 6 hours was

associated with higher in-hospital mortality, and in-hospital MACE. Door-to-needle time less than 30 minutes resulted in lower in-hospital mortality and in-hospital MACE in STEMI patients proving that early intervention significantly improved the outcomes. Patients in the Kerala ACS registry included patients slightly older than those in prior Indian ACS registries. Predischarge medical therapy with DAPT was high and similar to prior literature. Beta-blockers and statins were used more commonly than prior Indian registry data, while heparin, ACEI/ARBs, and CCBs were used less commonly. Though CAG rates were lower than prior Indian data (20% vis-a-vis 23% in the CREATE registry),³ the PCI rates were higher (12% vs. 7.5% in the CREATE registry).³ Both CAG and PCI rates were substantially lower than those in the ACTION^{64,65} and Euro Heart Survey ACS I and II.^{57,66} Thrombolysis in the setting of a STEMI diagnosis was lower in the Kerala ACS registry reported a lower rate of utilization of thrombolysis than CREATE³ as well as GRACE.⁵⁷

There were trends towards increasing annual rates of admission for ACS, CAG, PCI, and use of ACEIs/ARBs and β-blockers during the study period of 1 year in the study done by Isezu et al. along with decreasing rates of mortality and CABG (Fig. 2).

Outcomes of ACS has been influenced by the hospital setting as suggested in the AMIS registry,⁶⁷ where the hospitals categorized as grade A characterized by 24 hours coronary care unit, cardiac catheterization, and cardiac surgery services had lower mortality than category B hospitals where these services were either unavailable or were not

CAG, coronary angiography; ACEI/ARB, angiotensin-converting enzyme inhibitors/angiotensin II receptor blocker; BB, beta-blocker; CABG, coronary artery bypass grafting; PCI, percutaneous coronary intervention.

FIG. 2: Trends in interventions and mortality.

obtainable to the same extent (2.8% vs. 4.0%). Contrary to the belief that mortality in ACS is higher in Indians than the whites,^{68,69} a recent meta-analysis (of four recently published studies) demonstrated that the prognosis of CAD in South Asian population is not worse than whites, and the increased mortality rates in the former are due to the higher incidence of fatal and non-fatal CAD. Another recent study comparing South Asian STEMI population with the Europeans showed that though the former were younger and more likely to be diabetic, the survival at discharge was comparable.⁷⁰ The low mortality rate in the study by Isezuo et al. could have been influenced by the fact that the study population belonged predominantly to low or intermediate-risk group with lower rates of fatal outcomes and the clinical determinants of mortality were largely similar to the findings in previous reports.^{57,70-71} Another interesting observation recently was the higher mortality rates among young women with ACS with the difference disappearing with increasing age, with long-term prognosis similar or even better among elder women. They nonetheless probably indicate that the CAD epidemic is still on-going in India, and that there is increased awareness of the disease among the populace and improved compliance with evidence-based treatment guidelines among the physicians. Trends towards increasing admission rate for ACS, utilization of therapeutic advances, and fall in mortality were observed.

The outcome of timely fibrinolysis along with contemporary antiplatelets and antithrombotic (tenecteplase was used as the thrombolytic agent) followed by timely CAG in the pharmaco-invasive approach has been compared with the standard primary PCI in the STEPP-AMI study.⁷² Two hundred STEMI patients aged less than 75 years, who underwent either primary PCI or a pharmaco-invasive strategy within 12 hours of symptom onset were followed up for 1 year. The primary end-point (composite of death, cardiogenic shock, reinfarction, repeat revascularization of the culprit artery and congestive heart failure) was similar between the two groups at 30 days, 3 months, 6 months, and 1 year, although primary PCI had a trend towards benefit during the early phase of follow-up. Relatively affluent patients underwent primary PCI, a plausible explanation for the better long-term outcomes due to lifestyle changes and better adherence to medication. The findings corroborated with the well-known STREAM study.⁷³ Another important finding in this study is the nonrequirement of a stent in a significant number of patients who underwent thrombolysis followed by CAG due to insignificant disease (6.7%) and a better infarct related artery (IRA) patency rate and lesser thrombus burden. Failed thrombolysis occurred in 12.1% patients which is much less than that reported in the STREAM study (36.3%). The mortality rates in the pharmaco-invasive group stabilized after the initial three months period (6.7% followed by 8.9% after 3 months) whereas it continued to increase in the primary PCI group (1.3% at 30 days, 2.6% at 3 months, 3.2% at 6 months and 4.5% at 1 year). Another interesting finding is that the bleeding risk was similar between the two groups which were contrary to the previous

studies which had a higher bleeding in the thrombolysis arm. The increased utilization of the radial access for CAG in comparison to primary PCI could have been the reason for the similar rates of bleeding. The results of this study demonstrate the safety and efficacy of the pharmaco-invasive strategy in comparison to primary PCI under the age of 75 years which can alleviate the logistic and geographic barriers of primary PCI in the treatment of STEMI in India.⁷⁴

Interesting findings have surfaced from the Tamil Nadu STEMI (TN-STEMI) program. The implementation of the hub and spoke model of health care delivery for ACS as a system of care for the low and middle-income countries (LMICs) has proved to be beneficial. One-year mortality was lower in the postimplementation phase in the TN-STEMI program though there were no statistically significant differences between the pre- and postimplementation phases for cardiogenic shock, stroke, or in-hospital mortality. Patients presenting to the hub hospitals had a significantly lower in-hospital mortality compared to those who were initially evaluated at the spoke health care centers during the preimplementation phase, but this difference was abolished in the postimplementation phase. Postimplementation phase also saw an increase in utilization rates of medical therapy like aspirin, statins, and DAPT. Focusing on primary PCI as the exclusive mode of reperfusion is not feasible while developing a system of care for the LMICs despite its proven benefits. TN-STEMI program boasted of several of its key features like high rates of reperfusion at baseline (approximately 90%) reflecting the institution of care processes around measurement in the preimplementation phase, establishing transfer of patients with STEMI using ambulance services with paramedics,⁷⁵ use of the STEMI information technology kit for diagnosis and monitoring; the features which resulted in the findings of stable reperfusion rates and times to treatment combined with increases in primary PCI and the pharmaco-invasive approach after its implementation. The ominous finding from the TN-STEMI program was an increased utilization of primary PCI and the pharmaco-invasive approach in the spoke health care centers (by almost 10-fold from 3.5 to 31.3%) and a reduction of stand-alone fibrinolysis from 53.6% of patients in the preimplementation phase to 29.4% in the postimplementation phase.^{76,77}

CONCLUSION

There is a high burden of CVD especially ACS accounting for a significant percentage of mortality among the Indian population. STEMI is a major public health problem, often impacting the most productive years of an individuals' life. STEMI affects younger population in India when compared to the Western population. Various socioeconomic factors and CVD risk factors are unique to Indians affecting the epidemiology and burden of STEMI among Indians. More resources are needed to be directed towards applying the existing knowledge base to tackle the CVD epidemic in policy, programs, capacity building, and research arenas to address the socioeconomic differentials in the burden of disease and healthcare needs of Indians. Out-of-pocket payment

for medical care is the most common payment method for medical services in India, where insurance coverage is low, an issue which needs attention especially affecting the lower SES. Evidence-based pharmacotherapy and interventions as well as outcomes were favorably comparable to the data from developed nations. Trends towards increasing admission rate for ACS, utilization of therapeutic advances and fall in mortality were observed. Pharmaco-invasive therapy can be an excellent alternative to primary PCI in financially constrained situations and the age-old SK has beyond doubt proved its efficacy in saving lives. There are numerous data of ACS in India to date, and these demonstrate opportunities for improving the quality of ACS management by focusing on reducing symptom-to-door time, door-to-needle time, and inappropriate use of thrombolysis and increasing use of recommended drugs.

Choosing Fibrinolysis in STEMI: Economics over Efficacy?

Mullasari S Ajit, Meenakshi MS

INTRODUCTION

Since the first description of angina pectoris by Herbeden in 1772¹ to our current understanding of the genetic and molecular basis of coronary artery disease, the pathways of discovery, innovation, and therapeutic advancements have been truly remarkable. The fibrinolytic property of streptokinase (SK) was established in 1933 by William Tillett and Garner,² but the intravenous use of SK for clot resolution began in the 1980s. The breakthrough in the management of ST-elevation myocardial infarction (STEMI) patients was in 1986 when the GISSI I (Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardico) trial, the first large randomized trial, showed that intravenous thrombolytic therapy with SK improved survival. The antigenicity and less fibrin specificity of SK were undesirable properties, which prompted interest in finding other potential fibrinolytic agents such as tissue plasminogen activator (t-PA).

Choosing fibrinolysis in STEMI—economics over efficacy? The answer is definitely efficacy. But what in the Indian scenario? We have multiple tiers of healthcare systems, variable strata of population with different economical status. We do not have a common protocol of coronary care management from community to tertiary care level across the country and a universal comprehensive government insurance policy for all. Hence, we need to consider the economics in the poor and uninsured patients.

IMPORTANCE OF EARLY REVASCULARIZATION

Evidence from several randomized controlled trials (RCTs) shows that early revascularization, whether primary percutaneous coronary intervention (PPCI) or fibrinolysis, decreases the infarct size, preserves left ventricular function, and improves survival rates. PPCI has been proved to be the gold standard in achieving better thrombolysis in myocardial infarction III (TIMI III) flow and improved survival,³ when

done with a door to balloon time of less than 90 minutes.⁴ But this can be achieved in only 10% of the Indian population.⁵ Early reperfusion with thrombolysis is a good and feasible option in a developing country like India where PPCI is not possible for most of the patients.⁶

Data from the CREATE⁵ registry, a large prospective registry of acute coronary syndrome patients across major cities of India, shows that 60% of patients had STEMI (compared to 40% in developed countries) and the median time from onset of symptoms to hospital arrival was 300 minutes (140–170 minutes in developed countries). Among them, 59% received fibrinolytic therapy with a time interval of 50 minutes to undergo fibrinolysis after reaching the hospital and 9% underwent PCI during their hospitalization. The initial delay is by the patient due to lack of awareness, lack of access, lack of transfer facilities, and lack of knowledge about PCI capable centers.

PHARMACOINVASIVE STRATEGY

The pharmaco-invasive (PI) approach is gaining momentum in recent years. The STREAM trial (strategic reperfusion early after myocardial infarction) showed that a strategy involving early fibrinolysis with bolus tenecteplase (TNK) and adjunctive pharmacotherapy followed by PCI offers similar efficacy as PPCI in patients with STEMI who presented within 3 hours of symptom onset and who could not undergo PPCI within 1 hour of first medical contact (FMC). At 1 year, the combined endpoint of death, shock, reinfarction, and stroke did not show difference in both arms. The FAST-MI (French registry of Acute ST-elevation and non-ST-elevation Myocardial Infarction) study from France also showed lower 5-year mortality in the PI arm.

The STEPP-AMI⁷ trial, a prospective, observational, multi centric trial from India evaluated the efficacy of early fibrinolytic treatment with TNK followed by PCI (pharmaco-invasive) in patients presenting within 3–24 hours compared to PPCI and concluded that PI strategy was

safe, with 80% patency of infarct related artery (IRA), lower thrombus burden and better TIMI III flows at the time of the procedure and the outcomes were comparable with PPCI at 1 year.

FIBRINOLYTIC DRUGS—CLASSIFICATION AND COMPARISON

The available fibrinolytics (Table 1) are classified based on fibrin specificity. The commonly used fibrinolytics are compared in table 2. Thrombolysis can be initiated by the activation of the endogenous fibrinolytic system. The plasminogen activators convert plasminogen to plasmin, which degrades fibrin, a major constituent of clots. The fibrin-specific agents such as t-PA and its derivatives act in the presence of fibrin and do not induce a systemic lytic state but the less fibrin-specific agent such as streptokinase (SK) activates plasminogen irrespective of its association with fibrin and leads to degradation of fibrinogen, plasminemia, and depletion of coagulation factors.

Although by definition fibrinolytic therapy dissolves thrombus, paradoxically, the thrombin released from clot lysis may be prothrombotic as well.⁸ SK induces thromboxane (TXA2) synthesis and activates platelets, particularly in the presence of high titers of anti-SK antibodies.⁹ These may be the factors associated with increased reocclusion rates and adjunctive therapy with antiplatelets, anticoagulants, and GP IIb/IIIa inhibitors helps in maintaining IRA patency rates and prevent ischemic complications during PCI.

The platelet activation and platelet aggregation inhibition varies with different lytic agents, which warrants further studies on the optimum timing of PCI after thrombolysis. The optimal time would be theoretically, one when there is less prothrombotic effect and less bleeding. The platelet activation inhibition of newer fibrinolytics persists for 2 hours and that for SK persists for almost 12 hours.⁸ For practical purposes as per guideline recommendation, the optimal timing for PCI after newer fibrinolytics is 3 hours^{3,8} and the radial route is preferred.

EFFICACY OF FIBRINOLYTICS—BASED ON TRIALS

Streptokinase

The GISSI 1 trial and the International Study of Infarct Survival (ISIS) trials firmly established the efficacy of intravenous SK in acute myocardial infarction (AMI). In the GISSI trial, at 21 days there was 18% reduction in mortality following SK compared to the control group. The extent of the benefit was related to the time of onset of chest pain to SK infusion [risk ratio (RR) 0.74, 0.80, 0.87, and 1.19 for the 0–3, 3–6, 6–9 and 9–12 hours subgroups]. In ISIS-2 trial, patients with AMI randomized to SK and aspirin compared with neither treatment resulted in significant reduction not only in death (8% vs. 13.2%), but also stroke (0.6% vs. 1.1%) and reinfarction (1.8% vs. 2.9%). The GISSI trial marked the beginning of early revascularization in STEMI.

Alteplase

The Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO), GISSI, and ISIS investigators compared intravenous SK and t-PA in STEMI patients. Although no significant difference was observed between SK and t-PA in GISSI-2 and ISIS-3, the GUSTO trial demonstrated that an accelerated regimen of t-PA resulted in 14% reduction in mortality at 30 days and slight excess of hemorrhagic stroke. The phase-I TIMI trial demonstrated that alteplase resulted in reperfusion of twice as many occluded IRA compared with SK at 90 minutes.

Reteplase

Reteplase (r-PA) compared to accelerated alteplase infusion demonstrated no significant benefit in terms of reduction in 30-day mortality in GUSTO III trial. r-PA + abciximab did not provide significant benefit in 30 day survival in the GUSTO V trial. However a double dose r-PA (10 + 10 MU) utilized in the revitalising areas by planning, investment and development (RAPID) trial resulted in complete, rapid and sustained thrombolysis of IRA at 90 minutes and at 5–14 days (63% vs. 49%, p = 0.019; and 88% vs. 71%, p <0.001) compared with alteplase and improved regional and global left ventricular function at discharge. The RAPID II trial further confirmed the advantage of r-PA over accelerated t-PA in achieving higher rates of early reperfusion in the IRA and fewer coronary interventions. This, however, did not translate into improved clinical outcomes in the International Joint Efficacy Comparison of Thrombolytics (INJECT) trial, which demonstrated no significant difference between r-PA and SK in reducing 35-day mortality.

Tenecteplase

A single bolus TNK increased IRA patency rates (64% TIMI III flow with 50 mg bolus dose) in the TIMI 10A trial. In the TIMI 10B trial, TNK (40 mg) and alteplase produced similar rates of TIMI grade 3 flow at 90 minutes (62.8% vs. 62.7%, respectively, P = NS). Subsequently, the Assessment of the Safety and Efficacy of a New Thrombolytic (ASSENT-1) trial

[§]Bolus of 30 mg for weight less than 60 kg, 35 mg for 60–69 kg, 40 mg for 70–79 kg, 45 mg for 80–89 kg and 50 mg for 90 kg or greater.

[¶]Accelerated infusion with bolus of 15 mg followed by infusion of 0.75 mg/kg for 30 minutes, then 0.5 mg/kg (maximum 35 mg) over next 60 minutes, total dose not to exceed 100 mg.

[€]Cost in Indian rupees. Range of cost given depending on the various brands available.

[§]Intracranial hemorrhage is based on the presence of multiple risk factors. Based on many studies, the common risk factors include elderly, low body weight, and hypertension.

showed that the safety profile of TNK was comparable to alteplase. Assessment of the Safety and Efficacy of a New Thrombolytic (ASSENT-2) trial compared single-bolus TNK with accelerated dose t-PA and the 30-day mortality rate was 6.17% vs. 6.15%, intracranial hemorrhage (ICH) was 0.93% and 0.94%, major bleeding occurred in 4.66% and 5.94% ($p = 0.0002$). There was no specific subgroup of patients for whom TNK or t-PA was significantly better, except patients treated after 4 hours of symptom onset, in whom the mortality rate was 7.0% with TNK and 9.2% with t-PA. Furthermore, the ASSENT-3 trial demonstrated that the addition of enoxaparin to TNK reduced ischemic complications at the cost of increased bleeding.

CHOICE OF FIBRINOLYTIC IN ST-ELEVATION MYOCARDIAL INFARCTION

Early revascularization and establishing flow is very important in salvaging the myocardium in AMI. The TN-STEMI project with the “hub-and-spoke” model-of-care showed the importance of “any” form of early reperfusion after symptom onset followed by early coronary intervention. In south India, this model of system of care resulted in 3.4% absolute reduction in mortality at the end of 1 year in 2,167 patients. The majority of this difference was in the spoke centers (3.3% mortality reduction compared to only 1.1% in the hub centers), mainly due to early transfer to PCI centers with or without fibrinolysis.¹⁰

Multiple trials showed evidence for safety and efficacy of one drug over the other. The PI trials such as STREAM, CARESS-AMI, TRANSFER-AMI, and STEPP-AMI used mainly TNK as the fibrinolytic agent and showed better patency rates

of IRA and the MACCE rates in the PI group with TNK as compared to the primary PCI group. The greater convenience, simplicity in dosing, ease and speed of administration make TNK as the fibrinolytic of choice in all patients, in most situations.

But in the real world situation, cost and availability of bolus fibrinolysis is a major concern thus refocusing on SK. The circulating high titers of anti SK antibodies^{11,12} in endemic tropical countries, like India, leads to increased hypotension and allergic reactions and may be the cause for more reocclusion rates with standard dose of SK. But the recent subgroup analysis of the PI arm of the TN-STEMI¹³ program showed that, in the 94% of the patients in the PI arm who had thrombolysis with SK followed by a system of care, the postimplementation group of systems of care as compared to the preimplementation group, showed improved IRA patency (86% vs. 70.2%; $p < 0.001$), better TIMI 3 flow (25.4% vs. 37.5%; $p = 0.027$), and less thrombus burden (49.1% vs. 73.4%; $p < 0.001$), translating into lower target revascularization and fewer admissions in the PI arm. The mortality, reinfarction and stroke, in the postimplementation PI group with SK was comparable to that with newer fibrinolitics. The 2013 consensus statement for early reperfusion and PI approach in Indian STEMI patients, suggested that the choice of fibrinolytic is TNK (LOE Grade 1A), reteplase (LOE Grade 1B) and alteplase (LOE Grade 1C), and SK is used only when a fibrin-specific agent is not available or unaffordable (LOE Grade 2B).¹⁴

Reteplase and TNK are given as bolus agents making it suitable for prehospital fibrinolysis at community level or in the ambulance, whereas SK and alteplase given over 1 hour infusion, make it suitable for in-hospital use, rather than at

community level. In patients, presenting within 4 hours of symptom onset, the speed of reperfusion is important and TNK is the preferred agent, which acts quickly with bolus dose and has high patency rates. In those presenting after 4 hours of symptom onset, with lower risk of death, MI involving small territory and high risk of ICH (e.g., acute hypertension), SK, accelerated t-PA, reteplase, and TNK have approximately equivalent outcomes.

Rural patients with prolonged transport time to PCI capable centers or patients in urban setting where delay in transfer is expected due to distance or heavy traffic congestion, bolus fibrinolytics are preferred at community level. Patients reaching PCI capable or noncapable centers, in whom a door to balloon time of less than 90 minutes cannot be achieved due to prolonged transfer times, nonavailability of cath laboratory or manpower or financial issues may be thrombolyzed with bolus fibrinolytic agents. Patients not affordable for bolus fibrinolysis may be thrombolyzed with SK before prompt shifting to PCI capable centers.

CONCLUSION

Tenecteplase with its ease of dosing, speed of administration, and better patency rates, is the default choice of fibrinolytic in STEMI patients. But SK, reteplase, or alteplase may be chosen according to the availability, affordability, and physician's choice and experience. The goal of early revascularization with primary PCI, or thrombolysis with any fibrinolytic drug, should be initiated within 90 minutes or 30 minutes of FMC, respectively. Thrombolysis should be followed by transfer to PCI capable center as early as possible, which would be the practical approach in managing STEMI patients in low- and middle-income countries, like India. The government should provide a universal system of care for STEMI patients, with primary PCI and bolus fibrinolysis made available for all, across the country, at affordable costs.

Routine PCI after IV Thrombolysis—Is it Ready for Prime Time?

Lekha Pathak, Ankur Jhavar

INTRODUCTION

Currently, patients who present with ST-segment elevation myocardial infarction (STEMI), their management involves critical timed decision in every aspect of care including primary reperfusion strategy, triage and timely transfer to a percutaneous coronary intervention (PCI) capable tertiary center. At present, other ideal alternative option for STEMI patients residing in remote areas where primary PCI is not available is fibrinolytic therapy. Unlike unstable angina/non-ST-segment elevation myocardial infarction (UA/NSTEMI), STEMI is mostly characterized by total occlusion of the infarct-related artery.

Current STEMI 2017 guidelines¹ involve time slab of 120 minutes to reach to PCI capable center. If expected time delay is more, fibrinolysis (unless contraindicated) should be instituted. Complete reperfusion with reduced morbidity and mortality is desired outcome of any modality of therapy for STEMI patients. Timely reperfusion has gained superior importance than complete or near-complete reperfusion. Time has been given crucial importance when considering which reperfusion therapy approach is to be used.

Final infarct size is one of the best predictor of long-term adverse events in STEMI survivors. The introduction of a specific infarct-limiting therapy in clinical practice might have a massive clinical and socioeconomic impact. Primary angioplasty is considered gold standard, although multiple conditions attenuated superior result in India, some of them being skilled operator, economical and logistical factors, and well-equipped catheterization laboratories. If primary PCI takes more than 120 minutes from diagnosis, associated with higher mortality even in well-developed centers, they achieve mechanical reopening of infarct-related artery without much benefit. In India, 70% of patients with acute myocardial infarction (AMI) present in non-PCI centers. Instituting reperfusion therapy as early as possible is crucial. It is proposed that if fibrinolytic therapy is part of the primary reperfusion strategy, a strategy of routine or adjunctive PCI is superior to rescue or selective ischemia-guided PCI with

respect to adverse events. This approach is popularly known as pharmacoinvasive strategy.²

STRATEGY CLOCK IN STEMI

The short- and long-term prognosis of STEMI patients depends not only on reperfusion but also with time delay for initiation of treatment. Prehospital delay has been considered as marker for increased morbidity and mortality; however, the benefit is highly dependent on the time between the onset of symptoms and start of reperfusion therapy.^{3,4}

Although primary PCI is unequivocally superior to thrombolysis, the time to revascularization is still better marker of overall outcome. In meta-analysis of six randomized trials, prehospital thrombolysis has shown to shorten the time from symptom onset to treatment by 60 minutes with 17% reduction in the overall mortality.⁵ Data from CAPTIM (Comparison of primary Angioplasty and Prehospital fibrinolysis In acute Myocardial infarction) and WEST (Which Early ST-elevation myocardial infarction Therapy) trials, have suggested mortality benefit with prehospital thrombolysis for early presenters. The absolute survival benefit of angioplasty compared with fibrinolysis decreased by 0.24% for every additional 10-minute delay.⁶ PCI remained superior to fibrinolysis when time delay related to PCI extended to 120 minutes. Life saved by reperfusion per 1,000 treated patients is 65, 27, 25 and 8 when performed at 1 hour, 2–3 hours, 4–6 hours and 7–12 hours, respectively.⁷

TREATMENT DELAY IN STEMI

Apart from prehospital delay, other type of delay is health system-related delay, i.e., between first medical contact (FMC) to reperfusion treatment which is always a major concern. Health system-related delay directly correlates with increased mortality in STEMI patients as a rule “time is muscle” considering STEMI patients. Challenges to institution of early primary PCI include economical support, geographical area, trained cardiologist as well as other

medical staff and well-equipped catheterization laboratories. Practical application of STEMI guidelines is very difficult and many times not been fulfilled by many centers.

REPERFUSION STRATEGIES

Fibrinolysis

Nine landmark trials by the Fibrinolytic Therapy Trialists' Collaborative Group⁸ compared the outcomes of patients undergoing fibrinolytic therapy and those of controls and demonstrated statistically significant absolute reduction in 35-day mortality rates of approximately 30 per 1,000 for patients who arrived at the hospital within 6 hours of the onset of symptoms (Table 1). The greatest benefit was observed among patients with left bundle branch block (LBBB) or anterior STEMI.

Fibrinolytic therapy is currently indicated for patients with STEMI who have experienced symptom onset within the previous 12 hours and in whom electrocardiography (ECG) demonstrates ST-segment elevation of more than 0.1 mV in at least two contiguous precordial leads or at least two adjacent limb leads or new LBBB. The fibrinolytic agents currently approved for treating patients with STEMI include streptokinase, alteplase, reteplase, and tenecteplase. The thrombolysis in myocardial infarction (TIMI), phase 1 trial randomly assigned 290 patients with evolving AMI to alteplase or to streptokinase. Alteplase was far superior in achieving coronary reperfusion; twice as many occluded infarct-related arteries opened after 90 minutes with alteplase than with streptokinase. Assessment of the Safety of a New Thrombolytic (ASSENT)-2 trial,⁹ randomly assigned 16,949 patients to weight based single-bolus tenecteplase or to accelerated alteplase infusion. The 30-day mortality rates

were virtually identical. Tenecteplase has become the most widely used fibrin-specific agent because of advantage of single bolus dosing. If the reperfusion strategy is fibrinolysis, the goal is to inject the bolus of fibrinolytic within 10 minutes from STEMI diagnosis. This time is selected based on the median time from randomization to bolus recorded in the Strategic Reperfusion Early After Myocardial Infarction (STREAM) trial, which was 9 minutes.

Primary Percutaneous Coronary Intervention

Twenty-three randomized clinical trials¹⁰ compared primary angioplasty in myocardial infarction (PAMI) with fibrinolytic therapy and demonstrated that PAMI was better than fibrinolysis in reducing the incidence of short-term and long-term adverse outcomes, including death. It was found that patients undergoing PAMI, increases in the door-to-balloon time (especially by >2 hours) were associated with higher mortality rates.

Selection of either fibrinolysis or PAMI as the appropriate reperfusion strategy should depend on the clinical scenario. Primary PCI is generally preferable if it is rapidly available because it yields better outcome than fibrinolysis. The effectiveness of both fibrinolytic therapy and PAMI diminishes with the passage of time. Thus, PCI is generally preferred for patients who arrive at the hospital late after the onset of symptoms (>3 hours). Early initiation of fibrinolytic therapy may lead to outcomes that are similar to or better than those achieved with PCI.

Routine PCI after Fibrinolytic Treatment (Facilitated PCI)

This approach involves fibrinolysis followed by early and mandatory PCI. This procedure tries to improve patency by fibrinolysis before performing PCI. Potential advantages of this approach include earlier time to reperfusion, smaller infarct size, better patient stability, lower infarct artery thrombus burden, and greater procedural success rate. However, higher mortality was seen with this approach mostly due to stent restenosis rather than bleeding complications. Firstly, the prothrombotic circumstance caused by short application of fibrinolytic agents may have limited the benefit of PCI. Secondly, fibrinolytic agent would soften the fresh thrombus and divide them into small pieces. Thirdly, the differences in time of reperfusion may affect first 2 hours after the onset of infarction, and the time interval can hardly be met in many of the included studies which enrolled patients with less than 12 hours, 6 hours or 3 hours of symptom onset. Therefore, the time-dependency of PCI-mediated salvage may be considerably attenuated.¹¹

Rescue Percutaneous Coronary Intervention

In this approach, those patients who suffer failed thrombolysis are treated with emergency PCI to salvage jeopardized myocardium. Failed thrombolysis usually manifests as

TABLE 1: Important time targets in acute ST-segment elevation myocardial infarction (STEMI)

Intervals	Time targets
Maximum time from first medical contact (FMC) to electrocardiography (ECG) and diagnosis ^a	≤10 min
Maximum expected delay from STEMI diagnosis to primary percutaneous coronary intervention (PCI) (wire crossing) to choose primary PCI strategy over fibrinolysis (if this target time cannot be met, consider fibrinolysis)	≤120 min
Maximum time from STEMI diagnosis to wire crossing in patients presenting at primary PCI hospitals	≤60 min
Maximum time from STEMI diagnosis to wire crossing in transferred patients	≤90 min
Maximum time from STEMI diagnosis to bolus or infusion start of fibrinolysis in patients unable to meet primary PCI target times	≤10 min
Time delay from start of fibrinolysis to evaluation of its efficacy (success or failure)	60–90 min
Time delay from start of fibrinolysis to angiography (if fibrinolysis is successful)	2–24 hours

^aECG should be interpreted immediately.

persistent ischemic symptoms, hemodynamic instability and failure to achieve 50–70% resolution of maximal ST-segment elevation at 90 minutes after initiation of infusion. This approach was proved to be more effective than repeat thrombolysis.

Pharmacoinvasive Strategy

Recently, a strategy of combining fibrinolysis followed by transfer for early PCI (“pharmacoinvasive PCI”) has been shown to be an effective reperfusion strategy for STEMI patients presenting to non-PCI hospitals compared with fibrinolysis alone. In contrast to facilitated PCI, this approach includes PCI which follows fibrinolysis after some delay so that early prothrombotic phase would get resolved preventing the increased incidence of stent restenosis. This strategy aims at reduction of mortality seen with facilitated PCI.

Pharmacoinvasive strategy consists of administration of fibrinolysis at a non-PCI center followed by immediate transfer to a PCI-capable hospital for routine early catheterization performed within 2–24 hours of start of fibrinolytic therapy, regardless of whether thrombolysis results in successful reperfusion or not. Thus, the time to PCI is longer than with facilitated PCI.¹²

In the recent past, several clinical trials and patient registries using pharmacoinvasive strategy [GRACIA-2¹³ (Grupo de Análisis de la Cardiopatía Isquémica Aguda) TRANSFER-AMI¹⁴ (Trial of Routine Angioplasty and Stenting after Fibrinolysis to Enhance Reperfusion in Acute Myocardial Infarction), FAST-MI (French Registry of Acute ST-elevation or Non-ST-elevation Myocardial Infarction),¹⁵ WEST¹⁶] have demonstrated mortality that is comparable to that documented with primary PCI. These trials reinforced that pharmacologic regimen rapidly delivered, coupled with routine coronary intervention within 24 hours of initial treatment, may not be different from timely expert PCI.

Gracia-2 Trial¹³

This trial (n = 212) compared full tenecteplase followed by stenting within 3–12 hours of randomization (early routine post-fibrinolysis angioplasty; 104 patients) with primary stenting with abciximab within 3 hours of randomization (primary angioplasty; 108 patients) compared primary versus

facilitated angioplasty. All patients received clopidogrel, aspirin and enoxaparin to prevent reocclusion. The results showed that early routine post-fibrinolysis angioplasty resulted in higher frequency of complete epicardial and myocardial reperfusion following angioplasty. Thus, the pharmacoinvasive approach was equivalent to primary PCI despite performance of a delayed PCI.

Transfer-AMI Trial¹⁴

This study was conducted in Canada in high-risk STEMI (n = 1,059) patients transferred from community hospital to regional PCI center for urgent PCI within 6 hours of thrombolysis. It showed reduction in additional 6% death or myocardial infarction in post-tenecteplase angioplasty (30-day mortality 17.2% vs. 11.0%, p = 0.004), when performed after 6 hours of onset of symptoms.¹⁴

FAST-MI Trial¹⁵

Data of 1,714 patients from FAST-MI also showed a pharmacoinvasive strategy that combines thrombolysis with a liberal use of PCI yields early and 1-year survival rates that are comparable to those of PAMI.

WEST Trial¹⁶

In this study, 304 patients were randomized to tenecteplase alone and PCI if required and compared with PAMI. The trial showed similar low mortality in both the groups. Coronary intervention was done within 24 hours of initial therapy. This reinforced that pharmacologic regimen rapidly delivered, coupled with routine coronary intervention within 24 hours of initial treatment, may not be different from timely expert PCI.

The European Society of Cardiology (ESC) 2017 STEMI guidelines recommend early routine angiography 2–24 hours after successful thrombolysis. This time window avoids PCI during the prothrombotic period in the first few hours after thrombolysis and minimizes the risk of reocclusion with PCI delay of more than 24 hours (class IIa recommendation) (Table 2, Box 1 and Flowchart 1).¹ A pharmacoinvasive strategy improved outcomes because the delay between thrombolysis and PCI was more than 2 hours, i.e., long enough to prevent bleeding complications, and because most patients randomized in these trials presented within

BOX 1 | 2017 revised concepts

1. Time limits for routine opening of an infarct-related artery—0–12 hours (Class I); 12–48 hours (Class IIa); more than 48 hours (Class III).
2. ECG at presentation—left bundle branch block and right bundle branch block are considered equal for recommending urgent angiography, if ischemia persists.
3. Time to angiography after fibrinolysis—timeframe is set in 2–24 hours after successful fibrinolysis.
4. Patients taking anticoagulants—acute and chronic management presented.
5. Strategy selection and time delays:
 - a. Clear definition of first medical contact (FMC)
 - b. Definition of “Time 0” to choose reperfusion strategy (i.e., strategy clock starts at the time of STEMI diagnosis)
 - c. Selection of PCI over fibrinolysis when anticipated delay from STEMI diagnosis to wire crossing is less than 120 minutes.
 - d. Maximum delay time from STEMI diagnosis to bolus of fibrinolysis agent is set in 10 minutes.
 - e. “Door-to-balloon” term is eliminated from the guidelines.

Source: STEMI 2017 European Society of Cardiology guidelines.¹

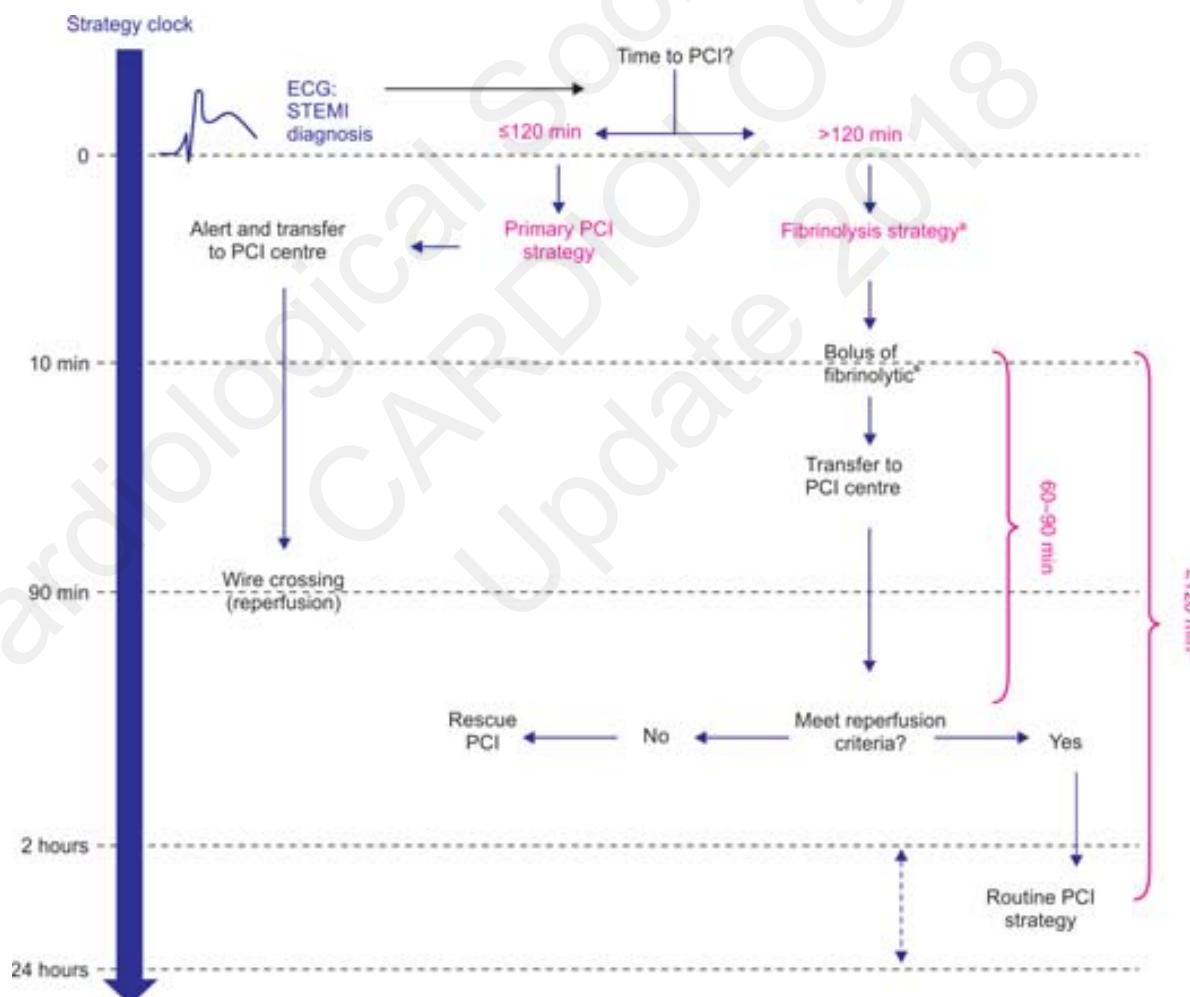

2–3 hours of symptom onset, when the time to reperfusion is critical.¹⁷ After 3 hours, the PCI-mediated myocardial salvage is less time-dependent.¹⁸

Pathak Trial¹⁹

This study compared primary angioplasty versus post-teneptecplase angioplasty in ST elevation AMI in 200 cases and found no difference between post-teneptecplase and PAMI patients with regard to infarct size and left ventricular ejection fraction which are powerful predictors of survival after AMI. Rather post-fibrinolysis angioplasty resulted in better and higher TIMI 3 epicardial and TIMI myocardial perfusion grade (TMPG) 3 myocardial perfusion. The post-teneptecplase angioplasty provided wider window from 3 to 12 hours for coronary intervention in STEMI, from FMC.

STREAM Study²⁰

This study evaluated whether a fibrinolytic-therapy approach consisting of prehospital or early fibrinolysis with contemporary antiplatelet and anticoagulant therapy, coupled with

*If fibrinolysis is contra-indicated, direct for primary PCI strategy regardless of time to PCI.

^b10 min is the maximum target delay time from STEMI diagnosis to fibrinolytic bolus administration, however, it should be given as soon as possible after STEMI diagnosis.

Source: STEMI 2017 European Society of Cardiology guidelines.¹

timely coronary angiography, provides a clinical outcome similar to that with primary PCI in patients with STEMI who present early after symptom onset. In this trial, 1,892 patients with STEMI who presented within 3 hours after symptom onset were randomly assigned to undergo either primary PCI or fibrinolytic therapy with bolus tenecteplase clopidogrel, and enoxaparin before transport to a PCI-capable hospital. If fibrinolysis failed, emergency angiography was performed otherwise; it was performed after 6–24 hours. Emergency angiography was required in 36.3% patients whereas the remainder of patients underwent angiography at a median of 17 hours after randomization. Thus, early prehospital fibrinolysis along with antithrombotics coupled with timely coronary angiography resulted in effective reperfusion in patients who presented within 3 hours after symptom onset. However, increased risk of intracranial bleeding was a concern with early fibrinolytic therapy.²⁰

CONCLUSION

Primary angioplasty in myocardial infarction is most preferable reperfusion strategy at present. However, multiple reasons being logistic, timely intervention possibilities may not be possible for many STEMI patients. Most STEMI patients are getting treated with fibrinolysis as of easy availability of pharmacological treatment than still at large deficit of appropriate catheterization laboratory centers in Indian scenario. Debate continues as to whether, and when, patients treated with fibrinolysis should undergo subsequent PCI. Current data support the strategy of early routine PCI after fibrinolysis rather than the conservative standard care approach.

Revascularizing Nonculprit Artery in AMI: Uniform Strategy or Case-based Approach

Ranjit K Nath, Kewal C Goswami

INTRODUCTION

Primary angioplasty or primary percutaneous coronary intervention (PCI) has been proved to be an excellent therapy for ST-elevation myocardial infarction (STEMI) that has been shown to improve immediate and long-term outcomes. While there is ample evidence to demonstrate that immediate revascularization is required to open the infarct-related artery (IRA), the clinician is faced with the dilemma of how to treat other diseased vessels which are seen in up to 50% of patients presenting with an STEMI.¹ The short-term and long-term prognosis of patients with multivessel coronary artery disease (MVCAD) is worse than the patients who have single vessel disease.² The worse prognosis of MVCAD is stems from clinical variables because such as older age, multiple risk factors or associated comorbid conditions, pre-existing ventricular dysfunction, additional vulnerable plaques, diffuse endothelial dysfunction, microvascular spasm, or inflammation, slow-flow or decreased contractility in noninfarct zones.³⁻⁵

Because of increased risk of subsequent MI and mortality in patients with MVCAD, these patient needs to be managed timely. The adverse impact of nonculprit lesions in STEMI patients raises the question as to whether revascularization will improve their outcomes. Many observational and randomized studies have shown that revascularization of nonculprit lesions will reduce the major adverse cardiac event (MACE). However, the optimal management strategy for management of MVCAD in STEMI patients is still controversial. Currently available evidence addressing the management of nonculprit coronary stenotic lesions at the time of primary PCI has yielded conflicting result.

The 2015 American College of Cardiology (ACC)/American Heart Association (AHA)/Society for Cardiovascular Angiography and Interventions (SCAI) guidelines⁶ currently recommend consideration of multivessel PCI (MVPCI) either at the time of primary PCI or as a staged procedure (class IIb), modified from culprit-vessel PCI (CV-PCI) only

in the absence of hemodynamic instability (class III). The 2017 European Society of Cardiology (ESC) guidelines for the management of acute myocardial infarction (AMI) in patients presenting with ST-segment elevation recommends routine revascularization of non-IRA lesions to be considered in STEMI patients with multivessel disease before hospital discharge (class IIa) or during index procedure in patients with cardiogenic shock.⁷

APPROACH TO THE MANAGEMENT OF NONCULPRIT LESIONS IN STEMI

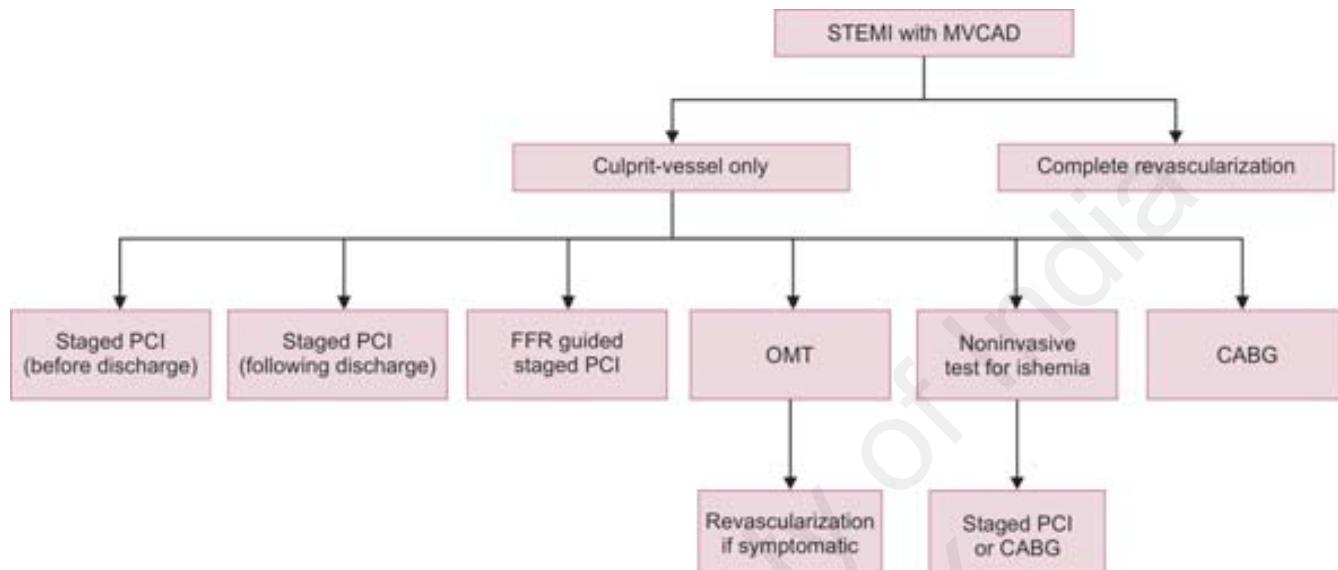

There can be various treatment approaches to manage STEMI patients with MVCAD either at the time of primary PCI or by staged approach (Flowchart 1).

Complete Revascularization during Index Procedure versus Culprit-Vessel Only

There are some advantages and disadvantages of complete revascularization during index procedure (Table 1) in comparison to the CV only approach. In the PRAMI (Preventive Angioplasty in Acute Myocardial Infarction) trial 465 patients with acute STEMI were randomized to either CV-PCI only (231 patients) or MVPCI involving CV and preventive PCI of other angiographically significant coronary stenosis (234 patients). PCI of the nonculprit lesions had to be performed at the index procedure and staged procedures were discouraged. Lesions that were more than 50% diameter stenosis in the non-CV were considered significant. Fractional flow reserve (FFR) was not used to assess lesion severity. Patients in cardiogenic shock, chronic total occlusions (CTOs) of the non-CV or those with significant left main disease were excluded. Among the patients who underwent CV only PCI, subsequent PCI was recommended only for refractory angina with objective evidence of ischemia.⁸ Although this study planned to recruit 600 patients, it had to be prematurely stopped at 23 months due to highly significant difference

FLOWCHART 1: Various options for management of MVCAD in acute myocardial infarction.

TABLE 1: Advantages and disadvantages of multivessel percutaneous coronary intervention in acute myocardial infarction

Advantages	Disadvantages
<ul style="list-style-type: none"> Decreases complications of repeated procedures Decreases chance of in-hospital recurrent ischemia or related arrhythmias Improves blood supply to hibernating myocardium or watershed area of infarction, hence improves ejection fraction and remodeling Reduces subsequent urgent revascularization Decreases duration of hospital stay, hence increases cost-effectiveness May decrease future MI and related mortality When access is very difficult or limited, repeat procedure may not be possible 	<ul style="list-style-type: none"> Procedure duration is long More radiation exposure Higher contrast use may cause contrast-induced nephropathy which can increase hospital morbidity and mortality Increased risk of stent thrombosis Increased periprocedural MI risk Nonculprit lesion severity may be exaggerated because of more catecholamine release, producing vasoconstriction More chance of slow-flow Occlusion/dissection/no-flow-related complication of major noninfarct artery can be catastrophic Operator experience becomes important factor in handling complex cases

MI, myocardial infarction; PCI, percutaneous coronary intervention.

in the primary composite outcome of cardiovascular death, nonfatal MI and refractory angina favoring preventive PCI [9% vs. 22%, hazard Ratio (HR) 0.35]. There were 21 events in the multivessel group versus 53 events in the culprit-vessel only (CVO) group, with nearly half of the events driven by refractory angina. Even when analyzed for the variables of death and nonfatal MI, the HR favored preventive PCI (HR 0.36). Thus, this trial demonstrated fewer MACE events amongst patients treated with MVPCI at the time of STEMI. However, this trial was limited by the liberal definition of lesion severity as well as the small number of events.

The CvLPRIT (Complete versus Lesion-only Primary PCI Trial) randomly assigned 296 patients to complete revascularization during the index hospitalization or IRA-only revascularization.⁹ The criteria for significant nonculprit stenosis were more than 70% diameter stenosis in other coronary arteries. Around 64% of patients received

complete revascularization at the time of primary PCI in complete revascularization group and in remaining one-third of patients revascularization was done before hospital discharge. FFR assessment was not used to look into the hemodynamic significance of the nonculprit lesions. The primary composite end point at 12 months occurred less often in the complete revascularization group (10.0% vs. 21.2%; HR 0.45, 95% CI 0.24–0.84). The MACE curves between the two groups separated early at approximately a month from the event and continued to do so even at one year. Most importantly there was no difference in the safety end points between the two approaches (major bleeding, contrast-induced nephropathy, or stroke). However, this trial was not powered to detect differences in the individual components of the primary composite end point of all-cause mortality, recurrent MI, heart failure, or repeat revascularization.

From CvLPRIT trial the following conclusions can be made:

- It showed 55% reduction in MACE in those patients with STEMI who underwent revascularization of nonculprit lesion in index admission with no adverse safety signal
- Those patients with immediate nonculprit lesion PCI showed a strong trend towards improved clinical outcomes compared with those undergoing a staged in-hospital procedure
- As the staging was based on clinicians' decisions and was nonrandomized, and also the number of patient in each strategy was less, it is difficult to draw a definite conclusion
- In view of the early separation of outcome measures in event curves, it can be suggested that a postdischarge late complete revascularization approach may not be a better option than in-hospital complete PCI.

The ACC guidelines presently do not clearly define whether revascularization of nonculprit lesion during performed in the index period or whether they should be performed as a staged procedure. The ESC guidelines however recommend that nonculprit revascularization during index PCI should only performed in patients presenting with cardiogenic shock.⁷

From a practical standpoint considering the possible risks and benefits of index complete revascularization, it may not be suitable to perform complete revascularization in all patients with AMI with MVCAD at the index period. Decision should be individualized based on patient condition, operator efficiency, availability of tools, and manpower, etc.

Complete revascularization at the time of index procedure is not recommended in following patients:

- Patients with less than TIMI III flow in the CV after angioplasty
- Acute hemodynamic or arrhythmic instability after CV angioplasty
- Who have risk factors for contrast induced nephropathy (like anemia, diabetes, known renal dysfunction or history of medical renal disease)
- Complex nonculprit lesions like calcified lesion, bifurcation, tortuous vessels, and anomalous origin
- Bleeding or other complications after culprit vessel PCI
- Chronic total occlusion lesions in non-CV
- If the patient has indication for valve surgery or coronary artery bypass grafting (CABG) for other vessel disease like complex left main disease or mechanical complication.

Culprit Vessel Only Primary PCI versus Staged PCI

Staged PCI of nonculprit arteries have some advantages especially in patients with advanced age, additional comorbid conditions and low left ventricular ejection fraction (LVEF). It is also associated with a lesser chance of developing contrast induced nephropathy.

The DANAMI-3-PRIMULTI (Third Danish Study of Optimal Acute Treatment of Patients with STEMI: Primary PCI in Multivessel Disease) trial randomly assigned 627 patients after culprit lesion treatment to either no further treatment

(313 patients) or complete revascularization of nonculprit lesions (314 patients). Complete revascularization was usually done after 2 days of index primary PCI and unlike PRAMI or CvLPRIT trial, FFR-guided PCI of the nonculprit lesions (>50% diameter stenosis) was performed in this trial.¹⁰ Patients in cardiogenic shock or those with indication for CABG were not included in this trial. The primary composite end point of all-cause mortality, nonfatal infarction, and ischemia-driven revascularization of lesions in non-IRAs occurred less often in the group with complete revascularization than in the CV only group (13% vs. 22%). The reduction in events was driven by a 69% reduction in the need for repeat revascularizations (5% vs. 17%). There was no difference in cardiac death or reinfarction between the two groups.

One important point observed was that approximately one-third of patients did not undergo nonculprit lesion revascularization in complete revascularization group, as FFR value was found to be above 0.80 despite the fact that initial angiogram showed significant stenosis. This supports that during AMI there is an increased chance that nonsignificant lesion may appear significant because of vasospasm and FFR will definitely play a role in such scenario and will improve the outcome.

Multivessel PCI versus Staged PCI

Observational studies by Varani et al.¹¹ and Jensen et al.¹² have shown increased mortality in MVPCI during index procedure group when compared to staged PCI group. They found a longer hospital stay and higher in-hospital mortality in MVPCI group than in the staged procedure group. This increased mortality could be because clinically more critical patients may have been selected for multivessel primary PCI. Also, this may be related to prolonged procedure-related complications like slow-flow in non-CV, large contrast load, hemodynamic instability like hypotension or arrhythmias, etc. Suboptimal result after angioplasty in culprit vessel before proceeding for nonculprit lesion revascularization can be another factor of poorer outcome.

Is Staged PCI Better than Multivessel PCI?

Recent meta-analysis by Li et al.¹³ has shown benefit of both short and long term mortality favoring staged PCI. This may be because of:

- Procedures done in routine hours with better support and tools
- Procedures done or supervised by experienced operators
- Patient already stabilized
- Already on adequate medications like dual antiplatelet therapy (DAPT), high-dose statin, and other required medicines
- Can have a plan in managing complex cases.

Chronic Total Occlusion as Nonculprit Vessel in STEMI

The occurrence of CTO in STEMI patients is not uncommon and its reported incidence varies from 10 to 15%. Presence

of CTO significantly increases mortality in these patients.¹⁴ Randomized trial have not shown any benefit of opening CTO lesions in patients of AMI. The benefit of opening the CTO was studied in the EXPLORE (Evaluating Xience and Left Ventricular Function in Percutaneous Coronary Intervention on Occlusions after ST-Elevation Myocardial Infarction) trial.¹⁵ About 304 patients with STEMI who underwent primary PCI and also had concurrent CTO in nonculprit vessels were included. A total of 150 patients were randomly assigned to early PCI of the CTO, and the remaining 154 patients were assigned to conservative treatment. Procedural success for CTO was 77%. This study has shown additional PCI of opening of CTO within 1 week of AMI was feasible and safe, but the primary outcomes of improvement in LVEF and left ventricular (LV) end diastolic volume at 4 months were not significant. However, in a subgroup analysis, patients who had CTO in the left anterior descending artery had a significantly higher LV function than in those who did not undergo a CTO recanalization strategy.

Thus, revascularization of CTO of nonculprit arteries in patients with AMI may not be beneficial or necessary, and if at all required it has to be done in a staged manner after testing for inducible ischemia. Factors determining need and success of CTO revascularization of nonculprit arteries will depend on (i) large area of supply by the CTO vessel; (ii) patient comorbid conditions and EF; (iii) the lesion complexity, calcification, etc., (iv) more importantly the experience and availability of CTO tools.

Meta-analysis on MVCAD in STEMI

A recent network meta-analysis by Elgendi et al. in 2017¹⁶ included ten randomized trials with 2,285 patients from the available trials. They compared four treatment strategies in STEMI with MVCAD undergoing primary PCI in these patients:

- Complete revascularization performed at the time of index procedure
- Culprit lesion only approach
- Staged PCI of nonculprit lesion performed before hospital discharge
- Staged PCI of nonculprit lesions performed a few weeks after discharge (not dictated by presence or absence of symptoms).

After median follow up of 25 months the following observations were made:

- Patients who underwent complete revascularization, regardless of strategy (at the time of index procedure or as a staged procedure) had a lower risk of MACE [risk ratio (RR) 0.57, 95% CI 0.42–0.77] as compared with those undergoing just CV-PCI
- The composite primary end point in these patients (MACE) has been largely due to a lower rate of urgent revascularization in the MVPCI arm as compared to culprit vessel only arm
- Multivessel PCI has been associated with a lower risks of all-cause mortality and recurrent MI (RR 0.76, 95% CI 0.52–1.12 and 0.55, 95% CI 0.23–1.28, respectively).

Percutaneous Coronary Intervention in STEMI with Cardiogenic Shock

The earlier common practice was that, if patient was in shock then non-CV should be opened at the same time and recent ESC (2017) guidelines also has given this a class IIa recommendation for MVPCI at index period if patient is in cardiogenic shock. But the recent CULPRIT-SHOCK trial has included 706 patients with STEMI who had MVCAD and in cardiogenic shock has shown some different findings.¹⁷ These patients were randomized either to culprit lesion only with options of staged PCI or complete revascularization at index period.

At 30 days the following points were noted:

- The primary end point of death from any cause or renal replacement therapy were higher in MVPCI group
- Recurrent MI or hospitalization for congestive heart failure were also higher in MVPCI group
- Staged or urgent revascularization was higher in culprit vessel only group
- Lack of benefit of MVPCI may be because of more dye use in MVPCI group causing contrast nephropathy as acute coronary syndrome (ACS) itself is a risk factor for nephropathy and also toxic effect of dye on myocardium whose function is already compromised by STEMI.

Therefore the role of nonculprit vessel angioplasty or complete revascularization in the setting of cardiogenic shock is not shown to be definitely beneficial in the only randomized trial done in this area till date. Hence the treatment needs to be strategized patient to patient. Complete revascularization may turn out to be beneficial in subgroup of young patients (age <50 years) with AMI. Result was neutral in female patients, diabetics, and anterior location of STEMI.

Technical possibility of better outcome can be expected if:

- The nonculprit lesions are critical but type A, short, proximal coronary lesions of major arteries and can be opened up easily without much additional time or contrast load
- Can be performed by experienced operators, avoiding prolonged ischemia to non-CV by complications like slow-flow, dissection, wedging by guide catheter, etc
- If required circulatory support is available and instituted in time.

Role of Fractional Flow Reserve in STEMI Patients with MVCAD

Fractional flow reserve use during ACS is controversial, and is because of important prerequisite for use of FFR of “maximal hyperemia”. Patients with ACS will have blunted response to adenosine; hence the optimal hyperemia may not be achieved effectively leading to FFR value being falsely negative.

Fractional Flow Reserve in Culprit Vessel

Fractional flow reserve may be of use in cases where deferred stenting of CV is planned, which is not a commonly used strategy of managing AMI. In fact the expert consensus

statement of SCAI by Lofti A et al. said that FFR should not be performed in the culprit lesions in patients with ACS.¹⁸

Fractional Flow Reserve in Nonculprit Lesions

The Compare-acute trial¹⁹ included 885 patients with STEMI to undergo complete revascularization of nonculprit lesion or no revascularization after primary angioplasty in a 1:2 ratio. FFR was done in both groups and the cut-off point for PCI was FFR value of less than or equal to 0.80 in revascularization group. The primary composite end point of death from any cause, nonfatal MI, revascularization, and cerebrovascular events at 12 months occurred less frequently in the complete revascularization group than in the CVO group (7.8% vs. 20.5%). This difference was primarily driven by reduction in repeat revascularization. In most cases, revascularization took place during the index procedure as compared to DANAMI-3-PRIMULTI trial, where FFR was done in staged procedure and it also showed improved outcome at 12-month in patients who underwent FFR-guided PCI of nonculprit lesion. So, results from these two trials suggest superior outcomes of FFR-guided nonculprit vessel angioplasty in a strategy of complete revascularization in AMI compared to angiographically guided revascularization.

Post-PCI Fractional Flow Reserve

Post-PCI FFR can be improved by postdilatation and by implanting additional stents, if the value is low after stenting. Studies have shown obtaining final FFR values of more than 0.91 had a significantly lower adverse event rate compared with a final FFR of less than or equal to 0.91 (19% vs. 30%; $p = 0.03$).²⁰

CONCLUSION

Patients with MVCAD in STEMI have higher risk for future morbidity and mortality mainly because of repeat MI or need for revascularization of nonculprit lesions. Evidence from randomized trials have shown that complete revascularization is better in terms of reduction in MACE than the CVO revascularization, but the difference is mainly driven by the need for repeat revascularization in non-CV, and not by death or MI. Among complete vessel revascularization groups, the staged PCI before hospital discharge seems to have better short- and long-term mortality benefit when compared to complete revascularization during index procedure. The recent culprit shock trial questioned the role of complete revascularization in cardiogenic shock during index PCI. FFR-guided complete revascularization has shown to be beneficial when strategy of complete revascularization is adopted, avoiding unwanted PCI. There are number of ongoing trials that are going to address this question in further detail. The ASSIST-MI trial be assessing infarct size by cardiac magnetic resonance imaging (MRI) to evaluate strategy of MVPCI versus culprit vessel only approach. The COMPLETE study will assess culprit only versus staged PCI with FFR

in 3,900 patients. The CROSS-AMI study will be evaluating staged PCI versus ischemia-guided strategy in 400 patients.

Improving Outcomes of Primary Percutaneous Coronary Intervention: Technical Aspects

Ambukeshwar Singh, Ayush Shukla, Nakul Sinha

INTRODUCTION

Coronary artery disease (CAD) is one of the most common noncommunicable diseases in our country causing significant mortality and morbidity. Acute ST-segment elevation myocardial infarction (STEMI) is a common presentation of CAD resulting in high morbidity and mortality. Timely reperfusion therapy has proven to be the best therapeutic option for the management of STEMI.¹ Primary percutaneous coronary intervention (PCI) is the most effective and predictable form of reperfusion therapy with low complication rate in comparison to thrombolysis with different agents.² According to the American College of Cardiology/American Heart Association (ACC/AHA) and the European Society of Cardiology (ESC) guidelines, primary PCI for management of STEMI is class IA indication within 12 hours of initiation of myocardial infarction (MI) and also highly effective between 12–24 hours if there is clinical and/or electrocardiography (ECG) evidence of ongoing ischemia. In case thrombolysis is contraindicated, it should be offered irrespective of time delay after the onset of MI.^{3,4} Worldwide figures indicate a 3–5% mortality at 30 days, 2.5% reinfarction, and 1% stroke after primary PCI.²

PREHOSPITAL OR PATIENT PREPARATION

Early diagnosis of STEMI and early reperfusion of the culprit vessel by primary PCI is the central concept of STEMI management and the best method of achieving its benefits. For achieving this goal, certain practical points and protocols have demonstrated universal ability. Early transportation of a patient to a cath laboratory-enabled center is one of the important steps. An 8 years follow-up study found a significant mortality benefit with primary (direct) transportation of patient to a cardiac center versus secondary transportation from another hospital.⁵ This should be accompanied by a prior information with (preferably)

electronic transfer of relevant parameters, preparedness of the on-call team with a ready cath laboratory, quick part and patient preparation, monitoring of relevant parameters, and a screening Echo to rule out any surprises being some of the essential components. Modifications depending on local prevailing facilities and conditions are preferable keeping in view the primary goal of offering an early revascularization. It is preferable that all the team members are assigned a fixed role to not only make things more efficient but also not to miss any important step. A designated team leader should assume the overall responsibility of supervising the preparations.

We will now attempt to outline only those current technical concepts and practices which are believed or have been shown to exert a positive (either direct or indirect) impact on the short and long-term outcome of primary angioplasty. There are many other equally important ancillary measures which will have to be judiciously employed depending on the clinical condition of the patient and are directed more toward stabilizing the patient's condition so that he/she can withstand the procedure better.

LOADING DOSE

The loading doses of antiplatelets should be given as early as possible after the diagnosis of STEMI is established. According to latest ESC and ACC guidelines, ticagrelor 180 mg or prasugrel 60 mg is the preferred antiplatelet agents after ruling out absolute contraindications. In case of nonavailability of these agents, use of clopidogrel must not be delayed. If there is a possibility of delay due to any reason, parenteral anticoagulant (enoxaparin) should be given. The role of cangrelor IV is under investigation.

Many trials have indicated a positive effect of preloading with high dose statins before PCI for ACS showing some benefit in recurrent MI, angina, and mortality along with thrombolysis in myocardial infarction (TIMI) and TIMI myocardial perfusion (TMP) scores.⁶

ROLE OF COUNSELING

While the patient is being prepared, a physician may be available to converse and explain to the family members regarding the disease, present condition of patient, along with relevant information regarding primary angioplasty including risks and benefit involved in the procedure. This is likely to make the family and attendants understand and appreciate better about the procedural risks and benefits and help in endorsing the decision immediately after the findings of angiography are communicated to them. This effort may primarily be seen as a time-saving measure to speed-up the process of revascularization.

ANGIOGRAPHY

Access Site

In the RIVAL (RadIal Vs femorAL access for coronary intervention) study STEMI subgroup and RIFLE-STEACS (Radial versus Femoral randomizEd investigation in ST-Elevation Acute Coronary Syndrome) trial, transradial approach was not only associated with a significant reduction of primary end point (death/MI/stroke), but also mortality in primary PCI.^{7,8} The STEMI-RADIAL (ST-Elevation Myocardial Infarction treated by RADIAL or femoral approach) trial showed that transradial approach resulted in significant reduction in major bleeding compared to transfemoral approach but at the cost of significant increase in access site crossover with transradial approach.⁹ If there is more than 3–5 minutes delay in getting transradial access or catheter passage due to spasm or an anomaly, it is better to crossover to transfemoral route. If there is indication of temporary pacing or one is suspecting bradyarrhythmia during procedure, transfemoral venous access should preferably be taken. Sometimes left radial artery can be easily cannulated and the intervention done smoothly with only minor positional adjustments.

Catheter Selection

In case of transradial access, tiger catheter is preferred one. Minimum but adequate numbers of angiographic view with use of lesser amount of dye or contrast is the foremost important precaution to be taken. In transfemoral access, nonculprit vessel maybe imaged first followed by culprit vessel directly with a guiding catheter. This usually avoids time delay in cath laboratory, all types and all sizes of catheters must be available, and in case of difficulty in engagement of vessel ostia, we should shift to another type of catheter instead of wasting time. A guiding catheter with good support and backup characteristics should be preferred mostly depending on the primary operator choice. Wider internal diameter catheters are usually more helpful in case thrombosuction, larger stents or a bifurcation strategy is required. Sheathless catheters having a smaller external but comparable internal diameter, can provide a viable solution in females, shorter patients or thinner radials.

Wiring

As most of the time culprit artery is totally occluded with thrombus with no antegrade flow, a soft tip wire with low tip load should be used, at least initially. After crossing the proximal portion of culprit artery, one should take an angiogram, as most of the time there is some antegrade trickling of dye which help in localizing the subsequent course of artery and negotiation of the wire.

Sex Differences

Generally all the large studies have shown a less favorable outcome for females versus males in primary PCI results. A recent pooled analysis, together with a German and European registry all bear testimony to this trend¹⁰⁻¹² This is probably a worldwide phenomenon, though more apparent in Indian conditions and is mostly related to low awareness, late recognition and more hesitation, indecision or inability to seek specialized treatment for acute myocardial infarction (AMI) in case of females with more subsequent delays coupled with economic factors.

Complete versus Culprit

Vessel Only Revascularization

This has been a subject of much thought and debate recently specially highlighted by the PRAMI (PReventive angioplasty in Acute Myocardial Infarction) trial results,¹³ though its design and conductance had been called in question. The COMPARE-ACUTE (FFR guided primary multivessel PCI to improve guideline indexed actual standard of care) trial¹⁴ which compared a culprit only strategy with a fractional flow reserve (FFR)-guided complete revascularization, showed similar mortality but, expectedly a lower subsequent intervention rate in the latter group. A meta-analysis of six studies favored the group with staged revascularization of nonculprit lesions with a significantly decreased mortality.¹⁵ However, the final word is still pending and possibly this aspect will still generate debate with personal and operator preferences also influencing the decision, of course influenced by the patients overall condition and tolerance of the culprit vessel revascularization which has to be done first. Another reasonable strategy advocates revascularization of nonculprit significant lesions before discharge.

Sometimes identification or recognition of the culprit vessel can be a matter of concern especially between left circumflex coronary artery (LCX) and right coronary artery (RCA). If the lesion morphology and ECG evidences are not very helpful, it is better to do both rather than spend valuable time in solving the issue.

Occasionally once the primary, proximal culprit lesion has been opened one encounters a distal chronic total occlusion (CTO) with a sizeable and good size distal vessel filling retrogradely. It is judicious to only do the culprit lesion, beyond a short attempt at probing the CTO, since otherwise the time, contrast load, and other factors may adversely affect the result of the primary PCI.

Predilatation

A strategy of “quick in-quick out” is probably the best in primary PCI as it also saves time and time is muscle. The benefits of direct stenting include reduced procedure time, quick restoration of antegrade flow, less thrombus fragmentation, and/or distal displacement and thus reduced chances of slow flow/no-reflow. Having said that it is also of utmost importance that the final result of angioplasty be at least optimal if not perfect. After wiring through the occluded artery, if antegrade flow is inadequate in even outlining the distal vessel, a strategy of uninflated (but perhaps at a neutral pressure) balloon passage can be helpful by partially displacing the thrombus distally and permitting distal assessment of the vessel health. However, this can be offset by attempt at direct stenting which if successful can perhaps contain the thrombus better between the stent struts and the vessel walls with minimal displacement. Data from the EUROTRANSFER registry suggest that when anatomically and technically feasible, the use of direct stenting techniques may result in improved long-term survival in patients with STEMI undergoing primary PCI.¹⁶ If even after a balloon passage, the flow does not improve and the operator believes that the lesion is an acute-on-chronic one, a short predilatation with a semicompliant balloon at low-to-moderate pressures may be necessary.

Postdilatation

Observational studies indicate that stent postdilatation does not seem to have any detrimental effects on patients' final angiographic results and long-term clinical outcomes. However, the option is left on the operator if he/she feels that the stent is under expanded. Slow flow/no-reflow may be induced by postdilatation at high pressures. In a study by Tasal et al., 405 patients were retrospectively evaluated, and it was found that postdilatation did not adversely affect the final angiographic parameters, and seemed to decrease the probability of stent thrombosis and target vessel revascularization (TVR).¹⁷ In another recent study by Soylu K et al., 124 patients were randomized to routine or no post dilatation during primary PCI with the former strategy being found to be associated with an increased risk of slow flow or no reflow in patients without angiographic stent expansion problems.¹⁸

Adjunctive Medications

The prehospital routine upstream use of glycoprotein (GP) IIb/IIIa inhibitors before primary PCI has not been demonstrated to offer any benefit and possibly increases the bleeding risk.¹⁹ Using GP IIb/IIIa inhibitors as bailout therapy in the event of angiographic evidence of a large thrombus, slow- or no-reflow, and other thrombotic complications is reasonable, although this strategy has not (and can possibly never be) been tested in a randomized trial.

Overall, at the present moment, there is no evidence to recommend the routine use of GP IIb/IIIa inhibitors for primary PCI. The intracoronary administration of GP IIb/IIIa inhibitors is also not superior to its IV use.²⁰

SLOW FLOW OR NO REFLOW

“Slow flow” and “no flow” represent differing degrees of the same phenomenon where a decrease in antegrade epicardial flow is there in the absence of a mechanical occlusion mostly due to distal microembolization and sludging. Certain drugs used by intracoronary route have been shown to reduce and perhaps reverse this phenomenon, but sometimes it can be extremely troublesome. Prevention is invariably a better option. Nicorandil has been used as an intravenous infusion for 24 hours after primary PCI to prevent slow flow. Adenosine has a role in prevention and treatment both. If it still happens during the procedure, the following drugs may prove to be helpful—adenosine 10–120 µg bolus, verapamil 100–200 µg bolus, or nitroprusside 50–200 µg; maximum up to 1,000 µg. However, there is no fixed protocol or sequence which has been found to be consistently helpful.

Cardiogenic Shock

Different trials have mostly indicated that in hemodynamically stable patients, complete revascularization of physiologically significant lesions may be beneficial in preventing progression of impending shock, but in unstable patients this strategy is likely to cause more harm. Thus, presently only culprit vessel revascularization, in the presence of cardiogenic shock, is the accepted strategy.^{21,22}

Timing of initiation of Impella device has also evoked some interest, with a registry data favoring early pre-PCI use of Impella in such situations with demonstration of a significant early survival benefit.²³

Thrombosuction

Since DeWoods landmark demonstration of thrombus being the primary culprit in the majority of AMIs, thrombus management has been at the core of interventional practices in AMI. A major limitation of primary PCI is the possibility of distal embolization of thrombus and failure to restore flow at the microvascular level even after creating a viable lumen in the artery. Indirect measures of microvascular tissue perfusion, such as the degree of ST-segment resolution or angiographic myocardial blush grade, have been shown to correlate with probability of death after primary PCI. Removal of thrombus by manual thrombectomy before stent deployment has the potential of reducing distal embolization and improving microvascular perfusion. The thrombus aspiration during PCI in AMI TAPAS (The Thrombus Aspiration during PCI in AMI Study) study showed improved myocardial blush grade (primary outcome) and lower mortality with thrombectomy.²⁴ Practice guidelines were subsequently altered to recommend routine manual thrombectomy. As a result, thrombectomy became a part of clinical practice and its use grew very rapidly. Subsequently meta-analyses²⁵ suggested that routine thrombosuction might increase the risk of stroke, but this finding was cautiously interpreted because it was based on a small number of events. Later, the thrombus aspiration in ST elevation myocardial infarction

in Scandinavia (TASTE)²⁶ trial showed no reduction in mortality at 30 days up to 1 year with routine thrombectomy. Although updated meta-analyses of thrombectomy that included the TASTE trial continued to suggest that a modest but clinically important benefit is possible, the efficacy of this procedure presently remains uncertain. In TOTAL trial²⁷ a strategy of routine manual thrombectomy during primary PCI did not reduce the risk of the primary outcome of cardiovascular death, recurrent MI, shock or heart failure within 6 months as compared with strategy of PCI alone with thrombectomy only permitted as a bailout. Stroke rates were higher in patients who had undergone routine thrombectomy than in those who underwent PCI only. After the results of TOTAL trial, ACC/AHA focused update 2015 has classified routine manual aspiration thrombectomy during primary PCI as a class III indication and class IIb for selective and bailout procedures. A recent meta-analysis of all the three major trials (TAPAS, TASTE, TOTAL)²⁸ found no difference in major end points. However, in a subgroup of patients with high thrombus burden, thrombus aspiration was associated with a slight reduction in CV mortality (2.5% vs. 3.1%, CI 0.65–0.98; $p = 0.03$) but with an increase in stroke or transient ischemic attack (TIA). Perhaps, in the near future improved thrombus detection and characterization techniques (not all TIMI 0 flow are large thrombus—there can be significant underlying lesions also), better patient selection, and improved hardware can show us the correct way in different patients.

Choice of Stent

The central principle remains same as for conventional angioplasty—A drug-eluting stent (DES) is almost always better than a bare-metal stent (BMS). In a large-network meta-analysis of trials assessing the safety and efficacy of DES versus BMS in the setting of STEMI, Palmerini and colleagues found significantly lower rates of cardiac death or MI and stent thrombosis in cobalt-chromium-based everolimus eluting stents (CoCr-EES) compared with both BMS and first-generation DES. Nearly all DES types also carried lower 1-year TVR rates than BMS. The authors concluded that DES were superior to BMS in STEMI patients, with lower rates of MACE and improved efficacy seen at as little as 30 days from the index procedure and maintained for up to 2 years.²⁹

In a pooled subgroup analysis from three randomised trials [the Intracoronary Stenting and Angiographic Results: test efficacy of 3 limus-eluting stents (ISAR TEST) 3, ISAR TEST 4 and Limus Eluted from A Durable versus ERodable Stent coating (LEADERS)] comparing outcomes in patients with acute MI between biodegradable polymer (BP) DESs (Yukon or Biomatrix) and durable polymer (DP) DESs (Cypher) at 4 years, MACE was significantly reduced with BP DES stents [hazard ratio (HR) 0.59, 95% confidence interval (CI) 0.39–0.90; $p = 0.01$]. Trends toward reduction were also seen for cardiac death and MI, and definite or probable stent thrombosis (3.6% vs. 7.1%, HR 0.49, 95% CI 0.22–1.11; $p = 0.09$). Thus biodegradable polymer DESs demonstrated a reduction in clinically indicated target lesion revascularization and very

late definite stent thrombosis up to 4 years in comparison to durable polymer DES, an effect which is likely to be potentially magnified in patients with STEMI.³⁰

Another concept that held a brief promise, during evolution of primary PCI was use of MGuard stent—a balloon expandable BMS (stainless steel-strut width-100 μm) along with a protection net (mesh sleeve fibres of 20 μm polyethylene terephthalate) with a net aperture size of 150 \times 180 μm . The belief was that it would be effective in minimizing distal embolization. However, its use was associated with some limitations like deliverability related to a higher crossing profile, a possible compromise of side branches due to its double-layer design, and a higher restenosis rates.

The MGuard stent can rarely also be used in vein grafts causing AMI when conventional PCI with distal protection devices is not feasible, as well as to seal coronary perforations that persist despite prolonged balloon inflation.

DEFERRED STENTING

The concept of deferred stent implantation even after restoration of near normal epicardial flow by a minimalist immediate mechanical intervention (MIMI) for STEMI management was proposed for the first time by Isaaz et al.³¹ Subsequent observational studies suggested that deferred stenting could have higher procedural success, and better 6-month ejection fraction together with lower rates of adverse events compared to immediate stenting. However, according to a recent comparative meta-analysis, a deferred-stenting strategy did not reduce the occurrence of no or slow reflow, death, MI, or repeat revascularization compared with immediate stenting in patients with STEMI but showed an improved LV function in the long term.³² In DANAMI-3-DEFER study, deferred stenting (48 hours after the index procedure) had no effect on the primary clinical outcome. Routine deferred stenting was associated with a higher need for TVR.³³ Based on these findings, routine use of deferred stenting is not recommended at present and we suggest reserving this strategy only for those patients where there is a large residual visible thrombus and near TIMI III flow has been achieved.

CONCLUSION

The primary goal of any medical treatment in medical science is to relieve symptoms and prolong life—these are very admirably, quickly, and reliably achieved by performing a primary PCI in a patient with a STEMI, with a good end result in terms of vessel patency (both acute and chronic) and achieving TIMI 3 flow with TMP grade 3. The balance of speed, logistics, technique, and maturity is perhaps tested to the utmost during this procedure. A judicious combination of these qualities based on sound and up-to-date knowledge and current concepts defines a wise interventionalist likely to deliver the goods most of the time. Achieving a cosmetically good result may sometimes be compromised for safety and settling for a cosmetically adequate but a functionally good

and safe result. Our first responsibility and endeavor should be to help the patient with minimal possibility of harm rather than satisfy our technical egos in pursuit of perfection.

Late Presenters with STEMI: Which is the Best Strategy?

Soumitra Kumar

INTRODUCTION

Any patient presenting 24 hours after onset of chest pain secondary to ST-elevation myocardial infarction (STEMI) represents a failure of the prevailing STEMI care system. The “total ischemic time” (symptom onset to initiation of reperfusion therapy) has two components: (1) patient delay and (2) system delay (including first medical contact to diagnosis and diagnosis to initiation of reperfusion therapy). The mean “total ischemic time” in Kerala Acute Coronary Syndrome (ACS) Registry¹ was 5 hours. When a patient presents as late as 24 hours after onset of symptoms, patient-related delay accounts for the main reason of delay and system-related delay becomes relatively insignificant. Proportion of latecomers (>12 h) is significant even in data from the west: 12% in GRACE (the Global Registry of Acute Coronary Events) study² and as high as 40% in the TETAMI (Treatment of Acute ST-Segment Elevation Myocardial Infarction Patients Ineligible for Reperfusion) study.³ In an Indian study⁴ done from Uttar Pradesh, India, 32.3% patients with STEMI presented after 24 hours.

Major benefit of revascularization of the infarct-related artery (IRA) is when the time from the onset of symptoms is less than 12 hours (Fig. 1). In the TETAMI Registry, 30 days mortality was only 4.4% in patients who received reperfusion therapy, but 12% in patients who did not receive it. Triple end point of death, myocardial reinfarction or recurrent angina occurred in only 11% of patients who were reperfused versus in 19.1% of patient who were not reperfused. In the ACOS registry, in-hospital mortality was 14% among nonreperfused patients compared to only 6.3% among reperfused patients.⁵

RISK STRATIFICATION IN LATECOMERS AFTER STEMI

- Clinical:* In the presence of hemodynamic or electrical instability and/or if patient continues to experience symptoms, a reperfusion-based strategy using percutaneous coronary intervention (PCI) is recommended and

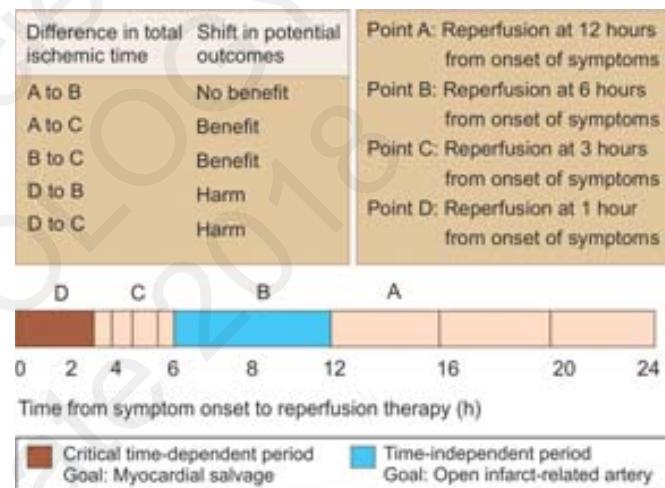

FIG. 1: Relationship of outcome and myocardial salvage as a function of total ischemic time.

endorsed by the current guidelines [American College of Cardiology/American Heart Association/The Society for Cardiovascular Angiography and Interventions (ACC/AHA/SCAI) and European Society of Cardiology/European Association for Cardio-Thoracic Surgery (ESC/EACTS)]^{6,7}

- Electrocardiography (ECG):* Predictive value of negative T wave as a marker of reperfusion is strong. When T waves are positive, probability of occluded IRA is high. Negative T waves in “early” latecomers can thus push invasive strategy with the expectation to salvage the greatest amount of residual ischemic myocardium⁸
- Angiographic:* Patency of IRA is important determinant of quantum of salvage by PCI independent of its timing. In their pivotal studies, Reimer and Jennings⁹ emphasized by their work in a dog model that reperfusion must be established within the first 3 hours of onset of symptoms to achieve significant myocardial salvage. However, there exists an important yet unrecognized interplay between

time to reperfusion and presence of residual coronary flow within the area at risk. Beyond 4 hours of symptoms, significant salvage only occurred in the presence of well-developed collateral vessels or preserved antegrade flow in the IRA. The time-related transmural progression of infarction is greater in patients with no residual flow in the myocardium in jeopardy and presence of collateral flow or antegrade flow in the IRA can indeed increase the time-window for perfusion in humans¹⁰

- *Left ventricular (LV) systolic function:* Among patients with STEMI, adverse events are markedly increased in those with LV ejection fraction (LVEF) less than 40% even when undergoing primary PCI;¹¹ however, given the prospect of myocardial salvage, these high-risk patients stand to accrue substantial clinical benefits from the procedure as well
- *Stress testing:* Exercise testing is useful in assessing exercise capacity, identifying persistent ischemia, and risk stratification for future cardiac events. Submaximal testing may be done in asymptomatic patients after 3–5 days and symptom-limited testing may be done in the same subset of patients after 5 days

The DANAMI-1 (DANish trial in Acute Myocardial Infarction)¹² and SWISS (Swiss Interventional Study on Silent Ischemia)¹³ trials have demonstrated beneficial effects of PCI performed late after myocardial infarction (MI) in patients with persistent ischemia on stress testing. The INSPIRE (Investigating New Standards for Prophylaxis in Reducing Exacerbations) trial¹⁴ assessed use of myocardial perfusion imaging for defining initial patient risk and in guiding role of intensive medical therapy versus coronary revascularization for reducing the total LV perfusion defect and extent of scintigraphic ischemia on single photon emission computed tomography (SPECT) imaging. Myocardial perfusion positron emission tomography (PET) provides an option for patient groups who may be more difficult to image with SPECT myocardial perfusion imaging (MPI), including obese patients, women, patients with previous nondiagnostic tests, and patients with poor LV function attributable to coronary artery disease (CAD) considered for revascularization

- *Myocardial viability:* In the VIAMI (Viability-Guided Angioplasty After Acute Myocardial Infarction) trial,¹⁵ patients not treated with primary or rescue PCI but otherwise in the non-high-risk category were subjected to either invasive (PCI) or a conservative (ischemia-guided) strategy if the infarct area was proven to be viable. Benefit in terms of composite end points of death, MI or unstable angina is seen at follow-up of 1 year and at long-term follow-up of median 8 years with initial in-hospital invasive strategy. The same investigators also reported in a substudy of the trial on the influence of viability and revascularization on LV remodeling. Viability early after acute myocardial infarction (AMI) is associated with improvement in LV function after revascularization. When viable myocardium is not revascularized, the LV tends to remodel with increased LV volumes, without

improvement of EF. Absence of viability results in ventricular dilatation and deterioration of LVEF, irrespective of revascularization status.

Various modalities which can be utilized to assess myocardial viability are thallium-201 or technetium-99m, SPECT, fluorodeoxyglucose (FDG)-PET, dobutamine stress ECHO, dobutamine stress cardiac MRI, and contrast-enhanced MRI.

REPERFUSION PCI IN LATECOMERS WITH STEMI

Open Artery Hypothesis

This hypothesis was first proposed by Eugene Braunwald in 1989 when he noted that patients with spontaneous recanalization of the IRA had fewer adverse events during following weeks and months. These effects are not likely to be attributable to small benefits in infarct salvage and probably arise from limitation of infarct expansion, reduction of LV remodeling development, scaffolding effect of reperfused vessel, a conduit for collateral vessel, improvement of blood supply to hibernating myocardium, increased infarct wound healing, development of contraction band necrosis rather than coagulation necrosis in infarcted myocardium, reduction of myocardial apoptosis, increased baroreceptor sensitivity and vagal activity and reduced ventricular arrhythmia. These mechanisms extended the time window of ischemia to 12 hours and possibly 24 hours after onset of AMI. However, the period after 24 hours of onset of AMI is more challenging. On the basis of OAT (The Occluded Artery Trial) study,¹⁶ routine PCI 3 days to weeks after AMI is not recommended for persistently occluded IRA in asymptomatic high-risk patients, since higher reinfarction rates were seen in the PCI group and yet, no difference were seen between PCI and conservative groups in terms of event-free survival after median follow-up of 3.2 years or LV systolic function at 1 year. Subsequently, Abbate et al.¹⁷ performed a meta-analysis and systematic review of randomized trials (total of 3,560 patients from OAT, SWISS III and several other small studies (Table 1) comparing late PCI (defined as >12 hours from symptom onset) with medical therapy in hemodynamically stable patients with primary end point of survival. PCI was associated with an overall improvement in survival with an odds ratio of 0.49 [95% confidence interval (CI): 0.26–0.94]. In addition, a greater improvement in cardiac function was observed over time in patients assigned to PCI than medically managed patients supporting the concept that late revascularization may reverse adverse cardiac remodeling over longer-term.

Based on these trial results, it is also reasonable to expect that those with a totally occluded IRA on initial diagnostic angiogram are less likely to see a survival benefit from late revascularization than those with subtotal occlusions, unless there are other high-risk features, such as inducible ischemia or significant viability. It is likely that patients with subtotal occlusions are more likely than those with total occlusions to have ongoing ischemia, which can predispose to further cell death. Late reperfusion probably beneficially interrupts this process and reduces the extent of adverse remodeling

TABLE 1: Randomized clinical studies of late perfusion more than 24 hours after onset of acute myocardial infarction

Study	No. of patients rep.: +/–	Method for rep	Time to rep	Sustained patency rep. +/–	Overall outcome
Topol et al. TAMI-6	71, 34/37	tPA+/-PTCA	12–48 h	60%/38% at 6 months	Negative (modality, LV volume, LV systolic function at 6 months)
Dzavik et al. TOMIIS	44, 25/19	PTCA	5–42 days; mean 21 days	43%/19% at 4 months	Negative (clinical outcomes, LV size and EF at 4 months); positive in the subset (LVEF at 4 months)
Horie et al.	83, 44/39	PTCA	>24 h	96%/13% at 6 months	Positive (LV volume at 6 months; death, recurrent MI, congestive heart failure at 50 months)
Yousef et al. TOAT	66, 32/34	Stenting	3 days–6 weeks; mean, 26 days	91%/19% at 12 months	Greater LV dilation but improved exercise tolerance and QoL with reperfusion at 12 months
Steg et al. DECOPI	212, 109/103	Stenting	2–15 days	83%/34% at 6 months	Improved LVEF but no difference in clinical outcomes at 2 years
Hochman et al.	2166, 1082/1084	Stenting	3–28 days; median, 8 days	–	Negative (event-free survival at 4 years) trend toward higher reinfarction rates in reperfusion
Davik et al.	381, 150/136	Stenting	3–28 days; median, 10 days	83%/25% at 1 year	Negative (LVEF at 4 years); trend toward less LV dilation in reperfusion

LVEF, left ventricular ejection fraction; MI, myocardial infarction; PTCA, percutaneous transluminal coronary angioplasty; tPA, tissue plasminogen activator; LV, left ventricular; QoL, quality of life; rep, reperfusion.

occurring in this setting. The BRAVE-2 (The Beyond 12 hours Reperfusion Alternative Evaluation) study¹⁸ enrolled STEMI patients between 12 and 48 hours and SPECT study at a median of 7.1 days showed a statistically significant reduction in final infarct size in those assigned to the invasive strategy. Thus, “not so latecomers” (12–48 hours) may stand to gain through reperfusion of hibernating myocardium in peri-infarct region. Busk et al.¹⁹ compared infarct size and myocardial salvage after primary angioplasty in patients presenting with symptoms less than 12 h versus 12–72 hours. Final infarct size in late presents (>12 h) was larger than in early presenters (<12 h) after primary angioplasty for STEMI. However, they concluded that substantial myocardial salvage could be obtained beyond 12 hours limit, even when the infarct-related artery was totally occluded.

Challenges of Late Revascularization

- Success rates as defined by residual diameter stenosis less than 20%; epicardial TIMI-3 grade flow do not exceed 85–90%. Ongoing microvascular damage also interferes with TIMI-3 perfusion grades
- Total occlusion of an IRA is commonly associated with a significant thrombotic burden. The thrombus is at least partially organized and thus mechanically more resistant to guidewire recanalization
- However, paradoxically, periprocedural complications occur only in a minority of patients with adverse coronary lesion features (e.g., unprotected left main lesion, true bifurcation disease, and severe calcification) or heavy thrombus burden
- When thrombus is angiographically evident, aggressive antithrombotic therapy and mechanical thrombectomy prior to stent implantation may be helpful in minimizing distal embolization and recurrent MI

- Remaining interventional strategy, e.g., choice of bare-metal versus drug-eluting stents, use of debulking or imaging [intravascular ultrasound (IVUS) or optical coherence tomography (OCT)], short- versus long-term dual antiplatelet therapy, should be decided on a case-by-case basis.

Overall, rationale and current guidelines for reperfusion with PCI for latecomers with STEMI has been summarized in boxes 1 and 2.

NONREPERFUSION OPTIONS FOR LATE PRESENTERS WITH STEMI

Antithrombotic Therapy

- Oral acetylsalicylic acid (ASA):* Current guidelines for treatment of STEMI in patients with platelet counts in the normal range recommend that ASA (aspirin) therapy is associated with relative risk reduction (RRR) in mortality rate of 20–25% irrespective of whether patients are receiving reperfusion therapies.¹⁹ True aspirin hypersensitivity remains an exception and use of ASA was not associated with more severe bleeding
- Thienopyridines:* The ACOS Registry⁵ reported that addition of clopidogrel to aspirin showed a reduction in major adverse cardiac and cerebrovascular events (death, nonfatal reinfarction and nonfatal stroke) in all subgroups of patients with STEMI including those who were not reperfused. The subgroup analysis of the COMMIT (Clopidogrel and Metoprolol in Myocardial Infarction Trial)²⁰ showed similar reduction of primary endpoints with clopidogrel irrespective of treatment with fibrinolytic agents (11% reduction with fibrinolytic therapy vs. 7% without)²¹

BOX 1**Rationale of reperfusion with percutaneous coronary intervention for latecomers (>24 h) with STEMI**

- The late open artery hypothesis is that coronary revascularization may yield clinically relevant benefit even when performed more than 12 h from symptom onset in a time-independent fashion. Proposed mechanisms for this include limitation of infarct expansion and remodeling through the influx of inflammatory cells and reduction in cellular degeneration through apoptosis
- Early support for this theory came from retrospective observation studies that found patency of the infarct-related artery (IRA) following thrombolytic therapy to be a favorable prognostic sign
- The BRAVE-2 study demonstrated that patients treated with an immediate invasive strategy within 12–48 h of acute myocardial infarction had reduced mortality at 4 years
- Patients with evidence of silent ischemia showed significant benefit from late PCI with a reduction in major adverse clinical events over a 10-year follow-up period in the Swiss Interventional Study on Silent Ischemia Type II study
- Myocardial viability may also be an important factor in determining who may benefit from late PCI based on early results from the Viability in Acute Myocardial Infarction trial
- Stable asymptomatic patients presenting more than 3 days from symptom onset who have total occlusion of the IRA and no evidence of severe silent ischemia showed no difference in overall mortality or major adverse clinical events in the Open Artery Trial
- Studies with higher event rates in the control arm have shown greater benefit from late PCI, suggesting that it is higher risk patients that have the most to gain from late revascularization
- Trials that enrolled patients with subtotal occlusion tended to show more benefit from PCI than those that only enrolled patients with total IRA occlusion, suggesting those with subtotal occlusions are more likely to have underlying viability and/or ischemia
- Busk et al. reported that substantial myocardial salvage can be obtained beyond the 12 h limit, even when the IRA is totally occluded
- A meta-analysis of randomized trials comparing late PCI to medical therapy demonstrated improved survival and greater improvement in cardiac function over time
- Late revascularization presents special challenges to the interventional cardiologist, requiring careful analysis of patient and angiographic variables to determine the most appropriate strategy
- Given the complexity and variety of possible factors in the spectrum of stable patients presenting late with acute myocardial infarction, we propose a patient-tailored approach and a management strategy based on the existing evidence

PCI, percutaneous coronary intervention.

- Glycoprotein IIb/IIIa receptor blockers:** The TETAMI randomized trial²² demonstrated that addition of tirofiban to either unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) did not provide additional benefit irrespective of the use of reperfusion. There are no data to support the use of intravenous glycoprotein IIb/IIIa inhibitors alone as an antiplatelet agent in the absence of reperfusion in STEMI

BOX 2**The European Society of Cardiology (ESC) 2017 STEMI guidelines²⁷**

- In patients with time from symptom-onset >12 h, a primary percutaneous coronary intervention (PCI) strategy is indicated in the presence of ongoing symptoms suggestive of ischemia, hemodynamic instability or life-threatening arrhythmias (class IC recommendation)
- A routine primary PCI strategy should be considered in patients presenting late (12–48 h) after symptom onset (class IIa B recommendation)
- In asymptomatic patients, routine PCI of an occluded IRA >48 h after onset of STEMI is not indicated (class IIIA recommendation)

- Unfractionated heparin:** Systematic overview by Collins et al.²³ revealed that in absence of aspirin, heparin therapy reduced mortality; however, in presence of aspirin, adding UFH reduced mortality and reinfarction but there was a significant excess of major bleeds (1% vs. 0.7%, $p < 0.001$)
- Low-molecular-weight heparin:** Available data suggest that compared with UFH, LMWHs given along with aspirin provide significant benefit in STEMI patients who present late or are ineligible for reperfusion therapy. Their use in these patients is supported by both current European and North American STEMI guidelines²⁴
- Fondaparinux:** In the subgroup of OASIS-6 trial,²⁵ in which patients did not receive reperfusion therapy, fondaparinux as compared to usual care (UFH infusion or placebo) significantly reduced the composite of death or myocardial reinfarction without increasing severe bleedings or strokes
- Parenteral direct thrombin inhibitor:** There are no data available on the role of direct thrombin inhibitors in STEMI with no-reperfusion therapy.

Nonantithrombotic Therapies

- Beta-blockers:** There is significant evidence of benefit with early use of beta-blockers in wide subset of STEMI patients without any contraindications. Benefits have been demonstrated for patients with and without concomitant fibrinolytic therapy and both early and late after STEMI
- Renin-angiotensin-aldosterone system inhibitors:** A large number of randomized clinical trials have assessed the role of angiotensin-converting enzyme inhibitors (ACEI) early in the course of acute MI. The SMILE (Survival of Myocardial Infarction Long-term Evaluation) trial²⁶ comprised only patients with anterior MI who had not received fibrinolytic therapy. Early use of an ACE inhibitor, zofenopril, in this trial conferred a trend of reduction in mortality in the first 6 weeks. These data support the role of ACEI with or without reperfusion therapy in STEMI
- Nitrates:** These are useful only in patients suffering from recurrent angina and should not be used if consequent hypotension limits the administration of beta-blockers or ACEI, who have significant prognostic benefits for STEMI patients

- Statins:** Early use of statins in ACS patients reduces both short- and long-term adverse outcomes.²⁰ However, recent statin trials were conducted in the setting of STEMI receiving reperfusion therapy.

CONCLUSION

- Late presenters of STEMI are well beyond the scope of conventional revascularization of IRA less than 12 hours after onset of STEMI and they have a higher incidence of death, myocardial reinfarction, and recurrent angina
- It should be remembered that delayed revascularization of IRA is fraught with lower success rate and benefits are also less certain
- Benefits of routine, i.e., nonischemia driven PCI of an angiographically significant stenosis in a patent infarct-related artery more than 24 hours after STEMI, are less well established but may have a survival benefit by virtue of improved cardiac function. Delayed PCI of a totally occluded infarct artery more than 48 hours after STEMI should not be undertaken in clinically stable patient without demonstrable evidence of ischemia or viability.

Acute Coronary Syndrome in Elderly

Surender Deora, Kewal C Goswami

INTRODUCTION

Aging is inevitable and irreversible demographic phenomenon. It not only affects the individual but also the whole society directly or indirectly. With the improvement in living conditions, better available healthcare facilities and declining fertility, there is demographic shift with more ageing population in the society. Cardiovascular disease (CVD) is the most common cause of morbidity and mortality in elderly and acute coronary syndrome (ACS) contributes to one-third of total deaths in United States.¹ In India also, CVD is the leading cause of death in 20.3% in men and 16.9% in women.² The definition of elderly varies with different countries and population. Most of the developed countries use the cutoff of 65 years for elderly but the United Nations has accepted the chronological age of 60 years as cutoff. In India, population age more than 60 years are categorized as elderly and according to population census 2011, there are 104 million elderly populations with 53 million females and 51 million males which is expected to increase three times to reach 300 million by 2050.³ The population of elderly in India is gradually increasing with 5.6% in 1961 which increased to 8.6% in 2011 and will be 20% of the total population in 2050. Most of the elderly population lives in rural area (~71%) as compared to 29% in urban area.⁴

The clinical presentation and management of ACS in elderly is challenging and is different as compared to younger patients. Advanced age itself is the most important risk factor for coronary heart disease and is an independent predictor of poor outcome. The mortality of ACS in elderly rises exponentially with age. Also there is paucity of data of ST-elevation myocardial infarction (STEMI) in the elderly population as they are underrepresented in majority of the clinical trials. In 593 published studies of ACS from 1996–2000, elderly individuals were only 6.7%.⁵ Even with newer trials like TRITON-TIMI 38 (Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition

with Prasugrel) and PLATO (Platelet Inhibition and Patient Outcomes) the representation of elderly population was 13% and 15%, respectively.^{6,7} The morbidity and mortality is high in elderly population as compared to younger population.⁸ The in hospital mortality is 2.1% in patients less than 55 years of age and it is increased to 26.3% in patients more than 85 years.⁹ Even the patients more than 80 years of age have double the mortality rate as compared to patients of 70 years.¹⁰ With the improvement in medical and invasive treatment, the mortality of ACS is declining but the burden of the disease is increasing as the elderly population is increasing because of the increased life expectancy. These elderly patients also may have the history of coronary artery disease in the young and are being treated previously either medically or by any invasive modality. Repeat ACS in these patients are more challenging because of extensive coronary artery disease and associated other organ diseases.

CHALLENGES IN ELDERLY

There are various factors which makes diagnosis and treatment in elderly population challenging. Usually the elderly patients have late presentation of STEMI because of various comorbid and socioeconomic factors. The symptoms are vague in nature and typical angina is less common.¹¹ The autonomic symptoms like dyspnea, nausea, vomiting, and syncope are more common.¹² Neurocognitive abnormalities are also frequently seen in this patient population which sometime makes the history taking and clinical examination difficult. The associated comorbid conditions like anemia, arthritis, hiatal hernia, abdominal discomfort, and renal dysfunction may mask the ischemic symptoms.¹³ More often these patients presents with heart failure. The interpretation of electrocardiogram may also be difficult because of the pre-existing conduction defects, pacing rhythm, left ventricular hypertrophy or previous myocardial infarction.¹⁴ Moreover, the elderly ACS patients usually present without significant

ST elevation because of more severe coronary involvement that may result in rich collateral network and ischemic preconditioning. The cardiac reserve is less and the chances of diastolic dysfunction are more. The coronaries are more diffusely diseased and calcified which makes the interventions more challenging and more prone for complications.^{15,16}

MANAGEMENT

The prognosis of ACS has improved significantly in the last two decades with evidence-based therapies. The benefit of more aggressive treatment in elderly is high as they are at the greatest risk of complications. The benefit of guideline-directed therapy has been seen in elderly patients with non-ST-elevation myocardial infarction (NSTEMI) with reduced in-hospital mortality.¹⁷ However, in real world clinical practice, the elderly are being treated more conservatively and even guideline-directed therapy not given because of fear of high risk of complications and therefore, has high mortality in spite of advancement in ACS management.^{18,19} The management of elderly ACS patients depends on ischemic burden of the disease. The approach to the elderly patients with STEMI should be individualized depending on comorbid conditions, ischemic burden, estimated life expectancy and patient choice. The patients with extensive ischemia need more aggressive therapies with antithrombin, antiplatelets and early percutaneous coronary intervention (PCI) and therefore should be risk stratified before initiating any treatment. There are no separate risk stratification score for elderly but the ACS validated score systems like TIMI risk score, GRACE (Global Registry of Acute Coronary Events) score can be used in elderly because age has been included as important predictor of survival and complication. Baseline functional status and frailty are also important predictors of bleeding, longer hospital stay, increased morbidity and mortality.^{20,21} The Gold Standards Framework (GSF) criteria may also help in deciding whether elderly ACS patient needs medical management or more aggressive invasive approach.²²

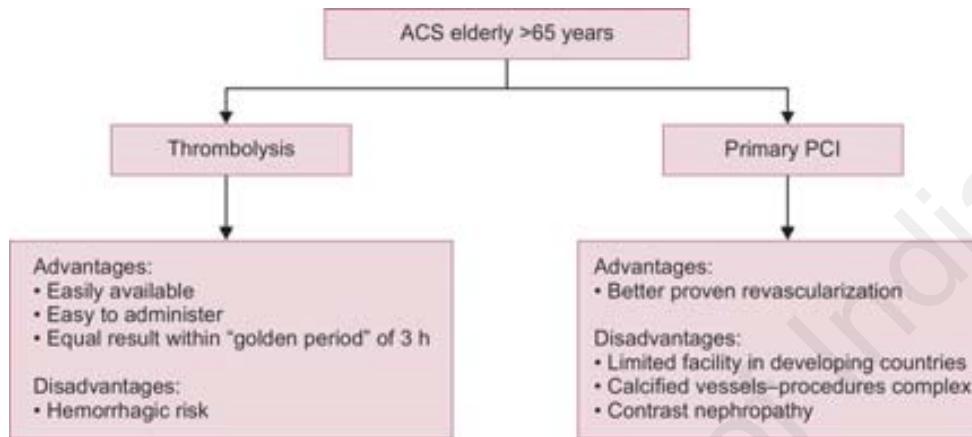

MEDICAL MANAGEMENT

The standard and goal of medical care remains same as in young population and is to save the myocardium as much as possible along with the symptom relief. Oxygen support, antiplatelets, statins, beta-blockers, and angiotensin-converting enzyme (ACE) inhibitors are indicated in the pharmacotherapy as in other ACS patients except if any contraindications are there. Thrombolytics are to be used in STEMI patients if the delay for primary PCI is more than expected time of 120 minutes. Elderly patients should not be denied fibrinolytic therapy although the risk of complications especially intracranial hemorrhage is more. But in real world scenario, the fibrinolytics are less commonly used in elderly. A study by Anderson et al. has shown that only 40% of the patients with STEMI aged between 75 and 84 years and only 20% above 85 years of age received fibrinolytic therapy.²³ The

choice of fibrinolytic therapy in elderly is not well defined. In the GUSTO I (Global Utilization of Streptokinase and TPA for Occluded coronary arteries) trial, the patients above 85 years of age fared better with streptokinase and but because of limited data the relative superiority cannot be proved.²⁴ Fibrin-specific agents like reteplase and tenecteplase are usually preferred and have relatively lower risk of bleeding as compared to streptokinase but are costly. An observational registry by Toleva et al. has shown the in-hospital death rate in the elderly with no reperfusion therapy was 20%, with primary PCI 13%, and with fibrinolysis 9%.²⁵ In their study, 30% of elderly patients with STEMI received no reperfusion as compared to 13% of the younger patients. Thus in conclusion, the outcomes of fibrinolysis in elderly population are excellent with the selective use of fibrinolytic agents.

Anticoagulants have been shown to decrease the mortality in ACS patients. In EXTRACT-TIMI 25 (the Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction treatment thrombolysis in myocardial infarction) study, the dose of enoxaparin in elderly more than 75 years of age was modified with no loading dose and maintenance dose of 0.75 mg/kg every 12 hourly.²⁶ There was no statistical difference in bleeding or hemorrhagic stroke was observed in elderly patients with age more than 75 years.

Antiplatelets should be given in all elderly patients with ACS. The loading dose of aspirin in elderly especially more than 75 years of age is 200 mg followed by 100 mg maintenance dose. Adjunctive antiplatelet like clopidogrel, prasugrel and ticagrelor should also be administered as per the indication similar to the young ACS patients but with caution especially in patients above 75 years of age. There are no specific studies in elderly patients with ACS for the antiplatelet but the data is from subgroup analysis of the other studies. The use of dual antiplatelet, i.e., adding clopidogrel to aspirin in CURE (Clopidogrel in Unstable Angina to Prevent Recurrent Events) study has shown benefit in reducing the primary end-point in NSTEMI patients. The subgroup analysis of CURE study in patients above 65 years of age has not shown any benefit in absolute or relative terms.²⁷ Prasugrel, a P2Y₁₂ receptor inhibitor is contraindicated in elderly population of more than 75 years and if weight is less than 60 kg. In TRITON-TIMI 38, there was no net benefit in elderly patients more than 75 years of age with ACS undergoing PCI and given 10 mg prasugrel because of increased risk of major bleeding and therefore suggested 5 mg in elderly patients. Similarly in PLATO trial of ticagrelor no net benefit was observed in elderly patients more than 75 years of age. Ticagrelor is an effective and more potent antiplatelet than clopidogrel but is costly which may be a limitation in old age patients especially in India and other developing countries. The American College of Cardiology (ACC)/American Heart Association (AHA) guideline is not clear on choice of second antiplatelet in elderly patients.²⁸ An ongoing study "POPular AGE" is an open label, multicenter trial in NSTEMI patients above 70 years of age randomized to either clopidogrel or more potent P2Y₁₂ inhibitor (prasugrel or ticagrelor).²⁹ The results

FLOWCHART 1: Advantages and disadvantages of thrombolysis versus primary percutaneous coronary intervention.

of this study may give some evidence in choosing second antiplatelet agent in ACS patients.

High-dose statins in elderly has been proved as effective and safe as in younger population. A subgroup analysis from PROVE IT-TIMI 22 (the Pravastatin or Atorvastatin Evaluation and Infection Therapy-Thrombolysis in Myocardial Infarction 22) has shown a greater reduction in adverse events and similar side effect in elderly who received high-dose statin regimen as compared to younger patients.³⁰ Beta-blockers are also relatively less frequently used in elderly. An observational study has shown that half of the elderly patients more than 65 years of age did not receive beta-blocker therapy. Patients with early beta-blockers therapy had lower in hospital mortality rate than who did not receive it.³¹ ACE inhibitors have been shown to reduce mortality at 1 year in elderly patients with STEMI.³² The patients with age 55–74 years, anterior STEMI and heart rate more than 80/min are the most to be benefited.³³

The side effect of polypharmacy is more in elderly. The adverse drug reaction increases with concurrent increase in the number of medication. With two medications it is 13% which increases to 38% with four medications and 82% with seven or more medications.³⁴ Therefore, in elderly selective medication according to guidelines should be used only and with caution.

THROMBOLYSIS VERSUS PRIMARY PERCUTANEOUS CORONARY INTERVENTION

Reperfusion therapies including fibrinolysis are indicated in elderly patients up to the age of 85 years.³⁵ The choice of preferred revascularization therapy by PCI or fibrinolysis does not depends on age but on many factors, e.g., time from presentation, door to balloon time, comorbid conditions, renal function and hemodynamic condition at the time of presentation (Flowchart 1).³⁶ The FRISC II (FRagmin and

Fast Revascularization during InStability in Coronary artery disease) study was the first to show the clinical benefit of invasive strategy in NSTEMI patients and the most of the benefit was in patients above 65 years of age although patients above 75 years of age were excluded.³⁷ Similarly, the benefit of invasive strategy was noted in TACTICS (Treat Angina with Aggrastat and Determine Cost of Therapy with an Invasive or Conservative Strategy) study with ACS patients above 65 years of age in reducing death, nonfatal myocardial infarction and rehospitalization at 6 months.³⁸ The transradial approach is preferred over femoral approach in elderly patients because less access site bleeding complications but with higher crossover to femoral approach.³⁹ The elderly ACS patients usually more often presents with NSTEMI and have complex multivessel disease and diabetes. This subset of patients is more often benefited by coronary artery bypass surgery as compared to PCI but with more prolonged hospital stay and post-surgical recovery.⁴⁰ But due to wide heterogeneity in elderly patients in terms of chronological age and biological age, each patient should be individualized for the choice of revascularization therapy. Patient should be counseled about the disease and its associated risk and prognosis, quality of life after revascularization and side effect of the medications especially need of dual antiplatelet post-PCI.

CARDIAC REHABILITATION

Elderly patients after ACS need special attention as they are vulnerable because of frailty, comorbid conditions, multiple medications and decreased neurocognitive abilities. There is increased risk of rehospitalization and death from cardiac and noncardiac causes and the mortality increases by 50% every 10-year after the age of 65 years.⁴¹ Patients should be discharged with clear advice for the compliance of medications and their schedule in local language, exercise and diet instructions and importance of cardiac rehabilitation. Lifestyle modifications, psychosocial support, and monitoring of risk factors are some of the components

of cardiac rehabilitation.⁴² Exercise training of elderly improves the sense of well-being, functional capacity, and cardiorespiratory efforts. Patients with strict compliance to medications and cardiac rehabilitation programs have less rehospitalization rates.

CONCLUSION

The morbidity and mortality in elderly population with ACS is high. The burden of the disease is increasing gradually as the elderly population is increasing with longer life expectancy. There is limited available data regarding the most effective way of management in elderly patients with ACS as they are underrepresented in major clinical trials. All elderly patients cannot be treated in the same way and treatment for each patient is to be individualized. Special attention has to be given to the associated comorbid conditions, ischemic burden and bleeding risk. Patients should be counseled for cardiac rehabilitation program to improve the quality of life post-ACS.

Right Ventricular Myocardial Infarction: An Update

Shishu Shankar Mishra, Biswaranjan Mishra

INTRODUCTION

Worldwide coronary artery disease (CAD) is a leading cause of morbidity and mortality. It is a huge health burden to the mankind and all nations in the contemporary time. A great amount of knowledge and research has accumulated on the left ventricular myocardial infarction (LVMI). Right ventricular (RV) involvement in myocardial infarction (MI) was first described in 1974.¹ RV myocardium receives blood supply from both right and left coronary arteries. RV wall is thinner compared to LV. Therefore, right ventricular myocardial infarctions (RVMIs) are relatively small and most of the myocardium remains viable. Subsequently, high rate of in-hospital mortality was seen to be associated with RVMI.²

DEFINITION

With a clinical background of MI, diagnosis of RVMI is made by the presence of elevation of the ST-segment more than equal to 1 mm in leads augmented vector right, V1, and/or in the right precordial leads V3R and V4R. It is recommended to record V3R and V4R seeking ST-segment elevation, to identify concomitant RVMI. Right-sided electrocardiography (ECG) is the most sensitive and specific, as ST elevation in V4R more than 1 mm has 100% sensitivity, 87% specificity, and 92% predictive accuracy.³

INCIDENCE

Isolated RVMI is rare, it is commonly associated with LVMI.⁴ In inferior wall MI (IWMI) and posterior MI of LV, the incidence of RVMI varies from 24 to 50%, out of which up to 50% are hemodynamically compromised. Compared to LVMI, RVMI is relatively rare. Lower incidence of RVMI is explained by its lower oxygen demand and increased supply. Relatively lower muscle mass and less workload keep the oxygen demand low, at the same time, coronary supply to RV muscles occurs in both systole and diastole along with more extensive collateralization which increases the supply. RV

myocardium also receives oxygen from inside the RV cavity by diffusion because of its thin wall.⁵

PATHOPHYSIOLOGY

The right coronary artery (RCA) primarily supplies the right ventricle. The first branch of RCA, conus artery, supplies blood to the RV outflow tract whereas the second branch supplies to the sinoatrial node. Then it courses in the atrioventricular (AV) groove giving off multiple small branches to anterior RV. RCA then divides into the acute marginal branch that runs anteriorly along the diaphragm, and the posterior descending artery (PDA) that runs posteriorly. In 90% of patients the PDA supplies the AV node; in the remaining 10% it receives blood from the left circumflex artery. PDA also supplies the inferior wall of both ventricles. PDA may arise from the left coronary circulation in 15% of the population called left dominant coronary circulation.⁶ Proximal RCA occlusions, occlusion of the RV branch or acute marginal branch result in RVMI. Occlusion of the left circumflex coronary artery in left dominant coronary circulation may also cause a RVMI.⁷

Right ventricular ischemia and infarction result in reduced RV systolic contraction along with RV diastolic dysfunction raising the RV filling pressure. This leads to a reduction in RV output and blood supply to the lungs and an increase in right atrial pressure. Reduced pulmonary flow decreases pulmonary venous return to left atrial (LA) and LV. In other words, it decreases LV preload or LV filling. This is expressed as reduced LV output and reduced systolic blood pressure (BP) in spite of a normally contracting LV. RV infarction leads to RV dilatation which alters the motion of the interventricular septum. Leftward shift of septum during diastole also impedes LV filling and further reduces cardiac output. LV dyssynchrony due to abnormal septal motion and loss of AV synchrony when there is AV block may also contribute to decreased cardiac output. Dilatation of RV enlarges the tricuspid annulus resulting in tricuspid regurgitation (TR) further jeopardizing forward RV output.

Increased RA pressure raises the jugular venous pressure (JVP) and increased systemic venous pressure may cause an edematous state.⁸

When RCA occlusion is proximal to right atrial branch, right atrial ischemia diminishes its contraction and increases RA pressure further increasing chance of atrial arrhythmia.⁹ Increased RA pressure cause secretion of atrial natriuretic peptide which may also adversely affect the already compromised hemodynamics.

Elevated right-sided filling pressure in presence of normal pulmonary artery and left-sided filling pressure is the hallmark of RVMI. RA pressure of 10 mm Hg and with pulmonary artery wedge pressure 1–5 mm Hg, had a sensitivity of 73% and a specificity of 100% in identifying hemodynamically important RVMI.¹⁰ RV pressure tracing may show an early diastolic dip and plateau resembling restrictive-constrictive physiology. Increased RA pressure may cause a right-to-left shunt across a stretched foramen ovale decreasing systemic saturation.¹¹

CLINICAL PRESENTATION

Chest pain, diaphoresis, nausea, and vomiting are the hallmark of clinical presentation in MI including RVMI. AV block and arrhythmia can produce syncope and palpitation. Hypotension may be responsible for postural symptoms and fatigue. Signs of right heart failure such as edema and raised JVP are often seen. When RA ischemia is absent, JVP shows prominent “a” with a prominent “x” descent, but when RA contraction is compromised due to RA ischemia, “a”, “x”, and “y” descent are diminished. In presence of significant TR, both “v” waves and “y” descent are prominent. TR murmur may be heard in some cases. Marked sensitivity to preload reducing agents such as nitrates, morphine, and diuretics is a clue to presence of RVMI. Rarely, it may be present with RV free wall rupture causing cardiac tamponade.¹²

The classical triad of presentation of RVMI are hypotension, raised JVP and clear lung fields. Jugular venous distention on inspiration, the Kussmaul's sign in a setting of IWMI indicates presence of RVMI. Pulsus paradoxus which represents an exaggeration of the normal inspiratory decline in systemic arterial pressure may be appreciated in some cases. At times, these signs appear only after administration diuretics or nitrates.¹³

DIFFERENTIAL DIAGNOSIS

The classical triad of hypotension, raised JVP, and clear lung fields may be observed in cardiac tamponade, constrictive pericarditis, restrictive cardiomyopathy, acute pulmonary embolism, severe pulmonary hypertension, right-sided obstructive mass lesions, and acute severe TR. Careful history, ECG changes, and particularly echocardiography can easily differentiate each condition.¹⁴

Electrocardiography

The ST-segment elevations in leads II, III, and augmented vector foot are almost always present as RVMIs are usually

associated with an IWMI. Several ECG findings arouse suspicion of associated RVMI. Disproportionately greater ST-segment elevation in lead III than in lead II is pathognomonic of RVMI.¹⁵ An ST-segment elevation in lead V4R more than 1 mm is a reliable marker of RVMI with a sensitivity of 93% and specificity of 95%. Elevation of ST segment across the entire right precordium from V1R through V6R may also occur which is 100% sensitive, 87% specificity with 92% predictive accuracy (Fig. 1). Height of ST-segment elevation in V4R has also been found to be an independent predictor of adverse outcome.¹⁶

Rarely an isolated RVMI may present with ST-segment elevation in leads V1–V4 making an erroneous diagnosis of anterior wall MI. But there are some differentiating features. ST-segment vector analysis shows the mean vector in RV infarction usually is directed anteriorly and to the right (>100). But in an anteroseptal infarct, the mean ST-segment vector is directed leftward between -30° and -90°. Thus mean ST-segment vector can differentiate between MI at these two different sites.¹⁷

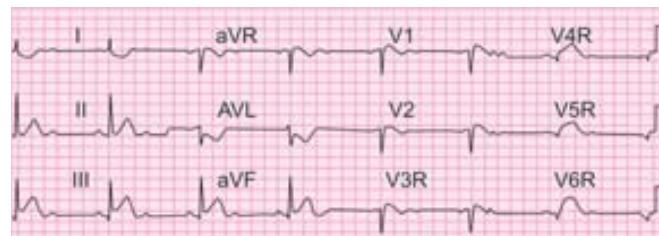

Arrhythmias are quite frequent in a setting of RVMI. There is a very high incidence of severe conduction disorders, complete AV or sinoatrial blocks which is present in nearly 50% of cases with ST elevation or a QS pattern in V3R, and/or V4R.¹⁸ The incidence of sustained ventricular tachycardia (VT) is also high. Although anterior wall LVMI is associated with the highest mortality rates, but incidence of significant AV block and arrhythmias is higher when inferior wall LVMI is associated with RVMI.¹⁹

Biomarkers

Cardiac enzymes will be elevated in RVMI quite similar to LVMI. As the mass of myocardium involved is less, it does not play a significant role in diagnosis of RVMI. Similarly, biomarkers may not be of much help in differentiating between hemodynamically significant pulmonary embolism and RVMI.²⁰

Echocardiography

The sensitivity and specificity of echo is 82% and 93%, respectively, for the detection of RV infarction. RV free wall hypokinesia is most specific for the diagnosis of RVMI. Wall

aVR, augmented vector right; aVL, augmented vector left; aVF, augmented vector foot.

FIG. 1: Electrocardiography in inferior wall myocardial infarction (MI) with right ventricular MI showing ST elevation in inferior leads, note the ST elevation in lead III is more than lead II, recording of right-sided leads V3R to V6R show ST elevation.

motion abnormality usually resolves in 3 months of time.²¹ Dilation of RV is often seen with paradoxical septal motion. Systolic function is depressed as measured by tricuspid annular plane systolic excursion (TAPSE) and tissue Doppler bases tricuspid annular systolic motion. Calculation of RV ejection fraction (EF) shows lower values using two-dimensional (2D) or three-dimensional (3D) based methods. Doppler examination frequently shows presence of TR. A low-velocity TR is hallmark of RVMI (Fig. 2).²² An abnormally

elevated RV myocardial performance index (MPI) of greater than equal to 0.30 or greater is suggestive of the presence of a RV infarction. Recently, newer techniques like 2D speckle tracking is gaining importance in diagnosis of RVMI.²³

Nuclear Imaging

Radionuclide ventriculography and ^{99m}Tc -pyrophosphate myocardial scintigraphy are sometimes used to assess RV wall motion and RV function including RV EF. RV dilatation

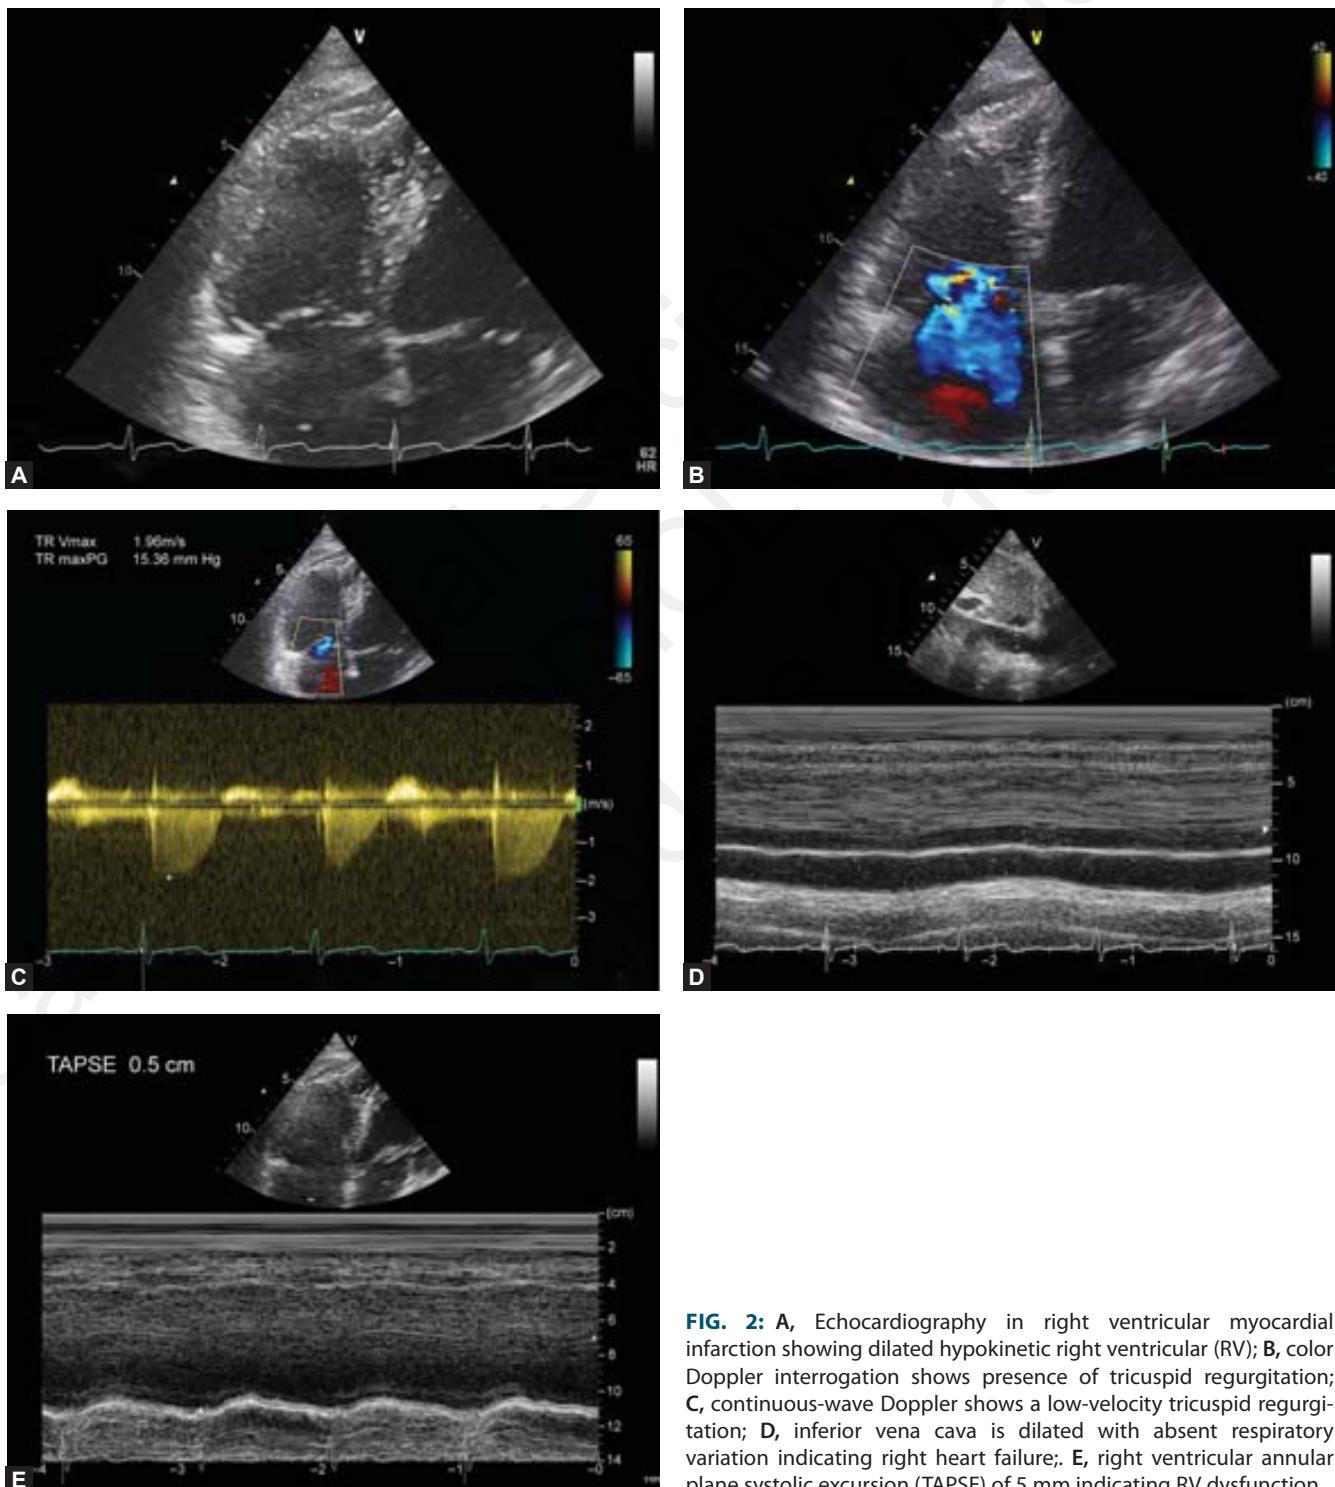

FIG. 2: A, Echocardiography in right ventricular myocardial infarction showing dilated hypokinetic right ventricular (RV); B, color Doppler interrogation shows presence of tricuspid regurgitation; C, continuous-wave Doppler shows a low-velocity tricuspid regurgitation; D, inferior vena cava is dilated with absent respiratory variation indicating right heart failure; E, right ventricular annular plane systolic excursion (TAPSE) of 5 mm indicating RV dysfunction.

and free wall hypokinesia give a diagnosis of RVMI. The ^{99m}Tc -pyrophosphate myocardial scintigraphy is useful to detect RVMI, but clinical utility is less due to logistic issues.²⁴

Cardiovascular Magnetic Resonance

Cardiovascular magnetic resonance (CMR) can accurately identify RVMI, but less availability, cost and patient discomfort in acute setting restrict its use in clinical practice.²⁵ RV free wall myonecrosis indicated by late gadolinium enhancement and obstruction are independent predictors of long-term outcome.²⁶

Coronary Angiography

Coronary angiography (CAG) is the gold standards for definitive diagnosis. Its role in initial evaluation and workup are limited. This invasive procedure is mainly used during intervention.

MANAGEMENT

The use of statin, dual antiplatelet agents, and supplemental oxygen are similar to all MIs. The special precautions and treatment modalities are highlighted below.

Avoidance of Nitrates and Diuretics

Drugs that produce venodilatation like, nitrates and diuretics reduce RV filling further and can exacerbate the state of low cardiac output and hypotension in RVMI. Therefore, it is critically important to avoid nitrates and diuretics once the diagnosis of RVMI is made or suspected.²⁷

Intravenous Fluid

The most important hemodynamic consequence of RV ischemia is significant decrease in LV preload. Mechanism of decreased LV preload is RV diastolic and systolic dysfunction that leads to decreased RV output, less blood returns to LV, reducing the filling (preload) of the LV. Therefore, the initial treatment requires the administration of IV crystalloid fluid sufficiently to increase RV filling. Generally 300–600 mL of

normal saline is infused intravenously preferably through a central line over 10–15 minutes initially as fluid challenge. Clinical response depends upon the baseline intravascular volume status. In volume depleted patients cardiac output increases and BP rises, but in patients with normal volume status there will be no change in cardiac output and BP. Further volume loading of RV may be harmful as it hampers LV filling through interventricular interactions and raised intrapericardial pressure. It is pertinent to have invasive hemodynamic monitoring to see that RA pressure and pulmonary capillary wedge pressure (PCWP) does not exceed 20 mm Hg.²⁸

Positive Inotropic Agent

After initial fluid challenge, if BP and cardiac output does not improve, but at the same time RA pressure and PCWP rise as seen by hemodynamic monitoring then positive inotropic agents such as dobutamine should be infused. In such cases, dobutamine infusion has shown to improve RV output, BP and RV EF. Inhaled nitric oxide when combined with dobutamine has the added benefit of reducing pulmonary vascular resistance (PVR) which decreases RV afterload. Milrinone, a phosphodiesterase III inhibitor, may also improve RV dysfunction by improving RV contractility. However, due to its nonselective action there is a risk of exacerbating systemic hypotension. The calcium sensitizer levosimendan may also improve RV function, by improving cardiac myocyte sensitivity to intracellular calcium without increasing calcium concentrations. These drugs produce increased inotropy as well as peripheral vasodilatation.²⁹

Restoration of Coronary Blood Flow

Early establishment of coronary blood flow is the key to a successful treatment. Early thrombolysis improves hemodynamics, clinical course and decrease mortality.⁴ Timely primary percutaneous coronary intervention (PCI) can dramatically improve clinical, hemodynamic, and survival parameters (Fig. 3). Early reperfusion also helps in stabilizing electrically and reduces chances of ventricular arrhythmias.³⁰

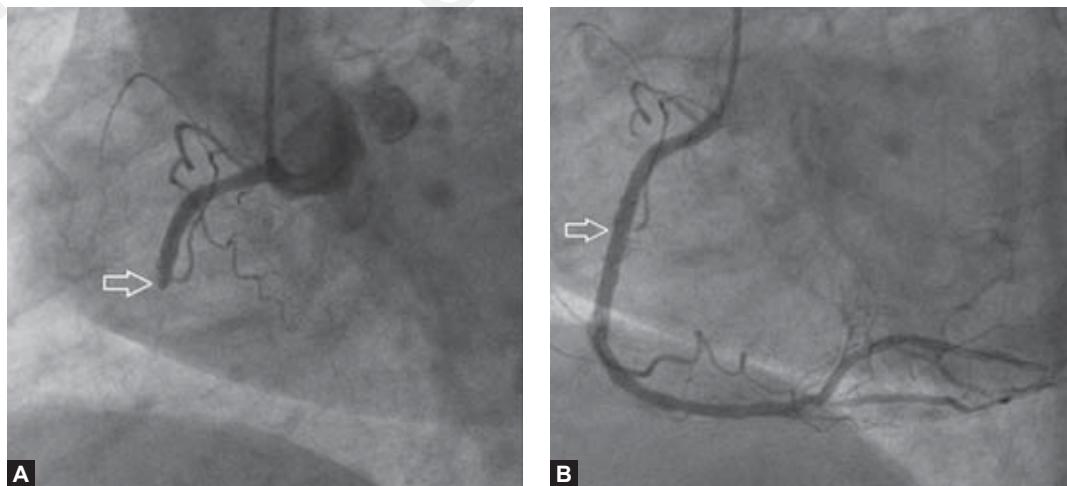

FIG. 3: A, Complete occlusion of proximal right coronary artery in a patient presenting with inferior and right ventricular MI (arrow); B, Post primary PCI establishment of flow (arrow) resulting in marked improvement in clinical and hemodynamic parameters.

Intra-Aortic Balloon Counterpulsation and Right Ventricular Assist Devices

Intra-aortic balloon counterpulsation (IABP) and RV assist devices are reserved for medically refractory cases despite successful reperfusion. IABP not only increases RV perfusion pressure, but also helps in improving septal contraction in an otherwise poorly contracting RV. RV assist device such as Tandem-Heart Percutaneous Ventricular Assist Device (Cardiac Assist Inc, USA) is able to bypass the dysfunctional RV allowing it to recover. Both surgical and percutaneous devices have shown to improve survival, venoarterial extracorporeal membrane oxygenation systems can bypass the pulmonary circulation too to further reduce RV load particularly in presence of pulmonary hypertension and pulmonary embolism.³¹

Correction of Arterial Ventricular Dyssynchrony

Restoration of sinus rhythm when there is atrial fibrillation (AF) and AV sequential pacing when there is AV block improves hemodynamics.³²

Inhaled Nitric Oxide

When there is refractory hypotension due to RVMI, inhaled nitric oxide has been tried successfully. It acts by decreasing PVR but without any effect on systemic vascular resistance. LV filling improves leading to improvement of cardiac output and BP.³³

Valve Replacement or Repair

Severe TR acts as a deterrent on improvement of forward RV cardiac output. In the setting of RVMI, both valve replacement and repair with annuloplasty rings can be used with good outcomes.

Patent Foramen Ovale Occluder Device

When hypoxemia occur secondary to right-to-left shunt across the atrial septum, occluding device closure of the same should be considered. Inhaled nitric oxide can decrease the right-to-left shunting till a device is placed.

PROGNOSIS

Short-term prognosis of patients presenting with RVMI is worse than those with isolated LVMI. In a study of 200 consecutive cases of acute inferior wall LVMI Zehender et al. found ST elevation in lead V4R has a highly negative predictive factor of both in-hospital mortality (31% vs. 6%) and all major in-hospital complications (64% vs. 28%).³⁴ In another study, Jacobs et al. did not find significant difference of mortality in acute MI presenting with cardiogenic shock due to either predominant RV or LV failure.³⁵ Foussas et al. found no significant difference in long-term mortality between patients with and without a RVMI, the poor in-hospital prognosis for patients with RVMIs was attributed to life-threatening arrhythmias.³⁶

CONCLUSION

Up to half of patients presenting with inferior LVMI has RVMI. Associated RVMI makes IWMI a special subclass having unique clinical, ECG, echocardiography, and hemodynamic findings. Routine recording of right-sided chest leads in IWMI is able to identify most cases. Presentation with high-grade AV block, sustained arrhythmias, low cardiac output, hypotension and right heart failure despite an adequate LV function and clear lung fields make RVMI a special category for prompt identification and management. Imaging techniques particularly echocardiography plays a crucial role in the diagnosis. Judicious management particularly avoidance of preload reducing agents, IV fluid, and inotropes should be considered. Early primary PCI, IABP, and RV assist devices and in selected cases tricuspid valve surgery, nitric oxide inhalation and device occlusion of PFO are lifesaving procedures, with positive outcome often saves life.

Cardiogenic Shock in Myocardial Infarction: Optimal Approach

Siddharthan Deepti, Sandeep Singh

INTRODUCTION

Cardiogenic shock is a devastating complication of acute myocardial infarction (MI). It is associated with a dismal prognosis despite recent advances in the care of patients with acute MI and the benefits associated with early use of reperfusion strategies. This chapter will review the definitions, incidence, outcomes, and optimal management of cardiogenic shock complicating MI.

DEFINITIONS

Cardiogenic shock is defined clinically as persistent hypotension [systolic blood pressure (SBP) <90 mm Hg for ≥30 minutes, or requirement of vasopressors and/or mechanical support to achieve SBP ≥90 mm Hg] despite adequate filling status with signs of impaired end-organ perfusion and pulmonary congestion.¹ Signs of hypoperfusion include cold/clammy skin and extremities, altered mental status, dizziness, loss of consciousness, oliguria (urine output <30 mL/hour), resting tachycardia, narrow pulse pressure, and increased arterial lactate levels (>2 mmol/L). In hemodynamic terms, it is characterized by a decrease in cardiac index (CI) associated with pulmonary capillary wedge pressure more than or equal to 15 mmHg. Thus, pragmatically speaking, cardiogenic shock is a clinical diagnosis and may be defined as state of ineffective cardiac output resulting from a primary cardiac disorder leading to inadequate tissue perfusion.²

INCIDENCE, TEMPORAL TRENDS, AND ETIOLOGIES

The most common cause of cardiogenic shock is acute MI. Other than acute MI, cardiogenic shock may also be caused by decompensated valvular heart disease, acute myocarditis, and certain arrhythmias. For the purpose of this chapter,

the focus will be on the management of cardiogenic shock caused by acute MI.

The incidence of cardiogenic shock complicating MI has been reported as ranging from 5 to 10%.³ There are conflicting reports on the temporal trends of cardiogenic shock in MI with some studies reporting a decrease in incidence over time while others showing a slight but statistically significant upward trend.^{4,5} The wide variability in the overall incidence rates and the differences in temporal trends have been attributed to the variations in the definitions of acute MI and cardiogenic shock, the characteristics of the population studied, and the rates of use of therapeutic options that may reduce the risk of cardiogenic shock. The incidence of cardiogenic shock in MI is greater in women and Asian and Pacific Islanders compared to whites, African Americans, and Hispanics.

The majority of patients with MI develop cardiogenic shock during the first 24 hours; only a minority develop this complication before hospital admission or late (>24 hours) after hospital admission. The median time of onset of cardiogenic shock after MI is around 6 hours. The most common cause of cardiogenic shock in acute MI is left ventricular (LV) dysfunction accounting for approximately 80% of cases, followed by severe mitral regurgitation (6.9%), ventricular septal rupture (VSR) (3.9%), right ventricular (RV) failure (2.8%), and cardiac tamponade (1.4%).

OUTCOMES

Cardiogenic shock remains the leading cause of death in patients with MI, though in-hospital mortality rates have reduced from formerly 80% to 35–50%. Mortality is highest (~80%) in cardiogenic shock resulting from VSR. The post-hospital outcomes in survivors of cardiogenic shock show a higher risk of death and/or hospitalization during the first year after discharge. The risk is time-dependent and is clustered mainly in the first 60 days after discharge.

MANAGEMENT

Flowchart 1 provides an overview of the management of acute MI complicated by cardiogenic shock.

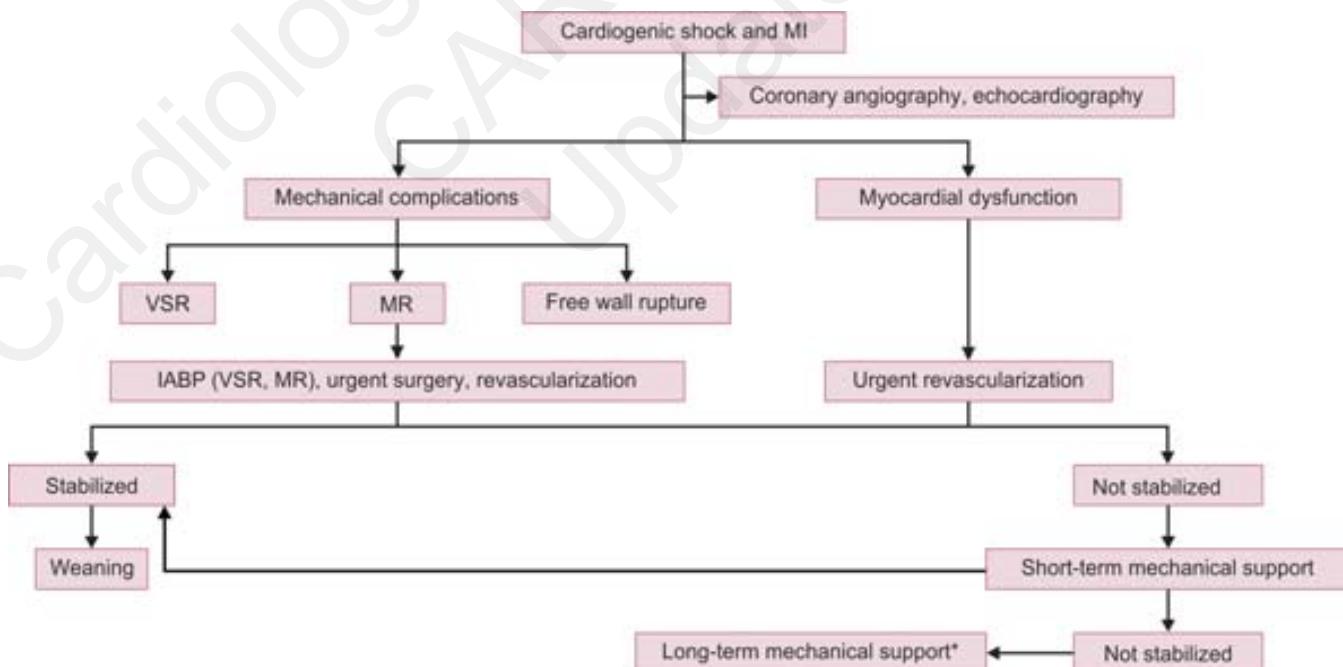

Reperfusion Therapy

Reperfusion is the mainstay of management of cases of MI complicated by cardiogenic shock. The preferred modality for reperfusion is percutaneous coronary intervention (PCI). As a result of its limited efficacy, thrombolysis followed by transfer to a PCI-capable center should only be reserved for cases in which PCI-mediated reperfusion is estimated to occur in more than 120 minutes.⁶

The efficacy of early revascularization in this subset was first demonstrated by the landmark randomized trial, "SHOCK" (Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock) published nearly two decades ago.⁷ This trial randomized patients with shock due to LV failure complicating MI to emergency revascularization or initial medical stabilization. Although the primary endpoint, 30-day mortality was not significantly different in the two groups [46.7% vs. 56.0%; difference, -9.3%; 95% confidence interval (CI) for the difference, -20.5 to 1.9%; $p = 0.11$], there was a survival benefit in the long-term, with significantly lower mortality at 6 months, 12 months, and through long-term follow-up (6 years). Accordingly, a class IB recommendation has been given to immediate PCI in patients with cardiogenic shock, if coronary anatomy is suitable. The rates of revascularization in this subset in the real world range from 27 to 54% in the USA, 47% in the GRACE registry, and 50% in a French registry to as high as 70% in a Swiss registry.

Culprit-only Percutaneous Coronary Intervention

The majority of patients with cardiogenic shock have multivessel or left main coronary artery disease. For example, in the SHOCK trial registry, of all the patients who underwent angiography, 16% had significant left main disease and 53% had three vessel disease. Based on pathophysiologic considerations, the guidelines gave a class II-C recommendation for consideration for complete revascularization during the index procedure in patients presenting with cardiogenic shock. This recommendation has however been challenged by the recently published "CULPRIT-SHOCK" trial.^{8,9} This trial compared culprit-vessel-only PCI with immediate PCI of all obstructive lesions (i.e., those with >70% stenosis of the diameter) in patients who had MI with cardiogenic shock. The study showed a significant clinical benefit of a culprit-lesion-only strategy with a reduction in the primary endpoint of 30-day mortality (an absolute 8.2% reduction) or severe renal failure requiring renal replacement therapy.⁸ At 1-year follow up, there was no significant difference in mortality between the two groups. The rates of rehospitalization for heart failure and repeat revascularization were, however, higher in the culprit-lesion-only PCI group at 1 year. This has been attributed to better survival of patients at extreme risk of death in the culprit-lesion-only PCI arm, who would have otherwise not survived long enough to develop heart failure.⁹ Thus, as of now, the evidence is in favor of employing a strategy of culprit-lesion-only PCI over initial multivessel PCI for patients with cardiogenic shock. However, it should be noted that the decision needs to be individualized depending on the patient's characteristics. For example, intuitive revascularization of a

IABP, intra-aortic balloon pump; MR, mitral regurgitation; MI, myocardial infarction; VSR, ventricular septal rupture.

FLOWCHART 1: Algorithm for management of acute myocardial infarction complicated by cardiogenic shock.

concomitant high-grade proximal left anterior descending coronary artery with less than TIMI 3 flow after dealing with an occluded right coronary artery culprit lesion may not be entirely inappropriate in a properly selected patient.

Access-Radial versus Femoral

The preferential use of radial arterial access for PCI in cardiogenic shock has been favored by the guidelines, if performed by an experienced radial operator, although, the benefit is less well established in this subset compared to patients presenting without shock. Radial access has been shown to be associated with a reduction in all-cause mortality as well as major adverse cardiac and cerebral events at 30-day follow-up in survivors of cardiogenic shock in a meta-analysis of registry patients. However, it should be kept in mind that obtaining a radial artery access may be challenging in hypotensive patients.

Role of Immediate Coronary Artery Bypass Graft (CABG) Surgery

No clear evidence exists to guide CABG vs. PCI in patients with MI complicated by cardiogenic shock, who are found to have multivessel or left main disease. Observational reports have shown no difference in the outcomes between the two. In the real world, the rates of immediate coronary artery bypass graft (CABG) in this subset have remained around 5–6% compared to PCI which have improved from 26–54%.

Antithrombotic Therapies as Adjuncts to Percutaneous Coronary Intervention

There are no separate randomized trials for patients with cardiogenic shock with regard to antiplatelet and anticoagulant drugs. The data from the trials performed in stable patients undergoing primary PCI is inferred to make similar recommendations for patients having cardiogenic shock. The special problems in this subset include the inability to swallow the oral antiplatelet drugs in intubated patients and the impaired enteral perfusion in the state of shock decreasing the oral bioavailability. The tablets need to be crushed and administered via a nasogastric tube. More liberal use of glycoprotein IIb/IIIa inhibitors or the parenteral antiplatelet cangrelor may be considered, though the evidence for the same is lacking.

Medical Management in the Coronary Care Unit

Monitoring

Arterial line insertion is recommended based on expert consensus for continuous monitoring of arterial blood pressure and regular blood gas analysis and lactate measurements. The target mean blood pressure in cardiogenic shock has not been established and has been extrapolated from noncardiogenic shock populations in which mean arterial pressure more than or equal 65 mm Hg is considered a reasonable target. Insertion of a central venous catheter should be considered; it aids in monitoring of central venous

pressure and provide a preferential route for administration of vasoactive substances. Lastly, monitoring with a pulmonary artery catheter has not been found to be of any clinical benefit in randomized studies and meta-analyses. However, pulmonary artery catheter has still been afforded a place in the major guidelines as a tool to provide hemodynamic data that can confirm the presence and severity of cardiogenic shock, RV involvement, and measurements of pulmonary artery pressures, transpulmonary gradient, and vascular resistance of the pulmonary or systemic arterial beds. It can also help in monitoring responses to therapeutic interventions. A class IIb recommendation has been given to use of pulmonary artery catheter in diagnosis and guiding therapy, especially in cases of diagnostic or management uncertainty or in patients with moderate to severe cardiogenic shock who are unresponsive to initial therapy.

Echocardiography

Serial transthoracic echocardiographic examinations are recommended at diagnosis and during coronary care unit (CCU) stay to evaluate changes in biventricular function, valve dysfunction, and exclusion or diagnosis of mechanical complications. LV ejection fraction and severity of mitral regurgitation have been identified as independent echocardiographic predictors of outcomes in a substudy from the SHOCK trial. Echocardiography may also aid in hemodynamic monitoring by providing estimates of cardiac output and filling pressures; though use in this area is not firmly established yet and can prove challenging.

Vasoactive Drugs

Vasopressors and/or inotropes may be required in the prehospital setting, in the catheterization laboratory during PCI and in the CCU. There is limited evidence for selection of an agent in cardiogenic shock. Norepinephrine is considered to be the agent of choice as first-line therapy as it has been shown to be safer than dopamine, vasopressin, or epinephrine and has a lower risk of arrhythmias. Dobutamine should be preferred in patients with predominant low cardiac output and preserved perfusion pressure. Regarding inodilators, levosimendan finds a place in patients on chronic beta-blocker therapy because its inotropic effect being independent of beta-adrenergic stimulation. Dopamine, epinephrine and vasopressin are not preferred as these have been found to have detrimental (increased lactate levels or atrial arrhythmias) or neutral effects in nonrandomized studies.

Nonvasoactive Pharmacologic Therapy

The “TRIUMPH” trial evaluated tilarginine, a nitric oxide synthase inhibitor, in patients with refractory cardiogenic shock complicating MI despite an open infarct artery. Early mortality rates were high in the therapy arm. A secondary analysis of the data from this trial showed administration of β -blockers or renin-angiotensin-aldosterone system antagonists in 25% of patients within the first 24 hours after cardiogenic shock diagnosis. Higher 30-day mortality was observed in the recipients of these agents.

Early statin use has been associated with a favorable outcome in an analysis from the Korean Acute Myocardial Infarction Registry. Critical care bundles of best-practice prevention strategies should be implemented to prevent hospital-acquired infections, stress ulcers, delirium, critical illness neuropathy, and venous thromboembolism.

Mechanical Circulatory Support

Intra-aortic Balloon Pump

The role of routine use of intra-aortic balloon pump (IABP) has been downgraded to class IIIB recommendation based on the results of the “IABP-SHOCK II” trial.¹⁰ This study compared standard therapy (early revascularization with best available medical care) with and without IABP in 600 patients with cardiogenic shock secondary to MI. No difference was observed in 30-day mortality (39.7% vs. 41.3%; relative risk 0.96, 95% CI 0.79–1.17) or in any key secondary endpoints such as length of ICU stay, renal function, or the rates of major bleeding, peripheral ischemic complications, sepsis, or stroke. There were no significant differences in these endpoints on follow-up at 12 months. However, crossover rate was high in the control group. There is a possibility that the trial enrolled patients without rapid deterioration and the sample is more representative of patients stabilized on vasopressor or inotropic support. The role of IABP in patients with severe shock with rapid deterioration requires further study. Currently, IABP is to be considered only in patients with cardiogenic shock secondary to mechanical complications.

Percutaneous Active Mechanical Circulatory Support Devices

There is lack of high-quality evidence to support the use of percutaneous active mechanical circulatory support (MCS) devices like TandemHeart and Impella as therapeutic adjuncts in the cardiogenic shock population. Temporary MCS devices can be used as a bridge to recovery, whereby the MCS is removed after correction of shock; a bridge to a bridge, whereby the MCS provides time for a provisional plan to transition to durable MCS after clinical stabilization; or a bridge to decision, in cases where hemodynamic instability, neurological uncertainty or multisystem organ failure may preclude a comprehensive assessment for durable MCS or transplantation.

The Impella CP, 5.0 unloads the LV completely with simple percutaneous insertion unlike the TandemHeart which requires an atrial septal puncture. Recently, a small study, the IMPRESS-in-Severe-SHOCK trial, compared Impella CP and IABP in patients with ST-elevation myocardial infarction (STEMI)-associated cardiogenic shock requiring MCS.¹¹ The trial was markedly underpowered for the assessment of the primary endpoint of all-cause 30-day mortality and failed to show any difference in the two groups. However, there was no benefit with respect to the other nonclinical endpoints as well including arterial lactate levels. This raises concerns about the efficacy of the device. On the other hand, registry data suggests improved outcomes using early active hemodynamic support with Impella CP in cardiogenic shock in patients with isolated left ventricle failure. An adequately

powered trial is needed before routine use of this device can be recommended.

A pilot feasibility study (the Detroit cardiogenic shock initiative) examined the effect of early MCS before PCI in patients who present with acute MI complicated by cardiogenic shock and observed favorable trends in survival.¹² The protocol of PCI following MCS needs to be validated in larger national studies before its widespread application.

Venoarterial Extracorporeal Membrane Oxygenation

Venoarterial extracorporeal membrane oxygenation (VA-ECMO) provides both respiratory and cardiac support and is appealing as a potential first-line MCS device in cardiogenic shock in view of possibility of its rapid deployment, applicability in case of malignant arrhythmias, and rapid improvement in oxygenation. The drawbacks include requirement of a specialist team for insertion and running and a relevant risk of thromboembolic events and limb ischemia. The increasing use of ECMO in patients with cardiogenic shock is promising; however, there is paucity of evidence to support its routine use. A recent observational study found increased mortality and higher cost of care without significant increase in length of stay with use of ECMO in cardiogenic shock. Future research including randomized studies is needed to clarify the role of this modality in this population.

Currently, percutaneous MCS devices have been given a class IIb-C recommendation for use in refractory cardiogenic shock.

Cardiogenic Shock Secondary to Mechanical Complications

Cardiogenic shock secondary to a mechanical complication of MI carries worse prognosis, especially with VSR where the early mortality is as high as 80%. The incidence of VSR previously ranged from 1 to 2% with a decrease to 0.2% in the current era of primary PCI. Immediate surgical closure is recommended in current guidelines in patients with cardiogenic shock not responding to medical therapy. IABP may be considered for initial stabilization before coronary angiography and surgery. Immediate percutaneous extracorporeal life support might be required in cases of refractory cardiogenic shock. However, surgery has been found to be futile with mortality approaching 100% in a subset of patients with VSR including the very elderly and patients with poor RV function. A possible alternative is percutaneous device closure of the VSR. There is paucity of hard evidence in favor of device closure of VSR. A meta-analysis of all published reports has shown similar mortality data with percutaneous VSR closure and surgery.

Papillary muscle rupture leading to acute mitral regurgitation and cardiogenic shock may complicate a minority (~0.25%) of cases of MI. Emergency surgery (valve repair/replacement) is recommended in this situation. Afterload reduction and IABP may help in stabilizing the patient in preparation for angiography and surgery. Operative mortality is high (20–25%).

Ventricular free wall rupture is known to complicate 2–3% of cases of MI. Emergent surgery is vital. Pericardiocentesis can be a life-saving temporizing measure in manifest tamponade and circulatory collapse.

Cardiogenic Shock with Right Ventricular Infarction

Acute RV infarction leading to cardiogenic shock is a special situation in which, in addition to reperfusion, volume support is indicated to maintain increased filling pressures and maximize flow to the left ventricle. Since, the viability of RV remains preserved longer after MI unlike its left counterpart, late reperfusion is an option in patients with inferior wall MI and RV dysfunction. Right ventricular assist device (RVAD) like the Impella RP system may be considered in patients with refractory RV shock. The prognosis of patients with cardiogenic shock secondary to RV infarction is no different than those without it.

Multiorgan Dysfunction in Cardiogenic Shock

Pulmonary edema usually accompanies cardiogenic shock and may necessitate mechanical ventilation in 60–80% of cases to improve gas exchange and to relieve the work of breathing. Acute kidney injury is seen in roughly one-third of patients with cardiogenic shock. Management is supportive with correction of hypoperfusion and avoidance or minimal use of nephrotoxic agents. Significant elevation of hepatic transaminases is observed with severe hypoperfusion and portends worse prognosis. As in renal dysfunction, restoration of hepatic perfusion is the key to management.

Cardiac arrest has been reported in 29–41% of patients with cardiogenic shock complicating MI. The management of brain injury in resuscitated patients is not clear. General postresuscitation measures include monitoring of hemodynamics, oxygenation, and ventilation to avoid secondary brain injury. Hypothermia is known to provide profound neuroprotection after resuscitation from cardiac arrest. Moderate hypothermia was evaluated in a small, nonrandomized study in 14 patients with severe cardiogenic shock with or without cardiac arrest (COOL Shock Study I & II). It was found to be safe and feasible in this setting with improvement in parameters of cardiac function for the duration of therapy. The role of hypothermia in patients on ECMO support is being investigated in an ongoing multicenter randomized controlled trial (HYPO-ECMO: NCT02754193).

Assessment of Prognosis

Multiple scoring systems have been developed to predict clinical outcomes in patients with cardiogenic shock. Some of the models are derived for the general ICU patients and include the APACHE (Acute Physiology and Chronic Health Evaluation)-II score and SAPS (Simplified Acute Physiology Score)-II scoring systems. Specific to cardiogenic shock, three

scoring systems are available, the Sleeper score (derived from the SHOCK trial), the CardShock risk score, and the IABP-SHOCK II risk score.

Independent predictors of mortality in the Sleeper score include anoxic brain injury, shock at admission, noninferior wall MI, increasing age, end-organ hypoperfusion, renal dysfunction (serum creatinine ≥ 1.9 mg/dL), prior CABG and SBP at admission. The CardShock risk score includes seven prognostic variables that were found to be independently associated with increased mortality: ACS etiology, age, previous MI, prior CABG, confusion, low LV ejection fraction, and blood lactate levels. Lastly, the IABP-SHOCK II risk score recognizes six variables as independent predictors for 30-day mortality: age more than 73 years, prior stroke, glucose at admission above 191 mg/dL, creatinine at admission above 1.5 mg/dL, thrombolysis in MI flow grade less than 3 after PCI, and arterial blood lactate at admission above 5 mmol/L.

These scoring systems find utility in counseling patients and families, in healthcare policy resource utilization decisions, in quality improvement systems, and design of trials to test novel therapies.

CONCLUSION

Cardiogenic shock is a life-threatening complication of acute MI that continues to have extremely high mortality in spite of advances in the care of patients with MI over the last two decades. As of now, reperfusion with PCI is the mainstay of management of these patients. Key aspects have been explored in randomised trials, the most important of which have been summarized in table 1. However, there are several issues that await clarification in future studies including the role of MCS, immediate CABG and optimal monitoring techniques.

TABLE 1: Important trials in management of cardiogenic shock complicating myocardial infarction

SHOCK (1991) ⁷	<ul style="list-style-type: none"> N = 302 Survival benefit in the long-term with emergency revascularization
IABP-SHOCK II (2012) ¹⁰	<ul style="list-style-type: none"> N = 600 No improvement in mortality at 30 days with IABP use
CULPRIT-SHOCK (2017, 2018) ^{8,9}	<ul style="list-style-type: none"> N = 706 Lower 30-day risk of death or severe renal failure with culprit lesion only PCI compared to immediate multivessel PCI*
IMPRESS-in-Severe Shock (2017) ¹¹	<ul style="list-style-type: none"> N = 48 No difference in 30-day mortality between Impella and IABP

*No significant difference in 1-year mortality between the two groups. Higher rates of rehospitalization for heart failure and repeat revascularization in the culprit lesion only PCI group at 1 year.

IABP, intra-aortic balloon pump; PCI, percutaneous coronary intervention.

Optimizing STEMI Care—Developing Regional Networks

Sabarirajan Sokkaiyan, Thomas Alexander

INTRODUCTION

The development and use of reperfusion therapy in ST-elevation myocardial infarction (STEMI) has been one of the great achievements of modern medicine in the United States of America and Western Europe. In the 1960s, 1-year mortality rates after STEMI approached 30% in these countries. However, their numbers are dramatically different today: under ideal circumstances, reperfusion therapy—in combination with cardiac care units and other evidence-based treatments—has now lowered 1-year mortality rates after STEMI to well under 10% in clinical trials. The goal of the last two decades in these countries has been to translate these outcomes under “ideal circumstances” into “real-world” practice.¹

Cardiovascular disease (CVD) is a major cause of morbidity and mortality in India. The recent nationwide survey published in Lancet has shown that the epidemiologic transition toward lifestyle diseases has been completed in all states in India.² CVD is now the dominant cause of death in India and therefore must be an area of priority in both planning and resource allocation. While public education to improve preventive strategies and to educate people on early recognition and management of coronary risk factors is important, there remains an urgent need to plan and improve acute cardiac care especially in managing patients with acute coronary syndrome (ACS).

Experience from the developed countries clearly show that developing regional STEMI networks significantly reduces morbidity and mortality of ACS. However, these systems require a high level of trained manpower, emergency medical services (EMS), and finance to implement. Low- and middle-income countries (LMIC) such as India will find replicating similar systems difficult and impractical. Therefore, it is imperative that STEMI networks developed for LMIC are not only practical but also accessible and equitable to the large number of patients who are from the below poverty level (BPL) strata of the society.³

MAGNITUDE OF THE PROBLEM

There are no accurate estimates of STEMI in India. Expert estimates indicate there could be between 1,500 and 2,000 STEMI per million per year. If this were to be accurate, then there could be upward of 2.0 million STEMI cases every year. This is a huge burden that requires urgent attention.

Data from the CREATE registry, published over a decade ago, looked at hospital data from 89 centers from 50 cities across India. There were 20,468 patients of which 12,405 had STEMI. Total 58.5% had thrombolysis and 8% had primary percutaneous coronary intervention (PCI).⁴ The Kerala ACS Registry showed that 41.4% had thrombolysis and 12.9% had primary PCI. Thus, these registry data, acquired over a decade ago, show a 55–65% reperfusion rate.⁵ Over the last decade these rates could have improved. However, these are mostly urban data and Kerala has been the best state in terms of healthcare delivery and social and health indices, and so may reflect a “best case scenario” and may not reflect the ground realities in the other parts of the country.

Data presented at the Interventional Council of India, showed that approximately 64,000 primary PCI were performed in 2016. Data collected from the pharmaceutical industry has shown that approximately 430,000 doses of thrombolytic doses were dispensed in 2016. Thus approximately 500,000 reperfusions were instituted in 2016 and would indicate only 25% of STEMI patients had reperfusion therapy.

It is therefore imperative to improve access to reperfusion therapy across the country.

Barriers to Access of Appropriate Care

- *Patient factors:*
 - Nonrecognition of symptoms
 - Gender disparity
 - Cost of medical care.
- *Transportation factors:*
 - Lack of ambulance services
 - Clear delineation of “STEMI hospital”

- *Hospital factors:*
 - Absence of clear protocol
 - Absence of trained “STEMI teams”.

Some of the nonsystem delays can be overcome by public education, using prehospital electrocardiography (ECG) as in the STEMI INDIA project, and accrediting and publicizing “STEMI hospitals”. This will ensure that patients do not lose time when they are admitted to “non-STEMI” hospitals and then must be transferred to another hospital for STEMI management. Thus, critical delays associated with “door-in-door-out” can be avoided.

Access to ambulance services and availability of universal insurance coverage for STEMI patients will ensure that all patients with STEMI can access appropriate care. For this it is important that governments, both at the Centre and the States, work together with the scientific societies to understand and help to implement these programs.

STEMI—Acute Care at First Point of Contact

In the absence of a clear-cut and well-developed STEMI network in India, patients present to a variety of medical facilities with complaints of chest pain. It is imperative to develop clear guidelines to assist these facilities in the appropriate management of STEMI patients.

These could include:

- Physician clinic or primary health centers (PHCs)
- Community health centers (CHCs) or hospitals with no coronary care unit (CCU) facility
- Thrombolytic center with CCU but without a cardiac catheterization facility
- Center with cardiac catheterization laboratory and primary PCI facility.

There have been recent attempts to develop guidelines to help PHCs and CHCs to manage patients with chest pain, as also to improve facilities and develop protocols to help manage patients with ACS. However, these initiatives will take time and require significant government funding.

DEVELOPING REGIONAL STEMI NETWORKS—THE STEMI INDIA EXPERIENCE

Regional STEMI networks to manage patients with STEMI have been developed in the United States and Europe and have played a critical role in reducing mortality in patients with STEMI. These systems have critically combined a well-developed EMS system with a strategy of primary PCI as the mode for reperfusion. This system is critically dependent on a high quality of infrastructure and medical capability. Countries such as India and other LMIC can seldom replicate these models.

The STEMI India model combines the two proven reperfusion strategies of primary PCI with the pharmacoinvasive strategy to build a hub-and-spoke model.⁶ The hub centers, located mostly in urban areas, have cath laboratories

and STEMI patients self-presenting or transported to these centers have primary PCI here. These hospitals also catheterize and do PCI for patients transferred from the spokes after thrombolysis—the pharmaco-invasive strategy of reperfusion. The hubs are connected to multiple spoke hospitals that are in the peripheral and rural areas. Patients presenting here are thrombolyzed and then shifted to the hub for catheterization (Fig. 1).

The TN-STEMI Project

The initial pilot study was the Kovai Erode Pilot study involving 84 patients over a 6-month period. The study tested the feasibility of the hub-and-spoke model and could show remarkable improvement in access to STEMI care. This was published in the Heart Journal.⁷

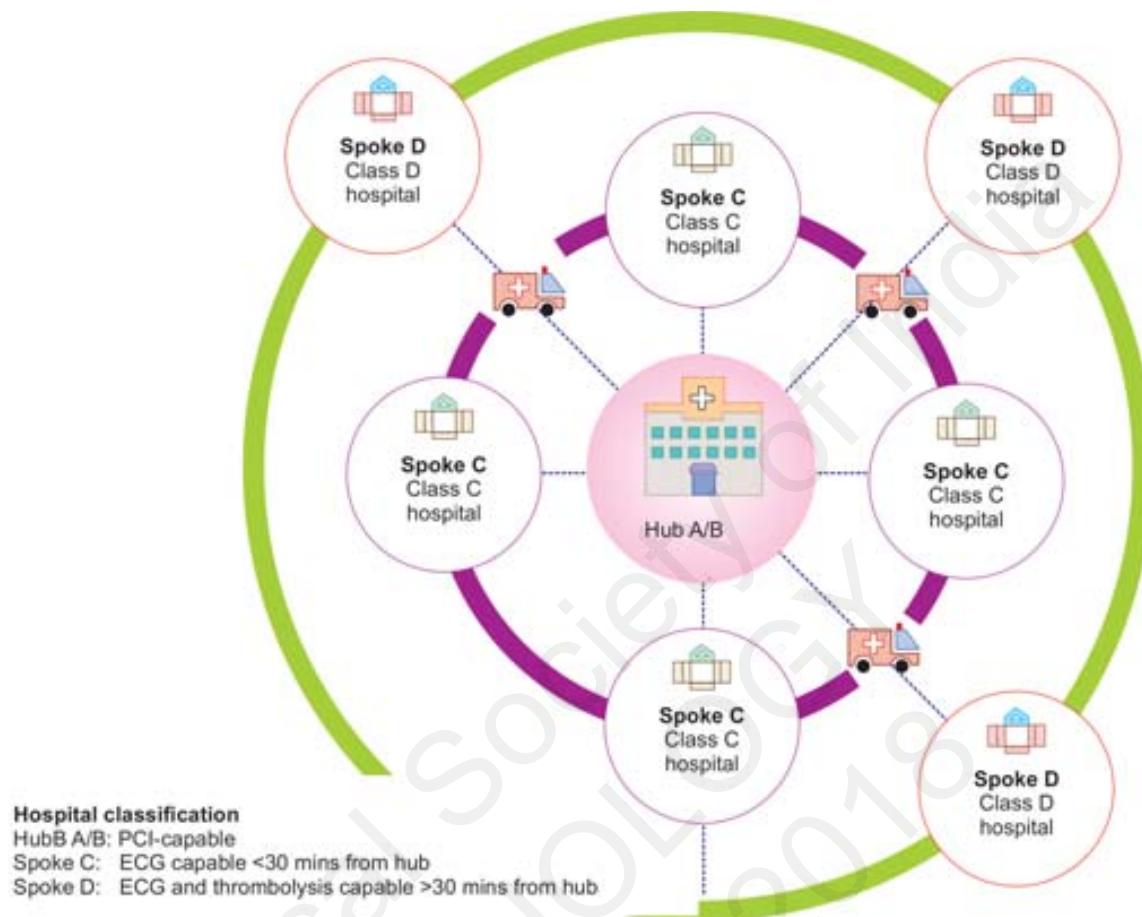

Based on this a larger study was planned and conducted in Tamil Nadu—The TN-STEMI Programme.⁸ This study was partly funded by the Indian Council of Medical Research (ICMR) and partly by STEMI India. The study had the active participation of the Tamil Nadu State Government through the Tamil Nadu Health Systems Project (TNHSP), the State ambulance network through GVK-EMRI (Emergency Management and Research Institute), and the State CM Health Insurance Scheme for BPL patients. The study was conducted in four clusters in Tamil Nadu.

The program resulted in the creation of an integrated, regional quality improvement program that linked the 35 spoke healthcare centers to the four large PCI hub hospitals and leveraged recent developments in public health insurance schemes, EMS, and health information technology.

This multicenter, prospective, observational program studied 2,420 patients 20 years or older with confirmed ECG and symptoms or signs consistent with STEMI at primary care clinics, small hospitals, and PCI hospitals in the southern state of Tamil Nadu in India. Data were collected from the four clusters before implementation of the program (pre-implementation data). There was a 12-week period for the pre-implementation data acquisition with the period extending from August 7, 2012, through January 5, 2013. The program was then implemented in a sequential manner across the four clusters, and data were collected in the same manner (post-implementation data) from June 12, 2013, through June 24, 2014, for a mean 32-week period.

Primary outcomes focused on the proportion of patients undergoing reperfusion, timely reperfusion, and post-fibrinolysis angiography and PCI. Secondary outcomes were in-hospital and 1-year mortality.

A total of 2,420 patient with STEMI [2,034 men (84.0%) and 386 women (16.0%); mean (SD) age, 54.7 (12.2) years] (898 in the preimplementation phase and 1,522 in the postimplementation phase) were enrolled, with 1,053 patients (43.5%) from the spoke healthcare centers. Missing data were common for systolic blood pressure [213 (8.8%)], heart rate [223 (9.2%)], and anterior myocardial infarction location [279 (11.5%)]. Overall reperfusion use and times to reperfusion were similar [795 (88.5%) vs. 1372 (90.1%)];

ECG, electrocardiography; PCI, percutaneous coronary intervention.

FIG. 1: The hub-and-spoke model for STEMI care model. This example from the STEMI India program is a well-tested formulation shown to work well in resource-challenged locations.

Source: Alexander T, Mallasari AS, Kaifoszova Z, et al. Framework for a National STEMI Program: Consensus document developed by STEMI INDIA, Cardiological Society of India and Association Physicians of India. Indian Heart J. 2015;67(5):497-502.

$p = 0.21$. Coronary angiography [314 (35.0%) vs. 925 (60.8%); $p < 0.001$] and PCI [265 (29.5%) vs. 707 (46.5%); $p < 0.001$] were more commonly performed during the postimplementation phase. In-hospital mortality was not different [52 (5.8%) vs. 85 (5.6%); $p = 0.83$], but 1-year mortality was lower in the postimplementation phase [134 (17.6%) vs. 179 (14.2%); $p = 0.04$], and this difference remained consistent after multivariable adjustment (adjusted odds ratio, 0.76; 95% confidence interval, 0.58–0.98; $p = 0.04$).

The Way Forward

Based on the success of the TN-STEMI Programme, the ICMR invited the health secretaries of 18 states and held a dissemination workshop to highlight the benefits of the TN-STEMI Programme and the modalities for a successful implementation. The Union Health Ministry has resolved to provide states with 60% of the cost of running a similar program. This should give a fillip to the program with many states implementing a similar program.

CONCLUSION

A hub-and-spoke model in South India improved STEMI care through greater use of PCI and has been shown to improve 1-year mortality. This model may serve as an example for developing STEMI systems of care in India and other low- to middle-income countries.

Working together with the government, utilizing technological innovation and working together with Cardiological Society of India (CSI) and STEMI India, it is possible to develop these regional STEMI networks. In an environment of resource constraints with a burgeoning population with coronary artery disease and STEMI, a comprehensive national STEMI program is critical to deliver reperfusion for all.

SECTION 8

Dual Antiplatelet Therapy

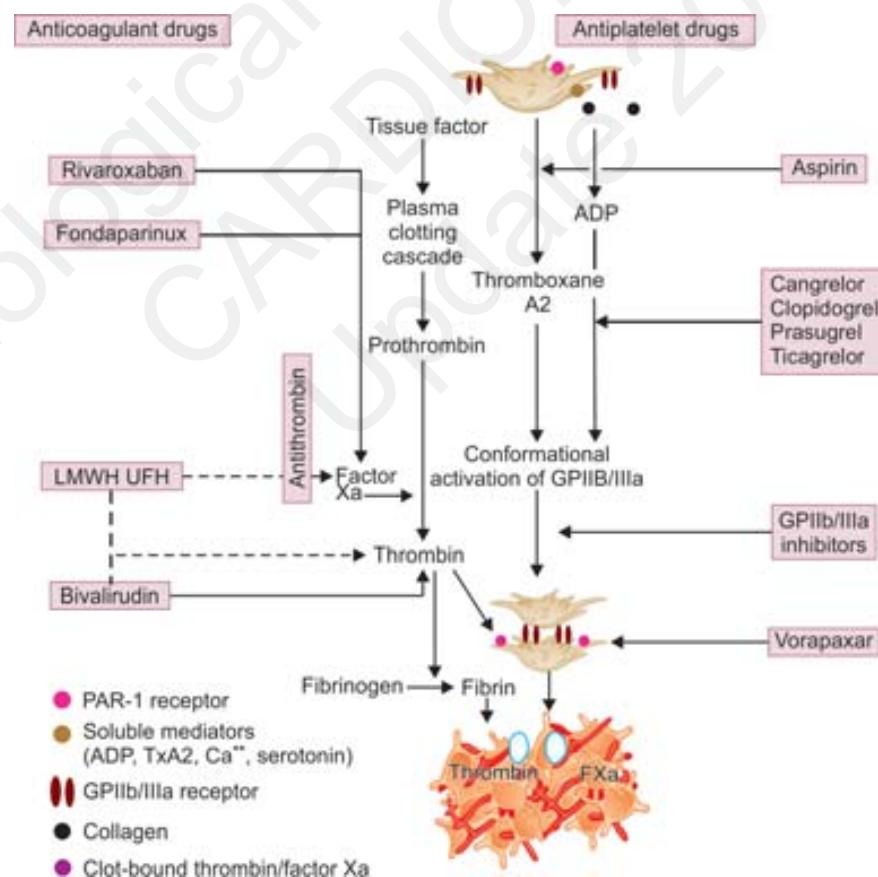

Choice of Dual Antiplatelet Therapy in Acute Coronary Syndrome: Is There a Consensus?

Hiremath MS, Deore RA

INTRODUCTION

As per National Informatics Center (NIC) data in 2015,¹ 30 lacs patients suffered from acute coronary syndrome (ACS). Of these 12 lacs received medical management, 67,000 received primary percutaneous intervention (PCI), and rest did not get the appropriate treatment.

Central to ACS is the vulnerable plaque rupture with formation of arterial thrombus triggering the positive feedback mechanism. This leads to platelet activation and fibrin formation leading to platelet aggregation. So, antiplatelets and anticoagulants are the mainstay of therapy for ACS (Fig. 1).

ADP, adenosine diphosphate; LMWH, low molecular-weight heparin; UFH, unfractionated heparin.

FIG.1: Antithrombotic and antiplatelet drugs for acute coronary syndromes. Figure depicts the targets available that can be used to inhibit coagulation and platelet aggregation.

In 1996, Schwomig et al.² first described the role of dual antiplatelet therapy (DAPT; aspirin with ticlopidine) over anticoagulation (aspirin with heparin followed by phenprocoumon) in patients undergoing intracoronary stent placement. Compared to anticoagulation group, DAPT group experienced 82% less myocardial infarctions (MIs) and 78% lesser repeat revascularization. In DAPT group, 1.6% patients reached primary cardiac end points and 1.2% reached primary noncardiac end points compared to 6.2% and 12.3% in anticoagulation group, respectively. This started the era of DAPT therapy in post-PCI population.

ASPIRIN

Aspirin is an inhibitor of cyclooxygenase I (COX-I) inhibitor leading of irreversible functional platelet inhibition, which lasts for the approximate 8–9 days life span of a circulating platelet. ISIS-2 (Second International Study of Infarct Survival) trial aspirin when used in post-thrombolysis patients significantly reduced early vascular mortality and this beneficial effect was maintained event at 10 years postevent.^{3,4} The antiplatelet effect of aspirin is at the dose range of 50–325 mg/day, with optimal effect at the dose of 75 mg/day, as proven in CURRENT OASIS-7 (Clopidogrel and Aspirin Optimal Dose Usage to Reduce Recurrent Events—Seventh Organization to Assess Strategies in Ischemic Syndromes) trial.⁵ There is no incremental benefit with higher doses of aspirin above 100 mg/day, above which bleeding risk increases incrementally. Most of the bleeding events with aspirin are gastrointestinal, at the incidence rate of \approx 2% per year.

Aspirin remains the backbone of anti-thrombotic therapy over which other antiplatelets are added.

TICLOPIDINE

Addition of second antiplatelet agent, adenosine diphosphate (ADP) receptor antagonist was shown to be superior by Schwomig et al.,² but hematological side effects (gastrointestinal problems—diarrhea, abdominal pain, nausea, and vomiting, neutropenia in approximately 2.4% of patients, severe neutropenia in 0.8% of patients, and, rarely, thrombotic thrombocytopenia purpura) and availability of superior molecule (clopidogrel) have rendered ticlopidine obsolete.

CLOPIDOGREL

Clopidogrel remains the most extensively studied and the most commonly used second antiplatelet in the DAPT-regimen. Clopidogrel, thienopyridine class, is a prodrug which irreversibly inhibits P2Y₁₂-receptor. The first randomized controlled trial (RCT) of clopidogrel in ACS patients was CURE (Clopidogrel in Unstable Angina to Prevent Recurrent Ischemic Events)⁶ trial. In this trial of the 12,562 patients with non-ST elevation acute myocardial infarction (AMI), 6,259 were given clopidogrel (300 mg immediately, followed by

75 mg once daily) and placebo arm was given only aspirin for 3–12 months. About 9.3% patients in the clopidogrel arm achieved primary end points (a composite of death from cardiovascular (CV) causes, nonfatal MI, or stroke) compared to 11.4% patients in the placebo arm [relative risk with clopidogrel as compared with placebo, 0.80; 95% confidence interval (CI) 0.72 to 0.90; p <0.001]. Similar benefit was also seen in secondary outcome of refractory ischemia (16.5% in study group vs. 18.8% in placebo group; relative risk, 0.86, p <0.001). In the angioplasty subgroup of the same study (PCI-CURE⁷) the benefit was even greater with 30% relative risk reduction in the primary end points. But this was at the expense of higher major bleeding in the clopidogrel-arm compared to the placebo arm (3.7% vs. 2.7%; relative risk, 1.38; p = 0.001), though life-threatening bleeds (2.1% vs. 1.8%, p = 0.13) and the hemorrhagic strokes were not significant.

Further clopidogrel was studied in ST-elevation myocardial infarction (STEMI) in CLARITY TIMI-28 trial [The Clopidogrel as Adjunctive Reperfusion Therapy (CLARITY)-Thrombolysis in Myocardial Infarction (TIMI)].⁸ In this trial, 3,491 STEMI patients were randomized to clopidogrel plus aspirin or aspirin only arm. The primary efficacy end point was the composite of an occluded infarct-related artery (defined by TIMI flow grade of 0 or 1) on angiography, death from any cause before angiography could be performed, or recurrent MI before angiography. There was 6.7% absolute reduction in the primary efficacy end points in the study group (15% in clopidogrel arm vs. 21.7% in placebo-arm). Similar to CURE study, there was an angioplasty subgroup of this trial (CLARITY-PCI)⁹ which showed 46% relative risk reduction in the, the 30-day composite of CV death, MI, or stroke (6.2% vs. 3.6%; p = 0.008) without any significant difference in major or minor bleeding between the two groups.

Medically managed STEMI patients were studied in COMMIT trial (The Clopidogrel and Metoprolol in Myocardial Infarction Trial).¹⁰ There was 9% relative risk reduction in the DAPT arm (aspirin plus clopidogrel) compared to placebo arm (aspirin alone), corresponding to nine fewer events per 1,000 patients treated for about 2 weeks. There was also a significant 7% proportional reduction in any death (7.5% DAPT arm vs. 8.1% aspirin only arm; p = 0.03). This effect is of independent of the other treatments used without significant increase in the risk of any bleeding either overall [134 (0.58%) vs. 125 (0.55%); p = 0.59], or in patients aged older than 70 years or in those given fibrinolytic therapy.

The Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CHARISMA)¹¹ trial studied role of clopidogrel in patients with either clinically evident cardiovascular disease (CVD) (secondary prevention) or multiple risk factors (primary prevention). A total of 15,603 patients were randomized to aspirin plus clopidogrel or aspirin plus placebo and followed for a median of 28 months. There was no difference in the primary end point of CV death, MI, or stroke, although the secondary end point, which included hospitalizations for ischemia, was significantly reduced. In this trial, there was a

suggestion of benefit with clopidogrel treatment in patients with symptomatic atherothrombosis (secondary prevention group) and a suggestion of harm in patients with multiple risk factors (primary prevention group).

Interindividual variability in responsiveness to clopidogrel: Clopidogrel being a prodrug requires 2-step conversion to its active metabolite, R-130964 in liver mediated by several CYP450 isoenzymes. Major genetic polymorphism in isoenzymes of CYP2C19 leads to loss of function, which is responsible variable response to clopidogrel, incidence being 20%. *CYP2C19**2 and *3 variants account for 99% of the loss-of-function alleles in Asians. Genetic analysis of CURE and CHARISMA study showed no impact of reduced function alleles on potential benefits of clopidogrel plus aspirin in the study population. More minor degrees of bleeding did seem to be associated with CYP2C19 polymorphisms. So these studies did not find any role of clopidogrel genotyping in stable coronary artery disease patients.¹² The Food and Drug Administration (FDA) announced a "Boxed Warning" on March 12, 2010, about the diminished effectiveness of clopidogrel in patients with an impaired ability to convert the drug into its active form. The FDA label revision does not mandate testing for *CYP2C19* genotypes or overall platelet function.¹³

Besides genetics, drug–drug interaction is an important cause for clopidogrel variability. Pharmacokinetic and pharmacodynamic data show proton-pump inhibitors (PPI) attenuate antiplatelet efficacy of clopidogrel, supplemented by various observational studies.¹⁴ Based on populations from two randomized trials, the PRINCIPLE (Prasugrel In Comparison to Clopidogrel for Inhibition of Platelet Activation and Aggregation) TIMI-44 trial¹⁵ and the TRITON (Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel)-TIMI-38 trial,¹⁶ PPI treatment attenuated the pharmacodynamic effects of clopidogrel and, to a lesser extent, those of prasugrel; but PPI treatment did not affect the clinical outcome of patients given clopidogrel or prasugrel. The US-FDA notifies that for patients taking clopidogrel the need for starting or continuing treatment with PPI should be re-evaluated and if required, other drugs to reduce gastric acidity to be preferred like H2-blockers or antacids.¹³

Higher loading doses (600–900 mg) have been evaluated.^{17,18} They appear to be safe and more rapidly acting; however, it must be recognized that the database for such higher loading doses is not sufficiently robust to formulate definitive recommendation (Table 1).

TABLE 1: Oral antiplatelet agents for acute coronary syndrome

	Aspirin	Clopidogrel	Prasugrel	Ticagrelor
Molecule chemical class	Acetylsalicylic acid	Thienopyridine	Thienopyridine	Cyclopentyl-triazolo-pyrimidine
Route of administration	Oral	Oral	Oral	Oral
Mechanism of action	Cyclo-oxygenase-1 inhibition	P2Y ₁₂ receptor inhibition	P2Y ₁₂ receptor inhibition	P2Y ₁₂ receptor inhibition
Loading dose	150–300 mg (80–150 mg intravenously)	300–600 mg	60 mg	180 mg
Maintenance dose	75–150 daily	75 mg daily	10 (5) mg daily	90 mg twice daily
Activation	Prodrug, hydrolysis by an esterase	Prodrug, variable hepatic metabolism	Prodrug, predictable hepatic metabolism	Active drug with additional active metabolite
Action	Irreversible	Irreversible	Irreversible	Reversible
Action onset	30–40 min	2–6 hours	30 min	30 min
Action duration	5 days	3–10 days	7–10 days	3–5 days
Interruption before surgery	No interruption when possible (5 days if high bleeding risk surgery)	5 days	7 days	5 days
Plasmatic half-life of prodrug	2–3 hours	30–60 min	30–60 min	6–12 hours
Inhibition of adenosine reuptake	No	No	No	Yes
Indications	<ul style="list-style-type: none"> • Stable CAD • ACS 	<ul style="list-style-type: none"> • Stable CAD • ACS 	<ul style="list-style-type: none"> • ACS scheduled for PCI 	<ul style="list-style-type: none"> • ACS • Stable CAD after MI
Contraindications	<ul style="list-style-type: none"> • Active bleeding • Hypersensitivity to aspirin • Severe hepatic failure 	<ul style="list-style-type: none"> • Active bleeding • Severe hepatic failure 	<ul style="list-style-type: none"> • Active bleeding • History of stroke or TIA • Severe hepatic failure (Child-Pugh C) 	<ul style="list-style-type: none"> • Active bleeding • History of intracranial bleeding • Moderate to severe hepatic failure • Coadministration with potent cytochrome CYP3A4 inhibitors

ACS, acute coronary syndrome; CAD, coronary artery disease; MI, myocardial infarction; PCI, percutaneous intervention; TIA, transient ischemic attack.

PRASUGREL

Prasugrel—a novel thienopyridine—is a prodrug, inhibits adenosine diphosphate-induced platelet aggregation more rapidly, more consistently, and to a greater extent than do standard and higher doses of clopidogrel. Prasugrel was first studied in 10,074 moderate- to high-risk ACS patients (74% were NSTEMI) in TRITON-TIMI-38¹⁶ trial. Patients were randomly assigned 13,608 patients with moderate-to high-risk ACS, of whom 10,074 (74%) had unstable angina (UA)/non-ST-segment elevation myocardial infarction (NSTEMI), to receive prasugrel (a 60-mg loading dose and a 10-mg daily maintenance dose) or clopidogrel (a 300-mg loading dose and a 75-mg daily maintenance dose) after coronary anatomy was defined, for a median follow-up of 14.5 months. Total 12.1% patients in the prasugrel arm experienced the primary efficacy end point [a composite of the rate of death due to CV causes (including arrhythmia, congestive heart failure, shock, and sudden or unwitnessed death), nonfatal MI, or nonfatal stroke] compared to 9.9% in clopidogrel arm [hazard ratio (HR) for prasugrel vs. clopidogrel, 0.81; 95% CI, 0.73–0.90; p <0.001]; conferring significant 2.2% absolute reduction and a 19% relative reduction with prasugrel. There was significant reductions in secondary end points of MI (9.7% for clopidogrel vs. 7.4% for prasugrel; p <0.001), urgent target-vessel revascularization (3.7% vs. 2.5%; p <0.001), and stent thrombosis (2.4% vs. 1.1%; p <0.001). This was at the expense of statistically insignificant increase in major bleeding (2.4% in prasugrel arm and 1.8% in clopidogrel arm; HR, 1.32; 95% CI, 1.03–1.68; p = 0.03), life-threatening bleeding (1.4% vs. 0.9%; p = 0.01), including nonfatal bleeding (1.1% vs. 0.9%; HR, 1.25; p = 0.23) and fatal bleeding (0.4% vs. 0.1%; p = 0.002). In the few patients who underwent coronary artery bypass graft (CABG), TIMI major bleeding through 15 months was also greater with prasugrel than with clopidogrel (13.4% vs. 3.2%, respectively; HR for prasugrel: 4.73; 95% CI: 1.90–11.82; p <0.001). The net clinical benefit in the TRITON-TIMI-38 study demonstrated a primary efficacy and safety end point rate of 13.9% in the clopidogrel group versus 12.2% in the prasugrel group (HR: 0.87; 95% CI: 0.79–0.95; p = 0.004). The US-FDA labeling information, derived from *post hoc* analysis of the trial patients suggested that there were three subgroups of ACS patients who did not have favorable clinical benefit from prasugrel because of higher risk of fatal or intracranial bleed. These subgroups were patients with a history of stroke or transient ischemic attack before enrolment, patients with a body weight of less than 60 kg had no net benefit, patients age more than 75 years.

Two double blind, placebo-controlled RCTs have addressed the question of DAPT timing in ACS. The Targeted Platelet Inhibition to Clarify the Optimal Strategy to Medically Manage Acute Coronary Syndromes (TRILOGY ACS) trial¹⁹ randomized patients with ACS who were initially medically managed with prasugrel or clopidogrel, in comparison to TRITON-TIMI-38 trial which prasugrel was given to ACS patients only after coronary anatomy is defined and patients are destined for PCI. For medically managed CS patients

prasugrel did not offered any benefit over clopidogrel and similar risk of bleeding observed.

In a NSTE-ACS (non-ST-segment elevation acute coronary syndromes) cohort, the ACCOAST study²⁰ compared prasugrel pretreatment (30 mg preangiography, followed by 30 mg postangiography), with 60 mg prasugrel loading postangiography and pre-PCI. There was no difference in the primary end point of CV death, stroke, MI, and urgent revascularization; although bleeding was nearly twice as high in the pre-treatment arm. This led to guideline recommendation guideline to recommend of avoiding pretreatment with prasugrel in patients diagnosed with NSTE-ACS.

TICAGRELOR

Ticagrelor is the first nonthienopyridine, direct ADP blocker and reversibly inhibits the P2Y₁₂ platelet receptor leading to more rapid and consistent platelet inhibition. Adenosine reuptake is also inhibited by ticagrelor, this causes symptoms of dyspnea (~5%) and bradycardia with occasional sinus pauses.

The Platelet Inhibition and Patient Outcomes (PLATO) study²¹ was a large, global, randomized clinical trial comparing ticagrelor (180 mg loading dose, followed by 90 mg twice daily) and clopidogrel (300–600 mg loading dose at investigator discretion, followed by 75 mg daily), and enrolled 18,624 patients with ACS. At 12 months, the primary end point—a composite of death from vascular causes, MI, or stroke—had occurred in 9.8% of patients receiving ticagrelor as compared with 11.7% of those receiving clopidogrel (HR, 0.84; 95% CI, 0.77–0.92; p <0.001). The rate of death from any cause was also reduced with ticagrelor (4.5%, vs. 5.9% with clopidogrel; p <0.001). PLATO major bleeding (the primary safety end point) was not different between the study arms. This was attributed to the rapidly reversible mechanism of action of ticagrelor. There was more non-CABG-related major bleeding observed in the ticagrelor group compared with clopidogrel (4.5% vs. 3.8%; HR, 1.19; p = 0.03), whereas CABG-related major bleeding was similar between the treatments (Table 2).

A phenomenon of “North American Paradox” was noted, in which patients enrolled in the United States had outcomes favoring clopidogrel and qualitatively different from the overall results of the trial. Extensive analyses suggested that a different dose of aspirin used in the United States compared with the rest of the world (325 mg vs. ≤100 mg) explained much of this difference. The hypothesis for this phenomenon was—higher doses of aspirin given with ticagrelor are associated with increased bleeding risks with the possibility of reduced efficacy as well. Ticagrelor in Patients With ST-Elevation Myocardial Infarction Treated With Pharmacological Thrombolysis—TREAT trial²² is a multicenter, randomized, open-label with blinded end point adjudication trial that enrolled 3,799 patients (younger than 75 years) with STEMI receiving fibrinolytic therapy in 152 sites from ten countries. The primary outcome of TIMI major

CABG, coronary artery bypass graft; PCI, percutaneous intervention coronary; PLATO, The Platelet Inhibition and Patient Outcomes; TRITON-TIMI, Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-Thrombolysis in Myocardial Infarction; T, test/study population; C, control population.

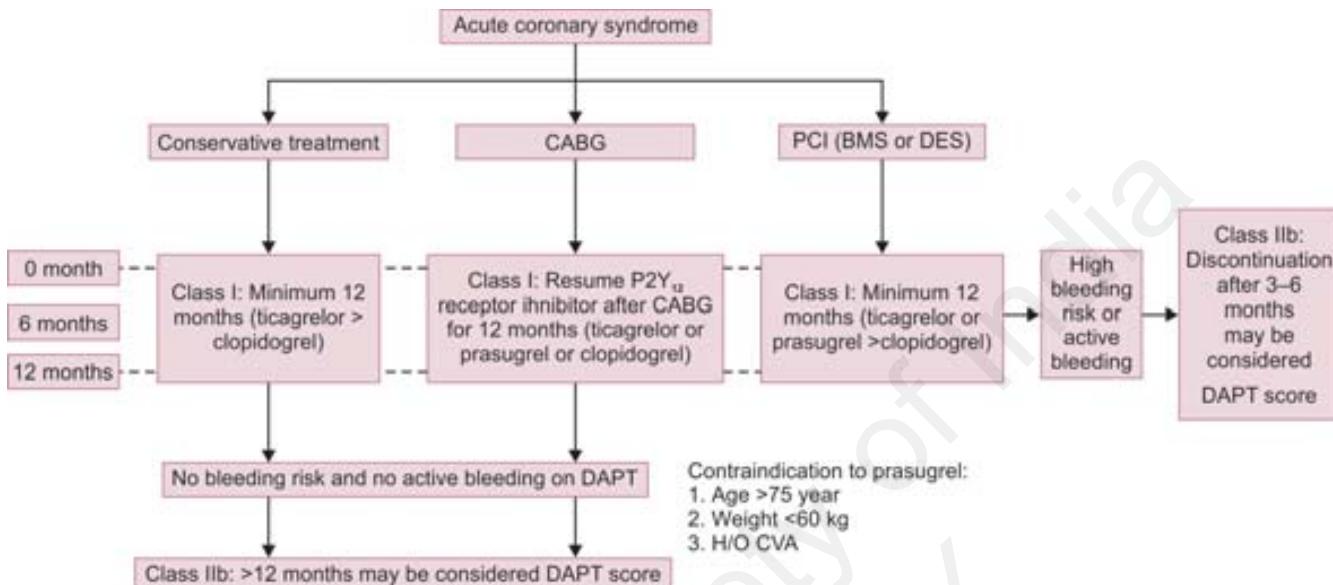

bleeding occurred in 0.73% of the ticagrelor group versus 0.69% of the clopidogrel group (p <0.001 for noninferiority). Although the trial was not powered for efficacy, there was no apparent ischemic benefit with ticagrelor. Among patients less than 75 years of age who were treated with fibrinolysis for STEMI, delayed administration of ticagrelor was noninferior to clopidogrel. Ticagrelor represents a treatment option in such patients (i.e., clopidogrel allergy); however, unless future trials show otherwise, ticagrelor is not preferential to clopidogrel after fibrinolysis for STEMI.

As per both European and American guidelines for management of ACS, aspirin forms the backbone DAPT-regimen. For second antiplatelet therapy, ticagrelor (regardless of initial treatment strategy) or prasugrel (only for patients undergoing invasive management) should be preferred over clopidogrel. But clopidogrel is the still the most commonly

used second antiplatelet because of wide availability and low cost (Flowchart 1).

CONCLUSION

For patients with ACS, aspirin forms the backbone of DAPT. For second antiplatelet, amongst the three available P2Y₁₂ inhibitors, ticagrelor has the most rapid-onset of action, most potent and having least side effects, also it can be used for medically managed patients and patients undergoing intervention. So, ticagrelor is the preferred second antiplatelet agent in the DAPT regimen. Clopidogrel being the most extensively studied drug, it is preferred in the patients with multiple risk factors and comorbidities. Prasugrel, though highly potent, has very limited utility because of risk of bleeding.

Optimal Duration of Dual Antiplatelet Therapy after Acute Coronary Syndrome: Current Status

Dhiman Kahali, Vivek Singh Rathore

INTRODUCTION

Acute coronary syndrome (ACS) is a disease spectrum that comprises of unstable angina, ST-segment elevation myocardial infarction (STEMI) and non-STEMI (NSTEMI). It is the main cause of mortality in coronary artery disease (CAD) and represents a principle form of its clinical presentation.

Antiplatelet therapy is the treatment where platelet activation and aggregation are reduced, which are the primary steps toward the formation of a thrombus after the disruption of plaque.

Although there are several potential combinations of antiplatelet therapy, the term and acronym dual antiplatelet therapy (DAPT) is used to specifically refer to combination antiplatelet therapy with the drugs aspirin along with a P2Y₁₂ receptor inhibitor (clopidogrel, prasugrel, or ticagrelor).

Dual antiplatelet therapy which includes acetylsalicylic acid (ASA) in addition to a P2Y₁₂ inhibitor is the principle treatment after an ACS or after patients undergoing a percutaneous coronary intervention (PCI), toward preventing recurrent ischemic events such as stent thrombosis.

Ever since the dawn of drug-eluting stents (DESs) era the rates of restenosis have dramatically decreased. Though the first-generation DESs have been associated with a slighter increased rates of stent thrombosis, which is the complication most feared in coronary stenting as it has higher mortality. Ever since the introduction of the new, second-generation DES, along with the usage of stronger P2Y₁₂ inhibiting drugs, the stent thrombosis rates have halved. The second-generation DES are indeed superior in all aspects.

Due to the improved status of the stents available to us today, the focus is now shifting toward the flipside of DAPT, such as the bleeding. The most important risk factor of stent thrombosis is due to discontinuation of clopidogrel prematurely. The quest to strike the right balance between lower complications of coronary stents and increased awareness of bleeding from DAPT leads to the probing question—What is the optimal duration of DAPT?

Dual antiplatelet therapy is mandatory in the first months after stent implantation until endothelialization has been

completed. As the risk of late stent thrombosis is less of a concern with second-generation DES, prolonged DAPT is now more aimed at preventing (recurrent) myocardial infarction (MI) not related to the implanted stent. Thus, rather than focusing on the stent or the angiogram alone, the key to success is to treat the patient's overall thrombotic risk.¹

RISK STRATIFICATION TOOLS FOR ISCHEMIA AND BLEEDING RISKS

The probing decision for a DAPT duration depends largely on the ischemic versus bleeding risks, and with the help of scoring systems it helps to tailor the DAPT duration maximizing ischemic protection and reduce the bleeding risks in a patient (Table 1).

The Dual Antiplatelet Therapy Score

The DAPT score was initially validated in patients who were enrolled in PROTECT (Patient-Related Outcomes with Endeavor vs. Cypher Stenting) trial.² This prediction rule identified nine factors [age, congestive heart failure/low left ventricular ejection fraction (LVEF), vein graft stenting, MI at presentation, prior MI or PCI, diabetes, stent diameter <3 mm, smoking, and paclitaxel-eluting stent] resulting in a score ranging from -2 to +10].³

Within the DAPT trial,⁴ a high-risk score (i.e., a score ≥ 2) showed a reduction in MI or stent thrombosis and cardiovascular (CV) or cerebrovascular events risk after a prolonged, 30-month DAPT, with only a modest increase in bleeding risk. And a low-risk score (<2) selected patients recruited in the DAPT trial who did not derive any reduction of ischemic events from prolonging DAPT, with a significant increase in moderate or major bleeding.⁴

PRECISE-DAPT Score

The PRECISE-DAPT⁵ (Predicting Bleeding Complications in Patients Undergoing Stent Implantation and Subsequent

TABLE 1: DAPT score and PRECISE-DAPT score systems

CHF, congestive heart failure; CrCl, creatinine clearance; DAPT, dual antiplatelet therapy; LVEF, left ventricular ejection fraction; MI, myocardial infarction; PCI, percutaneous coronary intervention; WBC, white blood cells.

Dual Antiplatelet Therapy) study had patients with CAD who underwent PCI either elective, urgent, or emergent. It generated a five-item [age, creatinine clearance (CrCl), hemoglobin, white blood cell count, and prior spontaneous bleeding] prediction algorithm in patients being treated with DAPT for out-of-hospital bleeding.⁵

This score was assessed in the PLATO (Platelet Inhibition and Patient Outcomes) trial⁶ and the Bern PCI registry. It was seen that a high-bleeding risk according to PRECISE-DAPT (PRECISE-DAPT score ≥25) a prolonged DAPT was not associated with ischemic benefit but a high-bleeding burden.⁵

Though, these risk prediction systems have not been tested as prospective randomized studies hence their value remains unclear.

TYPE OF P2Y₁₂ INHIBITOR AND TIMING OF INITIATION

Clopidogrel

Clopidogrel is the safer drug, especially in terms of skin and gastrointestinal disorders, neutropenia, and allergy though they have a similar degree of P2Y₁₂ inhibition and bleeding risk.

Prasugrel

Prasugrel's P2Y₁₂ inhibition is faster and greater having a more consistent degree of activity compared to clopidogrel. Prasugrel needs two metabolic steps in forming the active metabolite that is similar to clopidogrel active metabolite.

Ticagrelor

Ticagrelor comes from a newer chemical class, cyclopentyl-triazolopyrimidine, which is a direct oral, reversibly binding P2Y₁₂ inhibitor with nearly 12 hours of plasma half-life.

P2Y₁₂ Inhibitors in Patients of STEMI Treated with Lysis

The P2Y₁₂ inhibitor which has been extensively studied in patients with STEMI undergoing initial treatment with thrombolysis is clopidogrel. The STREAM study (Strategic Reperfusion Early after Myocardial Infarction)⁷ took patients below 75 years with clopidogrel 300 mg loading dose and to those above 75 years of age 75 mg once daily without loading dose.

While prasugrel or ticagrelor were allowed as per protocol in patients with prior treatment with lysis in P2Y₁₂ inhibitor-naïve patients or those with prior clopidogrel administration, respectively, there are insufficient safety data to recommend their concomitant use during or soon after thrombolysis.³

The TREAT (Ticagrelor in Patients with ST-Elevation Myocardial Infarction Treated with Pharmacological Thrombolysis) trial⁸ infers that among patients below 75 years treated with fibrinolysis after STEMI, late administration of ticagrelor was noninferior to clopidogrel. There was no excess of major bleeding, fatal bleeding, or intracranial bleeding with ticagrelor versus clopidogrel. Ticagrelor represents a treatment option in such patients (i.e., clopidogrel allergy); however, unless future trials show otherwise, ticagrelor is not preferential to clopidogrel after fibrinolysis for STEMI.⁹

TABLE 2: Recommendations on P2Y₁₂ inhibitor selection and timing (ESC, 2017)³

Recommendation	Class
In ACS, ticagrelor (180 mg loading dose, 90 mg twice daily) on top of aspirin is recommended, regardless of initial treatment strategy, including patients pretreated with clopidogrel (which should be discontinued when ticagrelor is commenced)	I B
In patients with ACS undergoing PCI, prasugrel (60 mg loading dose, 10 mg daily dose) on top of aspirin is recommended for P2Y ₁₂ inhibitor-naïve patients with NSTE-ACS or initially conservatively managed STEMI if indication for PCI is established, or in STEMI patients undergoing immediate coronary catheterization	I B
Pretreatment with a P2Y ₁₂ inhibitor is generally recommended in patients in whom coronary anatomy is known and the decision to proceed to PCI is made and in patients with STEMI	I A
In patients with NSTE-ACS undergoing invasive management, ticagrelor administration (180 mg loading dose, 90 mg twice daily), or clopidogrel (600 mg loading dose, 75 mg daily dose) if ticagrelor is not an option, should be considered as soon as the diagnosis is established	IIa C
In patients with stable CAD, pretreatment with clopidogrel may be considered if the probability of PCI is high	-
Clopidogrel (600 mg loading dose, 75 mg daily dose) with aspirin is recommended in stable CAD patients undergoing coronary stent implantation and in ACS patients who cannot receive ticagrelor or prasugrel, including those with prior intracranial bleeding or indication for OAC	-
Clopidogrel (300 mg loading dose in patients aged <75 years, 75 mg daily dose) is recommended on top of aspirin in STEMI patients receiving thrombolysis	-

ACS, acute coronary syndrome; CAD, coronary artery disease; ESC, European Society of Cardiology; NSTE, non-ST-segment elevation myocardial infarction; OAC, oral anticoagulant; PCI, percutaneous coronary intervention; STEMI, ST-segment elevation myocardial infarction.

TABLE 3: Measures to minimize bleeding while on dual antiplatelet therapy³

Recommendations	Class
Radial over femoral access is recommended for coronary angiography and PCI if performed by an expert radial operator	I A
In patients treated with DAPT, a daily aspirin dose of 75–100 mg is recommended	I A
A PPI in combination with DAPT is recommended	I B
Routine platelet function testing to adjust antiplatelet therapy before or after elective stenting is not recommended	III A

DAPT, dual antiplatelet therapy; PCI, percutaneous coronary intervention; PPI, proton pump inhibitor.

Timing of Initiation of P2Y₁₂ Inhibitor

A reasonable approach to start P2Y₁₂ inhibitor according to their approval studies is to start clopidogrel and ticagrelor as soon as possible whereas for prasugrel, it must be started only after decision for PCI based on coronary anatomy is established (Table 2).

Aspirin in Patients Treated with DAPT

Low-dose aspirin (<100 mg daily) is associated with less major and total bleeding while being compared with high doses, as because daily doses of 30–50 mg is usually adequate to inactivate the platelet cyclooxygenase-1 enzyme and inhibit thromboxane production completely.

Also, it must be noted that the efficacy of ticagrelor is reduced with higher doses of aspirin (>300 mg daily) compared to lower doses (<100 mg daily). To balance between the bleeding risks and ischemic events 75–100 mg of aspirin apparently is the optimal range.

Type, Dose of P2Y₁₂ Inhibitor and Duration of Treatment

According to the varying stages of CAD, the type and dose of P2Y₁₂ inhibitor are well established. Ongoing bleeds or previous intracranial hemorrhage are common contraindications for prasugrel and ticagrelor. And in patients below 75 years,

weighing under 60 kg or with history of cerebrovascular accident; prasugrel should not be used.

It is very common to switch between the P2Y₁₂ inhibitors mainly in episodes of minor bleeding or in those patients who have a low platelet reactivity which acts as a marker for risk for major bleeding (Table 3).

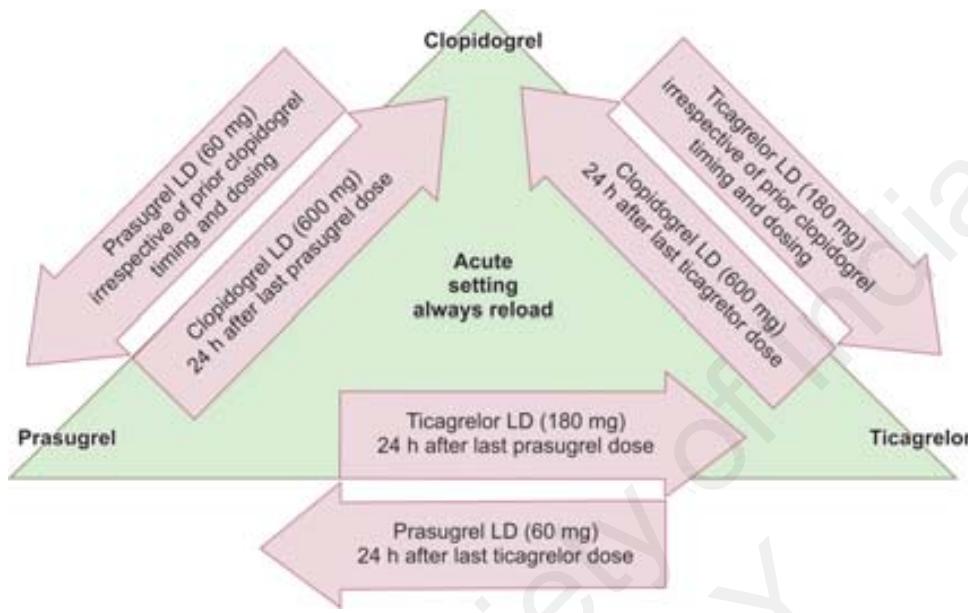

There are no properly powered randomized data on the long-term safety or efficacy of “switching” patients treated for weeks or months with a P2Y₁₂ inhibitor to a different P2Y₁₂ inhibitor. Therefore, this practice is generally discouraged.³

According to the 2017 European Society of Cardiology (ESC) guidelines,³ in patients with ACS who were previously exposed to clopidogrel, switching from clopidogrel to ticagrelor is recommended early after hospital admission at a loading dose of 180 mg irrespective of timing and loading dose of clopidogrel, unless contraindications to ticagrelor exist is a class I A indication (Fig. 1).

DAPT AFTER PERCUTANEOUS CORONARY INTERVENTION FOR ACS

DAPT with Novel P2Y₁₂ Inhibitors for 1 Year after PCI for ACS

Though both prasugrel and ticagrelor significantly increase risk of thrombolysis in myocardial infarction (TIMI) major noncoronary artery bypass grafting (non-CABG) related

FIG. 1: Switching between oral P2Y₁₂ inhibitors.

bleeds but the risk-benefit ratios are favorable. Data has established the 1-year course of DAPT, preferably with prasugrel or ticagrelor, for patients undergoing PCI for ACS, unless contraindicated.³

DAPT with Ticagrelor for Secondary Prevention after Myocardial Infarction

In the PEGASUS (Prevention of Cardiovascular Events in Patients with Prior Heart Attack Using Ticagrelor Compared to Placebo on a Background of Aspirin) trial,¹⁰ all the primary endpoints were consistently reduced with ticagrelor versus placebo, which was statistically significant for both 60 mg and 90 mg after MI and with 60 mg for stroke. There was an overall trend in reduction of CV mortality.

Those patients who had continued their treatment without (a major) interruption (≤ 30 days) derived more benefit from extended ticagrelor intake than those who interrupted their thienopyridine treatment for longer periods of time.³ Study result suggests that the patients who could continue the initial thienopyridine treatment were getting relatively greater benefit with DAPT continuation with ticagrelor.³

Patients having lower-extremity artery disease (LEAD), who are at greater ischemic risk, benefit hugely from extended ticagrelor. In this group of patients with ticagrelor versus placebo showed better primary efficacy endpoints and fewer ischemic and revascularization procedures were needed.

DAPT with Thienopyridines (Clopidogrel or Prasugrel) for Secondary Prevention after Myocardial Infarction

In the DAPT trial, trialists investigated the risks and benefits of extended versus standard duration of DAPT in patients with or without MI. Prasugrel was given to one-third of the

patients with MI and two-thirds received clopidogrel. In post-MI patient, extended DAPT when compared to aspirin alone showed reduction in stent thrombosis and major adverse cardiac events (MACE) significantly.

A meta-analysis study on DAPT effect (extended duration) in those patients who had MI including the PEGASUS and the subgroups of MI of studies—CHARISMA¹¹ (Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance), PRODIGY¹² (Prolonging Dual Antiplatelet Treatment After Grading Stent-Induced Intimal Hyperplasia), and DES-LATE¹³ (Drug-Eluting Stent-Late Coronary Arterial Thrombotic Event) with clopidogrel as well as ARCTIC-Interruption¹⁴ (dual-antiplatelet treatment beyond 1 year after DES implantation) and DAPT with clopidogrel or prasugrel interprets that there is a decrease in MACE when compared to giving aspirin alone. This benefit is attained at the cost of increased bleeding risk. Though the CV mortality reduction with DAPT was significant, but the absolute risk reduction was small (0.3%) with no difference seen in the all-cause mortality. This suggests a consistent effect amongst the three classes of P2Y₁₂ inhibitors (ticagrelor, clopidogrel, or prasugrel).

Beyond 1 year duration, it is reasonable to consider ticagrelor 60 mg twice a day as the drug of choice in prolonged DAPT in stable post-MI patients who have a lower bleeding risk, and to have clopidogrel as the reserved alternative if ticagrelor cannot be used (Table 4).

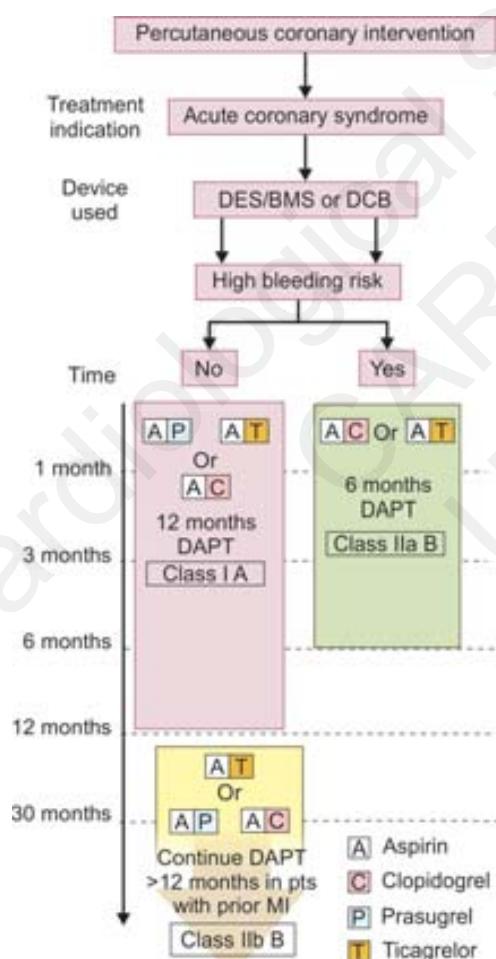

Shortening of DAPT Duration in Patients at High-bleeding Risk

After an ACS, the status of high-risk for bleeding is more challenging with regards to the duration and choice of DAPT (Fig. 2).

TABLE 4: Dual antiplatelet therapy duration in patients with acute coronary syndrome treated with percutaneous coronary intervention³

Recommendations	Class
In patients with ACS treated with coronary stent implantation, DAPT with a P2Y ₁₂ inhibitor on top of aspirin is recommended for 12 months unless contraindicated (e.g., PRECISE-DAPT >25)	I A
In patients with ACS and stent implantation, who are at high-risk of bleeding, discontinuation of P2Y ₁₂ inhibitor therapy after 6 months should be considered.	IIa B
In patients with ACS treated with bioresorbable vascular scaffolds, DAPT for at least 12 months should be considered	IIa C
In patients with ACS who have tolerated DAPT without a bleeding complication, continuation of DAPT for longer than 12 months may be considered	IIb A
In patients with MI and high ischemic risk, who have tolerated DAPT without a bleeding complication, ticagrelor 60 mg twice a day (bid) for longer than 12 months on top of aspirin may be preferred over clopidogrel or prasugrel	IIb B

ACS, acute coronary syndrome; DAPT, dual antiplatelet therapy; MI, myocardial infarction.

FIG. 2: Duration of DAPT in patients undergoing percutaneous coronary intervention.

A meta-analysis that includes six trials which compare the DAPT for 3 and 6 months duration to the 12-month duration suggested to consider to discontinue P2Y₁₂ inhibitor after a period of 6 months when the bleeding risk is high (Table 4).

DAPT IN PATIENTS TREATED WITH CABG SURGERY FOR ACS

Background

In ACS patients, the advantages of DAPT over aspirin alone is adequately proven to reduce the ischemic risks, but due to lack of dedicated studies in patients who will undergo CABG the evidence of DAPT benefits is limited.

There is an increase in the risk of perioperative bleed, increased need for transfusions and re-exploration when DAPT is continued till CABG, therefore it is recommended that P2Y₁₂ inhibitor should be stopped prior to an elective CABG whenever possible. An alternative is to defer elective surgeries until the DAPT treatment is completed.

In cases that are urgent, mostly the ACS group of patients, the thrombotic risk must be evaluated against the perioperative bleeding risk, while one waits for the effect of the drug P2Y₁₂ inhibitor to wear off (Table 5).

P2Y₁₂ Inhibitors

These drugs have different pharmacokinetic and pharmacodynamics properties and different inhibitory effects on platelets, thus the safe period for discontinuation of these agents also vary. In the CURE (Clopidogrel in Unstable Angina to Prevent Recurrent Events) trial,¹⁵ the substudy of the CABG group showed that discontinuation more than 5 days before CABG does not increase the bleeding risk. For prasugrel, a 7-day interval is recommended from the TRITON-TIMI 38 (Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-TIMI)¹⁶ and a 5-day period for ticagrelor.

However, newer data from the studies such as Swedish study and PLATO trial incline more toward a discontinuation period of 3 days.

Acetylsalicylic Acid

A meta-analysis which included 13 trials showed that ASA decreases the risk of perioperative MI while increasing postoperative bleeding, red cell transfusions, and increased surgical re-exploration.

The ASA of 100 mg was compared to placebo in the ATACAS (Aspirin and Tranexamic Acid for Coronary Artery Surgery)¹⁷ trial, where ASA was given on the day of the surgery in CABG patients. The ASA did not have any significant effect on the perioperative bleeding and neither did it reduce the incidence of thrombotic events.

Considering in to, the available evidence suggests that ASA given until the day of cardiac surgery has been associated with slight increase in risk of bleeding complications and significant decreased risk of perioperative MI. Platelet transfusions can be used if bleeding occurs during surgery. ASA can also be considered to be given throughout the perioperative period.

TABLE 5: Dual antiplatelet therapy in patients treated with cardiac surgery³

Recommendations	Class
In patients on aspirin who need to undergo nonemergent cardiac surgery, it is recommended to continue aspirin at a low daily regimen throughout the perioperative period	I C
In patients treated with DAPT after coronary stent implantation who subsequently undergo cardiac surgery, it is recommended to resume P2Y ₁₂ inhibitor therapy postoperatively as soon as is deemed safe so that DAPT continues until the recommended duration of therapy is completed	I C
In patients on P2Y ₁₂ inhibitors who need to undergo nonemergent cardiac surgery, postponing surgery for at least 3 days after discontinuation of ticagrelor, at least 5 days after clopidogrel, and at least 7 days after prasugrel should be considered	IIa B
In CABG patients with prior MI who are at high risk of severe bleeding (e.g., PRECISE-DAPT ≥25), discontinuation of P2Y ₁₂ inhibitor therapy after 6 months should be considered	IIa C
Platelet function testing may be considered to guide decisions on timing of cardiac surgery in patients who have recently received P2Y ₁₂ inhibitors	IIb B
In patients perceived to be at high ischemic risk with prior MI and CABG, who have tolerated DAPT without a bleeding complication, treatment with DAPT for longer than 12 months and up to 36 months may be considered	IIb C

CABG, coronary artery bypass grafting; DAPT, dual antiplatelet therapy; MI, myocardial infarction.

Testing of Platelet Function

There is a wide variability amongst the different drugs of P2Y₁₂ inhibitor group in terms of platelet inhibitory effect, duration, and magnitude of antiplatelet effect. The platelet function test may help in deciding the timing of surgery and also guide to gauge the antiplatelet effect where the duration of drug discontinuation is not clear.

The assessment of platelet aggregation capacity in the preoperative period can predict bleeding complications that is CABG-related in clopidogrel and ticagrelor-treated patients of ACS (Fig. 3).

The results suggest that in patients with ACS who are referred for CABG, the platelet function test is helpful in guiding the timing of CABG in patients taking P2Y₁₂ inhibitors.

DAPT FOR PATIENTS WITH MEDICALLY MANAGED ACS

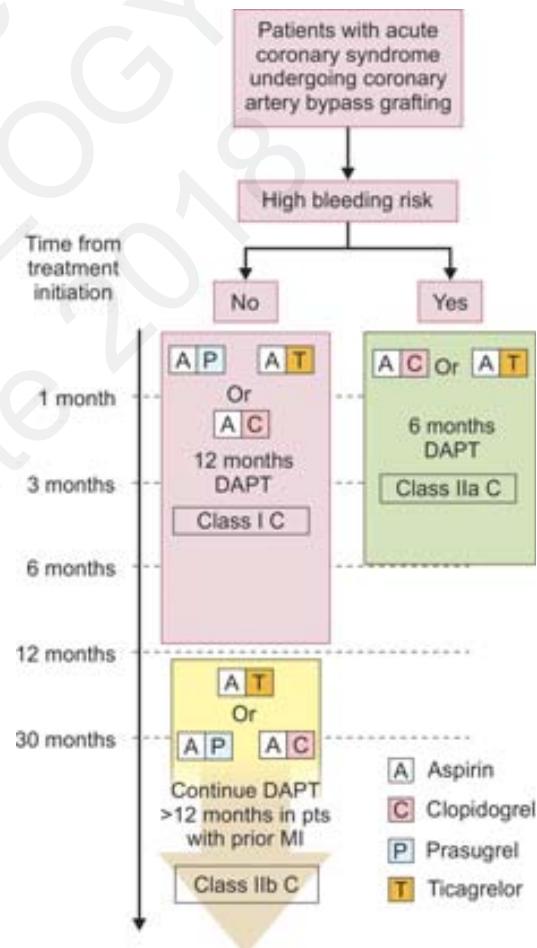

In ACS patients who are being managed medically, the studies from which the evidence is derived are the CHARISMA and CURE trials for clopidogrel, TRILOGY ACS (The Targeted Platelet Inhibition to Clarify the Optimal Strategy to Medically Manage Acute Coronary Syndromes) trial¹⁸ for prasugrel, and the PLATO and PEGASUS trials for ticagrelor (Fig. 4).

The CURE study shows evidence that a DAPT treatment of 9-month duration is beneficial when compared to a 1 month treatment in the NSTE-ACS patient group, irrespective of the management strategy.

Although the overall result of the CHARISMA trial do not show benefit of DAPT over aspirin alone, but the patients of post-MI subset in the CHARISMA trial shows benefit of DAPT in terms that antiplatelet drugs beyond 1 year reduce long-term ischemic recurrences, even if it is at the cost of higher bleeding episodes.

The results of TRILOGY study were negative for prasugrel in medically managed ACS.

In the medically managed subset of patients of the PLATO trial there was benefit from ticagrelor 90 mg given twice

DAPT, dual antiplatelet therapy; MI, myocardial infarction.

FIG. 3: DAPT duration in patients with acute coronary syndrome undergoing coronary artery bypass grafting.

daily when compared to clopidogrel with overall mortality reduction.

The PEGASUS trial draws evidence that consistent benefits and risks are drawn from ticagrelor.

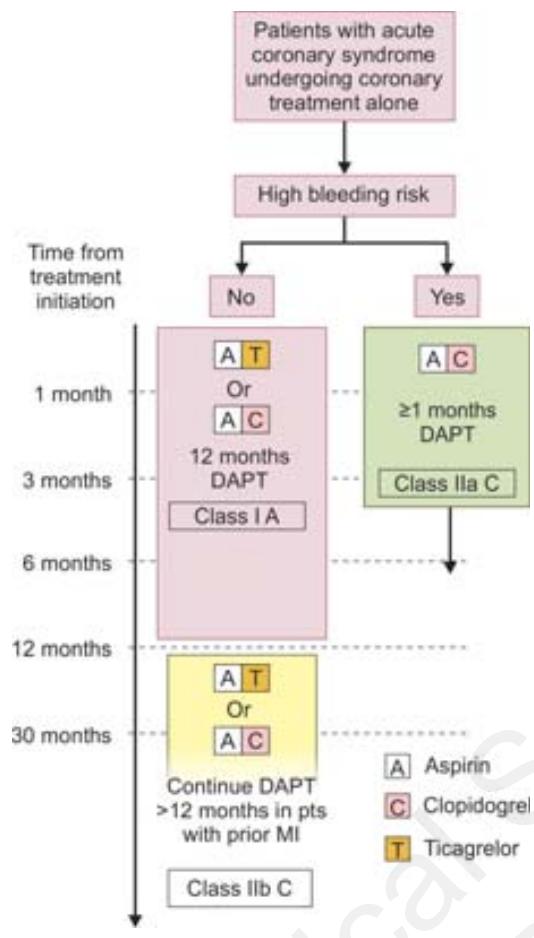

FIG. 4: Duration of DAPT in patients with acute coronary syndrome undergoing medical treatment alone.

Multiple sources reveal that the patients of ACS being medically managed receive the DAPT treatment less frequently comparing to the group of patients who undergo PCI (Table 6).

RESISTANCE TO DRUGS

It must be noted that resistance with both aspirin and clopidogrel is prevalent and can be deduced from the fact that a large number of patients despite being on these antiplatelets in adequate dosage and complete compliance may still have ischemic events.

Aspirin resistance has been estimated to exist, anywhere from 5 to 45% of the population. This prevalence of aspirin resistance is very important and of great alarming clinical concern. Aspirin resistance generally describes the failure of aspirin to produce an expected biological response (i.e., inhibition of platelet aggregation) or preventing the atherothrombotic events.¹⁹

Clopidogrel resistance is said to be clopidogrel fails to achieve the platelet inhibition effect. The initial results indicate that clopidogrel's low antiplatelet effect may lead to have more risk of having CV events. The interpatient

TABLE 6: Dual antiplatelet therapy duration in patients with ACS undergoing medical therapy management³

Recommendations	Class
In patients with ACS who are managed with medical therapy alone and treated with DAPT, it is recommended to continue P2Y ₁₂ inhibitor therapy (either ticagrelor or clopidogrel) for 12 months	I A
Ticagrelor is recommended over clopidogrel, unless the bleeding risk outweighs the potential ischemic benefit	I B
In medically managed ACS at high-risk of bleeding (e.g., PRECISE-DAPT >25), DAPT for at least 1 month should be considered	IIa C
In patients with prior MI at high ischemic risk who are managed with medical therapy alone and have tolerated DAPT without a bleeding complication, treatment with DAPT in the form of ticagrelor 60 mg bid with aspirin for longer than 12 months and up to 36 months may be considered	IIb B
In patients with prior MI not treated with coronary stent implantation, who have tolerated DAPT without a bleeding complication and who are not eligible for treatment with ticagrelor, continuation of clopidogrel with aspirin for longer than 12 months may be considered	IIb C
Prasugrel is not recommended in medically managed ACS patients	III B

ACS, acute coronary syndrome; DAPT, dual antiplatelet therapy; MI, myocardial infarction; PRECISE-DAPT, Predicting Bleeding Complications in Patients Undergoing Stent Implantation and Subsequent Dual Antiplatelet Therapy.

variability in clopidogrel response is multifactorial. It can be due to extrinsic or intrinsic mechanisms such as drug-drug interactions involving cytochrome P450 3A4 (CYP3A4), or genetic polymorphisms of the P2Y₁₂ receptor and CYP3As.¹⁹

In more advanced countries the practice of genetic testing to determine the susceptibility or resistance to the antiplatelet drugs is on the rise, however given the factors of cost and availability it still remains to be in use in India.

DURATION OF DAPT AFTER PCI IN PATIENTS WITH PERIPHERAL ARTERY DISEASE

Every third patient affected by CAD also has a coexisting peripheral artery disease (PAD). Considering in totality, antiplatelet therapy should be used for patients who are having a high-risk for ischemia such as the patients who are having polyvascular atherosclerosis in multiple vascular beds.

When considered in totality, antiplatelet therapy in patients who are at a higher ischemic burden (i.e., patients with atherosclerosis of multiple vascular beds). Overall ischemic burden (polyvascular atherosclerosis), clinical risk factors for disease progression, DAPT tolerance in the 1st year, and bleeding risk affect the risk-benefit ratio of prolonged DAPT in patients with MI and PAD.²⁰ So all high ischemic burden patients must be evaluated individually to

determine the risks and the benefits of a prolonged regime of DAPT. With the data that is available to us, a prolonged regime (>12 month) of DAPT should be considered strongly in patients post PCI with evidence of PAD and with absence of any excessive risk of bleeding.

Recommendations in Peripheral Artery Disease

At present, there is no evidence of use of aspirin in asymptomatic patients. The AHA/ACC (American Heart Association/American College of Cardiology) guidelines²¹ for ankle-brachial index less than 0.90 recommend use of antiplatelets as reasonable, whereas the ESC does not recommend its use in asymptomatic patients.

Patients with symptomatic PAD should be treated with antithrombotic therapy to reduce CV risk.²¹ Single antiplatelet therapy with either aspirin or clopidogrel is recommended.²¹ For those undergoing surgical revascularization, aspirin, clopidogrel, and rivaroxaban plus aspirin are all reasonable recommendations.

CONCLUSION

It will be fair to say that the optimal duration of DAPT after ACS is still debatable. To summarize, with the present stage of our knowledge DAPT should be continued till 1 year in a patient of ACS after PCI or even if on medical treatment following ACS. As SMART DATE (Safety of 6-month Duration of Dual Antiplatelet Therapy After Acute Coronary Syndromes) trial²² has clearly shown that discontinuing DAPT after 6 months results in increased incidents of MI and recurrent ischemic events, but if the chance of bleeding is very high, in those population or in the elderly patients DAPT can be stopped at 6 months. After stenting with a newer DES it is now somewhat acceptable, but as a routine we should continue DAPT till 1 year after the procedure and then we can think of discontinuing it. However, if the patient has got high chances of thrombosis such as in diabetics, patients with excessive thrombus load, recurrent angina then we may continue DAPT. And here a better choice would be low dose of ticagrelor 60 mg bid along with small dose of aspirin 75 mg daily till 3 years following the MI and the incidents of bleeding is not high, but the reduction of events is much lower because we know at 1-3 years after ACS, 1 in 8 patients tend to have recurrent ischemic event. It is relatively recent and important evidence that to prevent recurrent ischemic events in high-risk patients, it is fair enough to continue DAPT up to 3 years. And in our practice also we find that the incidents of bleeding are not so high in routine population even if we continue to use DAPT for longer durations. In an ongoing study on ticagrelor in the Indian population, we have seen that the incidents of bleeding are not high even if we continue it for another 2-3 years, but there is reduction of events in the trial, but due to confidentiality agreement we cannot tell details of the trial data as it is not yet submitted.

So to conclude we should continue DAPT for 1 year after stenting in a patient of ACS or even with medical treatment

and after 1 year in high thrombotic risk patient we can continue low-dose ticagrelor along with aspirin for another 2-3 years without any concern. Regarding the medical treatment of ACS patients, we have to give low-dose aspirin along with clopidogrel or ticagrelor 90 mg bid, but prasugrel has not been recommended as per the negative results found in TRILOGY trial with prasugrel. There are recommendations by the different international societies stating that ticagrelor and prasugrel should be used more frequently in patients with high thrombus load and where the blood is procoagulant like in diabetic population, in patients with STEMI or NSTEMI or in patients with chances of recurrent MI or recurrent ACS.

In case of CABG it is better to use the DAPT for a year and then to go for single antiplatelet agent. For PAD, along with ACS we can think of DAPT for a year and then a single antiplatelet agent can be used along with other drugs and trained exercise program.

Switching Between DAPT Agents: The Right Strategy

Harinder K Bali, Hiteshi KC Chauhan

DUAL ANTIPLATELET THERAPY CLINICAL CONUNDRUM UNRAVELED

Dual antiplatelet therapy (DAPT), comprising of aspirin given in conjunction with a P2Y12 receptor antagonist, is the backbone of treatment strategy in patients presenting with acute coronary syndromes (ACS) with the aim of preventing atherothrombotic events.¹⁻⁵

With a research timeline spanning 22 years⁶ and with over 35 randomized clinical trials, DAPT is one of the most meticulously and extensively researched treatment strategies in the annals of cardiovascular medicine (Fig. 1).² Over the

last two decades, DAPT has undergone rapid evolution from being merely a “local” stent-related treatment strategy to a wider “systemic” one capable of preventing thrombotic arterial occlusions.²

Despite intense clinical research leading to updated guidelines and focused updates on DAPT, practicing clinicians, across the world, often find it difficult to incorporate these into practice, especially considering different patient subsets, varied clinical settings, cost constraints, and drug availability issues in different geographical locations.¹⁻⁵

Availability of multiple oral P2Y12 inhibitors and a novel intravenous (IV) P2Y12 inhibitor has given physicians

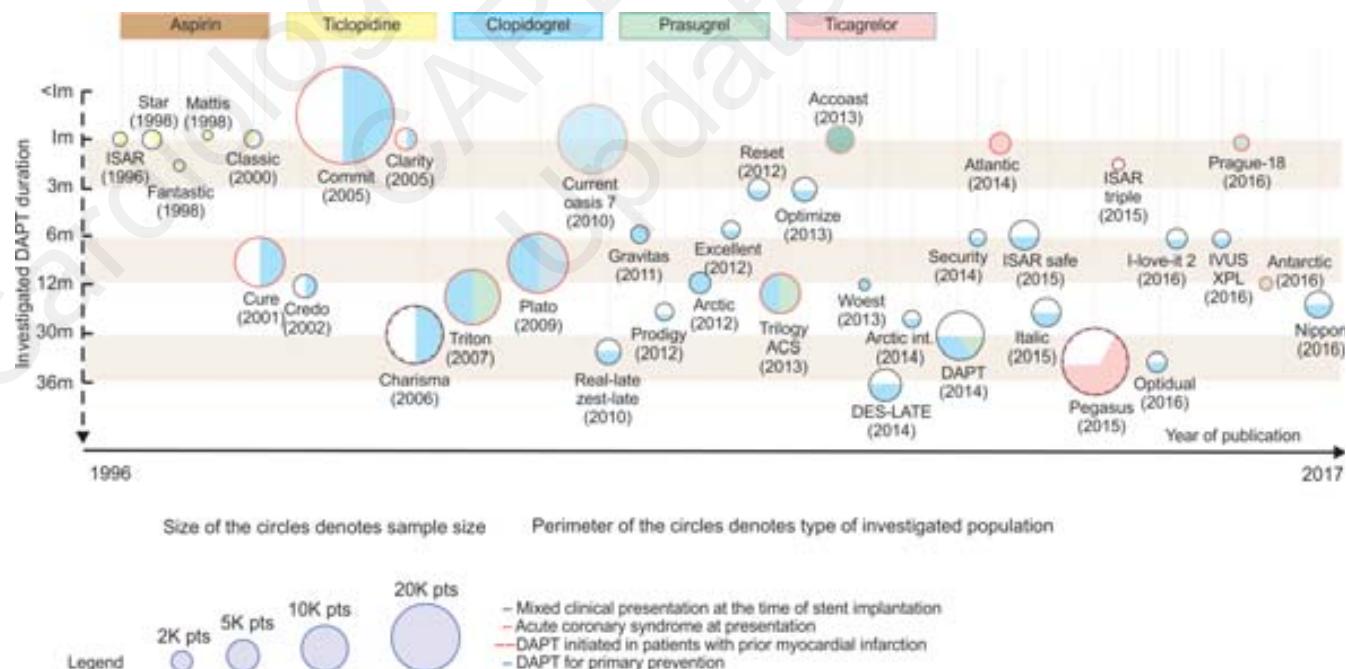

FIG. 1: History of dual antiplatelet therapy in patients with coronary artery disease.

Source: Reprinted with permission from: 2017 ESC focused update on dual antiplatelet therapy in coronary artery disease developed in collaboration with EACTS: The Task Force for dual antiplatelet therapy in coronary artery disease of the European Society of Cardiology (ESC) and of the European Association for Cardio-Thoracic Surgery (EACTS). Eur Heart J. 2017;39(3):213-60.

the apparently attractive option of switching antiplatelet therapy to address a multitude of factors: patient-specific characteristics, drug compliance issues, adverse effects, drug-drug interactions (DDIs) and cost considerations.^{7,8} Therefore, in spite of lingering concerns fueled by paucity of scientifically reliable data on safety and efficacy of switching between DAPT agents, it is undertaken quite frequently in clinical practice.²

All the aforementioned factors deepen the recurrent clinical dilemma physicians' face regarding personalization of DAPT therapy, including optimal type, duration, and ideal timing of switching of DAPT agents, while treating patients with different clinical manifestations of coronary artery disease (CAD).

It is, therefore, extremely important for physicians to be well versed with drug pharmacology, different switching modalities, available literature¹⁻⁸ and latest consensus recommendations to decide upon the right timing and strategy of switching antiplatelet therapies.⁹

The treating physician must tailor DAPT therapy for each individual patient after meticulously evaluating the trade-off between ischemic and bleeding risk: at initiation, during follow-up, and at completion.⁷

P2Y12 Receptor Antagonists

Pharmacological Profile

The unique pharmacological properties of P2Y12 receptor antagonists are of utmost clinical significance (Table 1).^{8,9} While switching P2Y12 inhibitors, these differences in their pharmacological profile, including drug half-life, site and mechanism of binding of P2Y12 receptors, and rate of onset and offset of drug effect, may enhance the potential for DDIs due to either inadequate or excessive platelet reactivity.

This may lead to adverse clinical outcomes (thrombotic or bleeding complications, respectively).⁹⁻¹¹

Oral P2Y12 Receptor Antagonists

- *Ticlopidine:* The first available platelet P2Y12 inhibitor, ticlopidine, is no longer used due to safety concerns¹²
- *Clopidogrel:* This “staple” quintessential second-generation thienopyridine retains its position of being the most prescribed P2Y12 inhibitor, worldwide.^{1,13} This prodrug is ~85% hydrolyzed by human carboxylesterase-1 into an inactive metabolite after intestinal absorption.¹⁴ Thereafter, cytochrome P-450 isoenzymes oxidize the remaining 15% to create an active metabolite, which binds the adenosine diphosphate (ADP) site irreversibly. The variable pharmacodynamic response to this drug attributable to myriad of factors, ranging from pharmacological properties to genotype polymorphism, lessens its stability and potency.¹⁵

In patients with stable CAD^{1,2} and in those presenting with ST-elevation myocardial infarction (STEMI) after thrombolysis,^{16,17} clopidogrel is strongly recommended as compared to its newer counterparts

- *Prasugrel:* It is also a prodrug-like clopidogrel. However, its active metabolite is generated faster and in higher plasma concentration via a single-step hepatic cytochrome [CYP] oxidation. Therefore, this third-generation thienopyridine achieves higher, consistent and more potent platelet inhibitory effect, as compared to clopidogrel.¹⁴ Due to irreversible binding of active metabolite and enhanced platelet inhibition achieved by prasugrel, platelet recovery time is longer at 7–10 days after treatment discontinuation, as compared to clopidogrel (5–7 days)^{18,19}

TABLE 1: Pharmacological profile of P2Y12—receptor inhibitors

	Clopidogrel	Prasugrel	Ticagrelor	Cangrelor
Drug class	Thienopyridine	Thienopyridine	Cyclopentyl triazolopyrimidine	ATP analogue
Administrative route	Oral	Oral	Oral	Intravenous
Dosing frequency	Once daily	Once daily	Twice daily	Bolus, infusion
Onset of action	2–8 h	30 min–4 h	30 min–4 h	2 min
Offset of action	5–7 days	7–10 days	3–5 days	30–60 min
P2Y12—receptor blockade	Irreversible	Irreversible	Reversible	Reversible
Prodrug	Yes	Yes	No	No
Half-life:				
A. Parent drug	~6 h	<5 min	6–12 h	3–6 min
B. Active metabolite	30 min	• Distribution half-life—30–60 min • Elimination half-life—2–15 h	8–12 h	Not applicable
Binding site	ADP	ADP	Allosteric	Undetermined
Type of binding	Competitive	Competitive	Noncompetitive	Undetermined

ADP, adenosine diphosphate; ATP, adenosine triphosphate.

- Ticagrelor:** This oral cyclopentyl-triazolopyrimidine is a direct-acting compound, which does not require hepatic metabolism. However, an active metabolite produced by the CYP3A4/5 enzymes is responsible for one-third of its effect.²⁰ This drug reversibly binds the P2Y12 receptors at a unique site through a noncompetitive, allosteric mechanism.²⁰

Ticagrelor rates higher on both potency and predictability, as compared to the older P2Y12 receptor antagonists.²⁰ However, this drug has two limitations: a quicker offset of action due to its reversible binding and a relatively short half-life of 6–12 hours, which necessitates a twice daily dosing and may compromise long-term compliance.²¹

The newer, more potent kids on the P2Y12-inhibitor block—prasugrel and ticagrelor—are recommended as first-line agents in ACS and in patients undergoing percutaneous coronary intervention (PCI), as they remarkably decrease the incidence of ischemic events, particularly the risk of stent thrombosis (ST).^{22,23}

Intravenous P2Y12 Receptor Inhibitor

Cangrelor: The only intravenous P2Y12 receptor inhibitor currently available is an ATP analogue, which directly and reversibly binds to the P2Y12 receptor at an undetermined site. Its effect is dose-dependent and is distinguished by a high level of receptor occupancy.^{24,25} Cangrelor is rapidly inactivated by ectonucleotidase via dephosphorylation. Therefore, platelet function is recovered within ~60 minutes of stopping its infusion.^{24,25}

Optimal Aspirin Dosing with P2Y12 Receptor Inhibitors

The optimal aspirin dose in patients on DAPT, which imparts maximal ischemic protection and minimal bleeding risk, is 75–100 mg.^{26–32} In patients on ticagrelor, a lower dose of aspirin is recommended as higher aspirin doses are known to compromise the efficacy of this potent P2Y12 inhibitor.³³

TABLE 2: Common clinical scenarios leading to P2Y12 inhibitor switching

Escalation from clopidogrel to prasugrel or ticagrelor	De-escalation from prasugrel or ticagrelor to clopidogrel	Changes between prasugrel and ticagrelor
A. Patients with ACS on clopidogrel	A. Patients with major bleeding (resolved) with high-risk features (clinical or angiographic) for ST or ACS	A. Patients with intolerance or side effects to a drug having high-risk features (clinical or angiographic) for thrombotic events
B. Patients with ST or ACS on clopidogrel	B. Patients with minor bleeding on either drug likely to affect compliance to it	B. Patients with ST or ACS on either drug
C. Poor metabolizers of clopidogrel	C. Intolerance or side effects to either drug in patients without high-risk features (clinical or angiographic) for ACS/ST	C. Patients on concomitant CYP3A inducers affecting ticagrelor metabolism
–	D. Patients having clinical indication for concurrent oral anticoagulation	–
–	E. Affordability issues, inadequate insurance, nonavailability of newer DAPT agents in a geographic region	–

ACS, acute coronary syndrome; DAPT, dual antiplatelet therapy; ST, stent thrombosis.

SWITCHING MODALITIES

Translation of Evidence from Randomized Trials, Registries, and Pharmacodynamic Studies into Clinical Practice

Switching DAPT agents should be approached with caution—as per latest guidelines² and expert consensus statement⁹—due to valid safety concerns. However, as already discussed, in clinical practice, certain scenarios may necessitate switching of DAPT agents² (Table 2).

As there is paucity of dedicated large scale clinical studies, current recommendations on switching modalities mostly rely on results of pharmacodynamic studies, sometimes exclusively so (Fig. 2).² Obviously, these pharmacodynamic studies do not have as compelling a scientific rationale as multicentric randomized clinical trials.

We would discuss each switching modality, taking into account the evidence from randomized trials, registries, and pharmacodynamic studies, to finally converge into latest expert recommendations on switching DAPT agents in clinical practice.

Switching modalities are categorized into:

- Switching between various oral P2Y12 receptor antagonists
- Switching between different oral P2Y12 receptor inhibitors and the novel IV P2Y12 antagonist.

SWITCHING BETWEEN VARIOUS ORAL P2Y12 INHIBITORS

In concordance with Academic Research Consortium (ARC) definition for ST time is established as per index event leading to initiation of P2Y12 receptor antagonist.³⁴ Switching between oral agents may, therefore, be categorized into acute (<24 h), early (1 day to <30 days), late (30 days to 1-year), and very late (beyond 1 year).⁹

Switching is subdivided into escalation, de-escalation, and change.^{2,8,9}

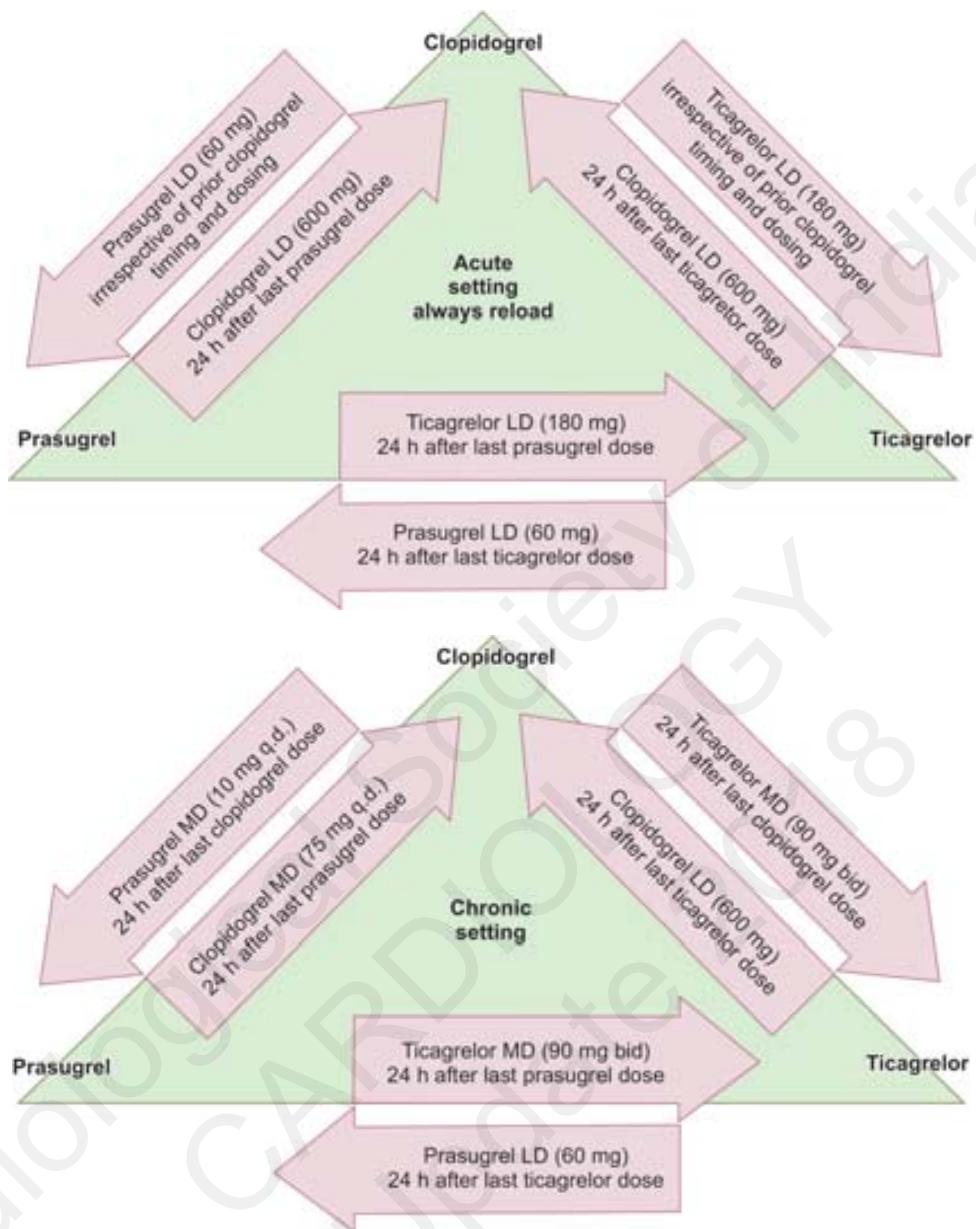

FIG. 2: Algorithm for switching between oral P2Y12 inhibitors in the acute and chronic setting.

Source: Reprinted with permission from: 2017 ESC focused update on dual antiplatelet therapy in coronary artery disease developed in collaboration with EACTS: The Task Force for dual antiplatelet therapy in coronary artery disease of the European Society of Cardiology (ESC) and of the European Association for Cardio-Thoracic Surgery (EACTS). Eur Heart J. 2017;39(3):213-60.

Escalation

Change from a less efficacious, oral P2Y12 antagonist with lower potency to a more efficacious and more potent oral P2Y12 receptor inhibitor is termed as escalation.

Evidence from Clinical Trials, Registries, and Pharmacodynamic Studies

Evidence from Clinical Trials

- Escalation from clopidogrel to prasugrel:** In the pivotal Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel – Thrombolysis in Myocardial Infarction 38 (TRITON-TIMI 38) trial, prasugrel was proven superior to clopidogrel in reducing ischemic endpoints, highlighted

by a marked risk reduction for myocardial infarction (MI).²³ The obvious caveat was higher rates of both non-coronary artery bypass grafting (CABG) and CABG-related major bleeding events in patients on prasugrel. However, this trial included only P2Y12-receptor-antagonist-naïve patients. Therefore, despite the compelling evidence it generated for the use of prasugrel; it, unfortunately, was unable to address the clinical consequences of this switching modality.²³

In contradiction, patients on a maintenance dose (MD) of clopidogrel at time of randomization were included in A Comparison of Prasugrel at the Time of Percutaneous Coronary Intervention or as Pretreatment at the Time of Diagnosis in Patients with Non-ST Elevation Myocardial

Infarction (ACCOAST) trial.³⁵ However, irrespective of clopidogrel pretreatment, there was no ischemic benefit and more major bleeding complications in patients administered prasugrel at time of diagnosis.³⁵

In the Targeted Platelet Inhibition to Clarify the Optimal Strategy to Medically Manage ACS (TRILOGY-ACS) trial, almost two-thirds of patients randomized to prasugrel had received a loading dose (LD) of clopidogrel. Similar bleeding risk was found in patients on either prasugrel or clopidogrel. However, this trial failed to reach its primary efficacy endpoint and therefore, these results need to be interpreted with caution³⁶

- *Escalation from clopidogrel to ticagrelor:* The ground-breaking PLATElet inhibition and patient Outcomes (PLATO) trial proved that in patients with ACS, irrespective of prior exposure to clopidogrel and treatment strategy (medical vs. invasive management), ticagrelor was more efficacious than clopidogrel in reducing ischemic events and as safe with no increase in major bleeding events.²²

However, as proven by the Administration of Ticagrelor in the Cath Laboratory or in the Ambulance for New ST Elevation Myocardial Infarction to Open the Coronary Artery (ATLANTIC) trial, prehospital treatment with ticagrelor in patients with acute STEMI failed to positively impact coronary reperfusion before PCI.³⁷ However, as patients on clopidogrel at presentation were not included, it is not possible to comment on impact of switching from clopidogrel to ticagrelor from results of this trial.³⁷

Au contraire, around one-third of patients, included in the Prevention of Cardiovascular Events in Patients with Prior Heart Attack Using Ticagrelor Compared to Placebo on a Background of Aspirin (PEGASUS) trial, were on clopidogrel at time of randomization.³⁸ Long-term maintenance therapy with ticagrelor in these patients led to a reduction in risk of cardiovascular death, MI, and stroke.

However, this superiority was partially offset by an increase in major bleeding rates.³⁸

Evidence from Registries

Numerous registries have documented prevalence of escalation from clopidogrel to the novel P2Y12 inhibitors from 5 to 50%.³⁹⁻⁵⁰ This “upgrade” switch occurs mostly in the catheterization laboratory during, or immediately after PCI.⁹ There are myriad of reasons necessitating this switch, including patient-specific factors, presentation with STEMI, in-hospital reinfarction, and socioeconomic characteristics.^{8,9} Although, these registries have documented no major safety concerns associated with switching, the fact that none of them were designed or powered for clinical outcomes dilutes the significance of these results, compelling one to view them with skepticism.^{2,8,9,39-50}

Evidence from Pharmacodynamic Studies

The failure of the TRITON-TIMI 38 trial to define an optimal strategy regarding escalation from clopidogrel to prasugrel has fueled a large number of pharmacodynamic studies being conducted on this switching strategy.^{8,23,51-66}

Au contraire, the paucity of pharmacodynamic studies on switching from clopidogrel to ticagrelor⁶⁴⁻⁶⁹ is attributable, in all likelihood, to indisputable clinical evidence from the PLATO trial,²² which abbreviates requirement of any further evidence for all intent and purpose.⁹

- *Escalation from clopidogrel to prasugrel:* The Switching Antiplatelet Therapy (SWAP) study evaluated the switch from clopidogrel to prasugrel in patients with ACS.⁵² 60 mg LD of prasugrel achieved increased levels of platelet inhibition and reduced high on-treatment platelet reactivity (HPR) within 2 hours.^{52,70} After 1-week, 10 mg MD of prasugrel achieved similar levels of platelet inhibition, irrespective of whether an LD was administered.⁵²

The Transferring from Clopidogrel Loading Dose to Prasugrel Loading Dose in Acute Coronary Syndrome Patients (TRIPLET) trial concluded that in patients with ACS undergoing PCI, pretreatment with clopidogrel (adding a 60 mg LD of prasugrel after 600 mg LD of clopidogrel) had no additive pharmacodynamic benefit, as compared to administering 60 mg LD of prasugrel alone⁵⁷

- *Escalation from clopidogrel to ticagrelor:* The Response to Ticagrelor in Clopidogrel Non-responders and Responders and the Effect of Switching Therapies (RESPOND) study was conducted in patients with stable CAD on aspirin therapy.⁶⁷ Ticagrelor therapy was efficacious in patients nonresponsive to clopidogrel.⁶⁷ Its antiplatelet effect was same in clopidogrel responders and nonresponders.⁶⁷

However, given that “upgrade” switching from clopidogrel to novel P2Y12 inhibitors is mainly done in the acute setting, the main limitation of the SWAP and RESPOND trials was that both of them studied patients with stable CAD only.^{52,67}

All pharmacodynamic studies on escalation from clopidogrel to ticagrelor document enhanced platelet inhibition and reduced HPR, especially after administration of an LD.⁵¹⁻⁷⁴ However, caution is required, while translating this evidence into practice, as clinical outcomes study data is not available currently.

Drug-drug interactions in patients previously exposed to clopidogrel (irrespective of whether they were given LDs or are on long-term maintenance therapy) are rare, while switching over to prasugrel or ticagrelor. This is because substantial numbers of P2Y12 receptors are still uninhibited in patients treated with clopidogrel, which are then subsequently blocked by LD of either prasugrel or ticagrelor.⁸

Translation of Evidence into Clinical Practice

- *Escalation during early, especially acute, phase of treatment:* Inadequate platelet inhibition may lead to ST in these patients, given high thrombotic milieu of coronary vasculature in first few weeks after an ACS or PCI.^{10,11} In the acute phase, escalation from clopidogrel to prasugrel or ticagrelor should occur with 60 mg or 180 mg LD, respectively.⁹ An LD is administered independent of timing of last dose of clopidogrel. Thereafter, it is reasonable to transit to long-term maintenance therapy with either prasugrel 10 mg in a once daily dosing regimen or ticagrelor 90 mg twice a day^{2,9}

- Escalation during chronic or late phase of treatment:* In chronic or late phase of treatment, an LD regimen is not required. The patient may be started on a MD regimen of 10 mg once daily prasugrel or 90 mg twice daily ticagrelor approximately 24 hours after last dose of clopidogrel.^{2,8,9}

De-escalation

Stepping down from novel P2Y12 inhibitors to clopidogrel is defined as de-escalation.⁹

The prevalence of “downgrade” switching is 5–14% in in-patients. Patients at higher risk for bleeding—“elderly patients, patients having low-body weight, those with history of cerebrovascular accident, patients recuperating from CABG, those diagnosed with atrial fibrillation or flutter, or while starting oral anticoagulation”—are usually de-escalated to clopidogrel while in-hospital.⁹

Switching between P2Y12 receptor inhibitors, mostly de-escalation is done in 5–8% of patients’ postdischarge.^{9,39–44} De-escalation in outside hospital scenario is usually attributable to cost issues, increased risk of bleeding with prasugrel or ticagrelor or significant nonbleeding side effects such as dyspnea with ticagrelor.^{22,38,75,76}

Evidence from Clinical Trials, Registries, and Pharmacodynamic Studies

Evidence from Clinical Trials and Registries

In the Timing of Optimal Platelet Inhibition After Acute Coronary Syndrome (TOPIC) study, in patients with ACS at 1-month post-PCI, switching from ticagrelor or prasugrel directly to clopidogrel was found to reduce bleeding rates with no documented increase in ischemic occurrences.⁷⁷ The caveat was that this study was inadequately powered to assess ischemic outcomes.⁷⁸

In patients diagnosed as ACS undergoing percutaneous coronary revascularization, a “guided de-escalation strategy”, comprising of prasugrel administration in acute phase, followed by de-escalation to clopidogrel in maintenance phase, was compared to the standardized protocol of long-term treatment with prasugrel in the Testing Responsiveness to Platelet Inhibition on Chronic Antiplatelet Treatment for ACS (TROPICAL-ACS) trial.⁷⁹

At 1-year, net clinical benefit was similar in both groups with no increase in ischemic events and statistically insignificant reduction in bleeding.⁷⁹

However, the Switching from Clopidogrel to New Oral Antiplatelet Agents During Percutaneous Coronary Intervention (SCOPE) registry results infuse a note of caution into considering an early de-escalation of P2Y12 inhibitors in patients with ACS. This switch makes them vulnerable to increase in platelet reactivity and HPR in acute phase.⁵⁰ Therefore, early de-escalation of P2Y12 inhibitors in these patients may increase risk of ischemic events without a reduction in bleeding rates.⁵⁰ However, upgrade switching from old to novel P2Y12 inhibitors led to no ischemic or bleeding risk during the entire study period and was deemed safe.⁵⁰

Evidence from Pharmacodynamic Studies

Pharmacodynamic studies associated with de-escalation to clopidogrel therapy are few in number and show high platelet reactivity and HPR rates.^{54,55,64,67,80–82}

Speed of offset of drug action has important therapeutic implications during de-escalation therapy. Important considerations are delineating the optimal time to administer clopidogrel dose and to determine whether clopidogrel should be given as an LD or just a MD of clopidogrel is adequate, especially in patients at high bleeding risk.^{8,80}

In the Optimising crossover from ticagrelor to clopidogrel in patients with acute coronary syndrome (CAPITAL OPTI-CROSS) study, the “ downgrade” switch to clopidogrel was made at next scheduled dose of ticagrelor.^{78,80} However, based on pharmacodynamics data from the RESPOND study, clopidogrel dose may be administered up to 24 hours after last ticagrelor dose.⁶⁷

These pharmacodynamic studies report lower bleeding events. Despite a higher number of patients with HPR, there is no report of increase in the incidence of thrombotic events.^{9,54,55,64,67,80–82}

De-escalation therapy carries a risk of DDI, particularly when crossing over from ticagrelor to clopidogrel, as highlighted by the Switching Antiplatelet Therapy – 4 (SWAP – 4) study results.^{8,80,83}

It is not sure whether an LD of clopidogrel would mitigate the high levels of platelet reactivity in entirety.⁸³

Considering the paucity of data, potential for DDIs during de-escalation therapy related to high HPR and most importantly, the fact that all aforementioned studies were inadequately powered for clinical outcomes; the optimal strategy to de-escalate from novel P2Y12 inhibitors to clopidogrel is undefined, as of now.^{2,9} Large scale studies are definitely the need of the hour to evaluate the safety and efficacy of de-escalation strategy, especially in the acute setting.

Translation of Evidence into Clinical Practice

De-escalation from Ticagrelor to Clopidogrel

Considering the rapid offset of action of ticagrelor, de-escalation should be done with a 600 mg LD of clopidogrel, regardless of timing of switching (acute, early, or late).⁹ This confers a short-term 48 hours pharmacodynamic advantage and potentially obliterates the time gap in platelet inhibition.⁸ However, in patients at high bleeding risk, it is reasonable to de-escalate to clopidogrel with a MD only.^{8,9}

De-escalation from prasugrel to clopidogrel:

- During early, especially acute, phase of treatment:* It may be reasonable to de-escalate with 600 mg LD of clopidogrel
- During chronic or late phase of treatment:* In stable patients or in chronic setting, clopidogrel in a MD of 75 mg may be administered approximately 24 hours from last dose of prasugrel.^{2,8,9}

Changes

“Parallel” switching between novel P2Y12 inhibitors—prasugrel and ticagrelor—are called changes.⁹

Prevalence of this switch in registries ranges from 2 to 4%.^{8,39-42}

With its once daily dosing, switching over to prasugrel from ticagrelor may improve long-term patient compliance to therapy.⁸ In patients at high-risk for ischemic events, ticagrelor-associated dyspnea is another important reason to switch over to prasugrel.⁹ Patients with ACS pretreated with prasugrel prior to a coronary angiogram and those, who are not scheduled to undergo coronary revascularization, may be switched to ticagrelor.^{39,42,44}

Evidence from Clinical Trials, Registries, and Pharmacodynamic Studies

There is scant evidence to endorse a switch between prasugrel and ticagrelor.^{39-42,84,85}

- Switch from ticagrelor to prasugrel:* In the Switching Antiplatelet Therapy [SWAP-2] study, there was a documented increase in platelet reactivity in patients crossed over to prasugrel therapy measured 12 hours after last MD of ticagrelor. In addition, at 24 hours and 48 hours, platelet reactivity increased in the prasugrel group, as compared to preswitch levels.⁸⁴ An LD of prasugrel partially offset this increased reactivity, but did not bring it down to preswitch levels.⁸⁴

Switching to prasugrel may be extended to approximately 24 hours after last dose of ticagrelor. This may provide extra time for P2Y12 receptor blockade to decline and thereby, limit increases in platelet reactivity.^{9,84}

- Switch from prasugrel to ticagrelor:* The Switching Antiplatelet Therapy [SWAP-3] study documented that crossover from prasugrel to ticagrelor was associated with transiently higher levels of platelet inhibition, regardless of administration of LD.⁸⁵ However, no DDIs or increase in HPR rates were noted during the study.⁸⁵

Translation of Evidence into Clinical Practice

- Switching from ticagrelor to prasugrel:* 60 mg LD of prasugrel is preferred, regardless of timing (early or late). It is best to avoid switching with a 10 mg MD, as pharmacodynamic data suggests a potential DDI.^{2,8,9}
- Switching from prasugrel to ticagrelor:* A standard 90 mg twice daily MD regimen may be used, as pharmacodynamic studies do not suggest any DDI related to this change.^{9,85}

Summation of evidence from clinical trials and registries on switching between oral P2Y12 receptor inhibitors^{9,39-48,77,79} is highlighted in table 3.

Recommendations on switching between oral P2Y12 inhibitors in clinical practice^{2,8,9} are highlighted in table 4.

TABLE 3: Switching oral P2Y12 receptor inhibitors: Evidence from major randomized clinical trials and registries

Study Acronym	Study authors	Clinical presentation	Switching modality (prevalence)	Clinical outcomes
GRAPE	Alexopoulos et al. ³⁹	ACS undergoing PCI	Escalation C → P: 40.1% C → T: 50.3% De-escalation P → C: 1% T → C: 4.3% Change Between P and T: 4.3%	1-month outcome: Higher risk of bleeding and less MACE in patients switched from C to P or T compared with those treated with C only

ACS, acute coronary syndrome; ADP, adenosine diphosphate; CABG, coronary artery bypass grafting; MACE, major adverse cardiovascular events; NACE, net adverse clinical event; NSTEMI, non-ST elevation myocardial infarction; PCI, percutaneous coronary intervention; STEMI, ST elevation myocardial infarction; UA, unstable angina.

TABLE 4: Recommendations on switching between oral P2Y12 inhibitors

P2Y12 inhibitor stopped	P2Y12 inhibitor started	Recommendation
Acute or early phase		
Escalation:		
Clopidogrel	Prasugrel	<ul style="list-style-type: none"> • 60 mg LD, irrespective of last clopidogrel dose • Start MD ~24 h after last clopidogrel dose
Clopidogrel	Ticagrelor	<ul style="list-style-type: none"> • 180 mg LD, irrespective of last clopidogrel dose • Start MD ~24 h after last clopidogrel dose
De-escalation:		
Prasugrel	Clopidogrel	600 mg LD 24 h after last prasugrel dose
Ticagrelor	Clopidogrel	600 mg LD 24 h after last ticagrelor dose
Change:		
Prasugrel	Ticagrelor	180 mg LD 24 h after last prasugrel dose
Ticagrelor	Prasugrel	60 mg LD 24 h after last ticagrelor dose
Late or very late phase		
Escalation:		
Clopidogrel	Prasugrel	10 mg MD 24 h after last clopidogrel dose
Clopidogrel	Ticagrelor	<ul style="list-style-type: none"> • 90 mg twice daily • Start MD 24 h after last clopidogrel dose
De-escalation:		
Prasugrel	Clopidogrel	75 mg MD 24 h after last prasugrel dose
Ticagrelor	Clopidogrel	600 mg LD, 75 mg MD 24 h after last ticagrelor dose
Change:		
Prasugrel	Ticagrelor	90 mg MD 24 h after last prasugrel dose
Ticagrelor	Prasugrel	60 mg LD 24 h after last ticagrelor dose

LD, loading dose; MD, maintenance dose.

SWITCHING BETWEEN ORAL AND INTRAVENOUS P2Y12 INHIBITORS

Bridging

Switching from an oral P2Y12 inhibitor to cangrelor is termed as bridging.⁹

Patients scheduled for surgical procedures require discontinuation of oral P2Y12 inhibitor therapy to mitigate their bleeding risk and should be “bridged” over to cangrelor.^{2,8,9}

Evidence from Clinical Trials, Registries, and Pharmacodynamic Studies

The Bridging Antiplatelet Therapy with Cangrelor in Patients Undergoing Cardiac Surgery (BRIDGE) trial⁸⁶ and various *in vitro* and *ex vivo* investigations⁸⁷⁻⁹² highlighted that cangrelor resulted in high levels of platelet inhibition and no DDI in patients discontinuing thienopyridine therapy before cardiac surgery.⁸⁶⁻⁹² The reason for no DDI is probably that patients on oral P2Y12 inhibitors have unbound receptors that are occupied and inhibited by cangrelor.⁹

However, there is extremely scarce data to endorse safety and efficacy of cangrelor as a bridging modality in real-world clinical practice.^{9,93}

Translation of Evidence into Clinical Practice

Effects of oral P2Y12 inhibitors persist with significant levels of P2Y12 inhibition after drug discontinuation.⁹³ Therefore, bridging with cangrelor should be initiated according to timing of discontinuation of the specific drug: earlier in patients on clopidogrel or ticagrelor (2–3 days) and later in patients on prasugrel (3–4 days).⁹

Transition

When a switch occurs from IV cangrelor to oral P2Y12 inhibitors, mostly after PCI, it is termed as transition.⁹

Evidence from Clinical Trials, Registries, and Pharmacodynamic Studies

In the Cangrelor versus Standard Therapy to Achieve Optimal Management of Platelet Inhibition (CHAMPION-PHOENIX) trial, cangrelor infusion during PCI led to a significant decrease in ischemic events, including ST, with no increase in severe bleeding.⁹⁴

However, in absence of any clinical outcomes study, single-center observational data^{95,96} are grossly inadequate to prove either safety or efficacy of this novel IV P2Y12 inhibitor in patients, subsequently transited to oral P2Y12 receptor inhibitors.

A multitude of pharmacodynamic studies have investigated the potential for DDI during concomitant administration of these drugs.^{86-91,97-99} These DDIs are a potential nightmare for interventional cardiologists as reduced platelet inhibition may lead to thrombotic events in the peri-PCI period.

- *Transition from cangrelor to clopidogrel:* Administration of clopidogrel during cangrelor infusion was associated with a diminished antiplatelet effect, as active metabolites of thienopyridines are unable to bind to P2Y12 receptors, as the latter are still blocked by cangrelor.^{99,100}

By the time receptors become free for binding by thienopyridines after stopping cangrelor infusion, majority of active metabolites are eliminated from the system, thus compromising maintenance of platelet inhibition levels.^{9,100}

However, when clopidogrel is administered after cangrelor infusion, its antiplatelet effect is retained as cangrelor has a

rapid offset of action and subsequently, P2Y12 receptor site become free to bind to active metabolite of clopidogrel^{8,9,90,91,97}

- *Transition from cangrelor to prasugrel:* As already discussed, prasugrel has a higher concentration and longer half-life, as compared to that of clopidogrel.¹⁴ Therefore, an LD of prasugrel given at time of initiation of cangrelor infusion led to a faster and stronger platelet inhibition in stable patients undergoing an elective PCI in the Impact of Extent of Clopidogrel-Induced Platelet Inhibition During Elective Stent Implantation on Clinical Event Rate—Advanced Loading Strategies (ExcelsiorLOAD2)¹⁰¹
- *Transition from cangrelor to ticagrelor:* In contradiction to thienopyridines, no interaction was observed for transition from cangrelor to ticagrelor. This is probably attributable to its unique pharmacodynamic properties—it is direct acting, binds the P2Y12 receptor at a distinct site, and has a half-life of 6–12 hours. The latter is of utmost clinical significance as it implies that postdiscontinuation of cangrelor infusion, it is still systemically present to bind with P2Y12 receptors.^{9,89} Therefore, ticagrelor can be administered prior to initiation of, during, or after discontinuation of, cangrelor infusion without any DDIs.

Translation of Evidence into Clinical Practice

- *After noncardiac surgery:* Clopidogrel in LD should be resumed after noncardiac surgery as soon as possible. It is not advisable to administer potent P2Y12 inhibitors—prasugrel or ticagrelor—after major noncardiac surgery, considering their potency may heighten the risk of serious bleeding in these patients^{2,8,9}
- *At time of PCI:*^{8,9} In patients on cangrelor infusion during PCI, timing of transition to oral P2Y12 inhibitors is drug-specific.
 - *Cangrelor to clopidogrel:* Loading dose of 600 mg of clopidogrel may be given at time of stopping cangrelor infusion
 - *Cangrelor to prasugrel:* Loading dose of 60 mg of prasugrel may be given either at time of discontinuing cangrelor infusion or up to 30 minutes before end of infusion
 - *Cangrelor to ticagrelor:* Ticagrelor can be administered at any time prior to, during or at end of cangrelor infusion.

Summation of evidence from pharmacodynamic studies on switching between IV or oral P2Y12 receptor inhibitors^{9,51-57,59-69,80-82,86,89,90,91,97,98,101} is highlighted in table 5.

TABLE 5: Switching Oral or intravenous P2Y12 receptor inhibitors: evidence from pharmacodynamic studies

Study acronym	Authors	Clinical presentation	Switching modality	Clinical outcomes
–	Rollini et al. ⁵¹	CAD	Escalation: C → P	Outcomes at 1 week: Two minor bleeding
SWAP	Angiolillo et al. ⁵²	Prior ACS	Escalation: C → P	Outcomes at 15 days: Bleeding by TIMI criteria was reported in 12.5% of the C 75 mg MD group, 8.5% of the P 10 mg MD group, and 13.6% of the P LD + MD group
–	Payne et al. ⁵³	Healthy subjects	Escalation: C → P	Outcomes at 22 days: No differences in bleeding episodes or other adverse events
PRINCIPLE-TIMI44	Wiviott et al. ⁵⁴	Planned PCI	Escalation: C → P	Outcomes at 29 days: Bleeding occurred in four subjects switching from C to P
			De-escalation: P → C	Outcomes at 29 days: No bleeding events in subject switching from P to C
ACAPULCO	Montalescot et al. ⁵⁵	UA/NSTEMI	Escalation: C → P	Outcomes at 60 days: There were no differences in any non-CABG-related TIMI major or GUSTO severe/life-threatening bleeding events
			De-escalation: P → C	
TRIGGER-PCI	Trenk et al. ⁵⁶	Stable CAD with HPR undergoing PCI	Escalation: C → P	Outcomes at 6 months: TIMI major non-coronary artery bypass graft bleeding occurred in three patients on P and one patient on C
TRIPLET	Diodati et al. ⁵⁷	ACS undergoing planned PCI	Escalation: C → P	Outcomes at 72 hours: Treatment-emergent adverse events were three in the placebo LD/P 60 mg group; four in the C 600 mg LD/P 60 mg LD group; and seven in the C 600 mg LD/P 30 mg
			Escalation: C → T	Outcomes at 1 week: One minor bleeding, 26 patients with dyspnea
–	Nührenberg et al. ⁵⁹	STEMI undergoing PCI	Escalation: C → P	N/A

Continued

Study acronym	Authors	Clinical presentation	Switching modality	Clinical outcomes
–	Parodi et al. ⁶⁰	CAD undergoing PCI	Escalation: C → P	Outcomes in hospital and at 6 months: There were no differences in major or minor TIMI bleeding rates or in BARC bleeding rates or ischemic events between the patients switching and naïve
–	Aradi et al. ⁶¹	ACS undergoing PCI	Escalation: C → P	Outcomes at 1 year: Rates of thrombotic complications in HPR group were similar to those in the no HPR group without any difference in MACE. No excess of major bleeding after switching to P in HPR group compared to those without HPR
–	Mayer et al. ⁶²	ACS with HPR undergoing PCI	Escalation: C → P	Outcomes at 30 days: 1.7% combined death/stent thrombosis and 8.7% TIMI major bleeding
–	Lhermusier et al. ⁶³	ACS with planned invasive strategy	Escalation: C → P	Outcomes at discharge: No differences in bleeding between groups
–	Lhermusier et al. ⁶⁴	ACS	Escalation: C → P Escalation : C → T	N/A Outcomes at 24 hours: One bleeding event following switch to T 90 mg
–	Alexopoulos et al. ⁶⁵	ACS with HPR	Escalation: C → P Escalation: C → T	Outcomes at 30 days: No patient exhibited a major adverse cardiovascular event or a major bleeding event Outcomes at 30 days: No major adverse cardiovascular event or a major bleeding event
–	Koul et al. ⁶⁶	STEMI undergoing PCI	Escalation: C → P Escalation: C → T	Outcomes in-hospital: 1.1% major bleeding Outcomes in-hospital: 3.3 % major bleeding
RESPOND	Gurbel et al. ⁶⁷	Stable CAD	Escalation: C → T	Outcomes at 30 days: Four patients (two nonresponders and two responders) experienced the five serious adverse events, and all events occurred during or after T therapy. One major and three minor bleeding events occurred during T treatment, and no bleeding events occurred during C treatment
SHIFT-OVER	Caiazzo et al. ⁶⁸	ACS	Escalation: C → T	Outcomes at 30 days: No deaths nor strokes were reported after switch
CAPITAL RELOAD	Hibbert et al. ⁶⁹	STEMI	Escalation: C → T	N/A
CAPITAL OPTI-CROSS	Pourjabbar et al. ⁸⁰	ACS	De-escalation: T → C	Outcomes at 30 days: No differences in MACE, TIMI major bleeding or stent thrombosis between groups
–	Kerneis et al. ⁸¹	ACS	De-escalation: P → C	Outcomes at 30 days: No major bleedings
POBA	Deharo et al. ⁸²	ACS with LPR	De-escalation : P → C	Outcomes at 30 days: No bleeding events after switching to C
–	Angiolillo et al. ⁸⁶	ACS	Thienopyridine → Cangrelor	Study-defined excessive CABG—surgery-related bleeding not significantly different between Cang (11.8%) or placebo (10.4%). Ischemic end points prior to surgery were low: 2.8% with Cang, 4.0% with placebo
–	Schneider et al. ⁸⁹	Stable CAD	Cangrelor → Ticagrelor	No adverse events during study duration

Study acronym	Authors	Clinical presentation	Switching modality	Clinical outcomes
–	Schneider et al. ⁹⁰	Stable CAD	Cangrelor → Prasugrel	No adverse events during study duration
–	Schneider et al. ⁹¹	Stable CAD	Cangrelor → Clopidogrel	N/A
Predefined substudy of CHAMPION-PCI and CHAMPION-PLATFORM randomized trials	Angiolillo et al. ⁹⁷	CAD undergoing PCI	Cangrelor → Clopidogrel	Not Reported
–	Steinhubl et al. ⁹⁸	Healthy subjects	Cangrelor → Clopidogrel	N/A
ExcelsiorLOAD2 Trial	Hochholzer et al. ¹⁰¹	CAD without MI	Cangrelor → Oral P2Y12 Inhibitors	The incidence of 30-day ischemic and bleeding events similar between groups

CAD, coronary artery disease; ACS, acute coronary syndromes; PCI, percutaneous coronary intervention; TIMI, thrombolysis in myocardial infarction; MD, maintenance dose; LD, loading dose; CABG, coronary artery bypass surgery; NSTEMI, non-ST-segment elevation myocardial infarction; STEMI, ST-segment elevation myocardial infarction; UA, unstable angina; HPR, high on-treatment platelet reactivity; MI, myocardial infarction; N/A, not applicable.

TABLE 6: Recommendations on bridging or transitioning between intravenous and oral P2Y12 inhibitors

Bridging: From oral to IV P2Y12 inhibitor			
Oral P2Y12 inhibitor	IV P2Y12 inhibitor	Days to withhold P2Y12 inhibitor prior to procedure	Recommendation
Clopidogrel	Cangrelor	5	Initiate cangrelor 0.75 mcg/kg/min without bolus 2–3 days after stopping clopidogrel
Prasugrel	Cangrelor	7	Initiate cangrelor 0.75 mcg/kg/min without bolus 3–4 days after stopping prasugrel
Ticagrelor	Cangrelor	5	Initiate cangrelor 0.75 mcg/kg/min without bolus 2–3 days after stopping ticagrelor

Transitioning: From IV to oral P2Y12 inhibitor			
IV P2Y12 inhibitor	Oral P2Y12 inhibitor	Days to withhold P2Y12 inhibitor prior to procedure	Recommendation
Cangrelor	Clopidogrel	N/A	600 mg LD to be given immediately after cangrelor infusion is discontinued
Cangrelor	Prasugrel	N/A	60 mg LD to be given immediately after cangrelor infusion is discontinued
Cangrelor	Ticagrelor	N/A	180 mg LD to be given at start of cangrelor infusion (ideal) or up to infusion discontinuation

LD, loading dose; N/A, not applicable; IV, intravenous.

Recommendations on switching between IV and oral P2Y12 inhibitors in clinical practice^{2,8,9} are provided in table 6.

PLATELET FUNCTION TESTING AND SWITCHING OF P2Y12 INHIBITORS

In patients on P2Y12 receptor antagonists, high and low platelet reactivity is a strong indicator of ischemic and bleeding risk, respectively.^{2,11} Therefore, scientifically speaking, individualized antiplatelet therapy based on platelet function monitoring should be advocated to adjust or switch antiplatelet therapy.^{2,102} However, randomized trials demonstrate no significant clinical impact of using platelet function tests to either modify or switch therapy.^{56,103-106}

THE WAY FORWARD: WHAT IS THE RIGHT STRATEGY TO SWITCH DAPT?

Switching between DAPT agents remains a clinical conundrum. As current recommendations are derived largely from pharmacodynamic studies and registry data, dedicated prospective studies are needed to provide important insights into optimal and clinically safe switching strategies.

Until new clinical or pharmacokinetic/pharmacodynamics data become available, one has no option, but to adhere to current evidence. However, as practicing physicians, it is imperative that one tailors switching of DAPT, if required, on an individualized basis; keeping in view pharmacological properties of P2Y12 inhibitor therapies and timing of disease presentation (acute or chronic).

Management of Bleeding in Planned or Unplanned Surgery in a Patient on Dual Antiplatelet Therapy

Sameer Dani

INTRODUCTION

In this industrialized world, patients suffering from cardiovascular diseases are increasing day by day and a number of them are treated with percutaneous coronary intervention (PCI) with stent implantation for major coronary events. Platelets play a major role in the pathogenesis of these events.

Platelet aggregation and rupture of unstable plaque lead to thrombus which underlies the pathogenesis for acute coronary syndrome (ACS).^{1,2} In medical practice, dual antiplatelet therapy (DAPT) is routinely used as a mainstay therapy for ACS.³ In cases of ACS where PCI was done with the use of ballooning or stent implantation, risk of stent thrombosis and during the phase of re-endothelialization the use of DAPT is unavoidable.⁴

Dual antiplatelet therapy itself carries a risk of bleeding in patients who are taking it regularly for ACS and who are not even exposed to any surgical procedures.⁵ In early postoperative period in addition to bleeding risk there are higher chances of risk of thrombosis due to hypercoagulable state as a result of systemic inflammation.^{6,7} Out of all the patients undergoing PCI, approximately 6–20% are posted for noncardiac surgery within the first 2 years after PCI.⁸ Out of these, 45–50% who received a drug-eluting stent (DES) undergo surgery in less than 12 months, in which, the use

of DAPT is compulsory.⁹ Patient on perioperative DAPT should be individualized with the combined decision of anesthesiologist, cardiologist, and surgeon to lower the risk of both ischemia and bleeding.

DUAL ANTIPLATELET THERAPY AND PHARMACOLOGY

Aspirin and a P2Y12 inhibitors are together considered as DAPT, but the available antiplatelets can be generally classified into five types based on their mechanism of action: cyclooxygenase (COX)-1 inhibitor (aspirin), P2Y12 inhibitors (clopidogrel, prasugrel, ticagrelor, cangrelor), glycoprotein (GP) IIb/IIIa inhibitors (abciximab, eptifibatide, tirofiban), phosphodiesterase-III inhibitors (dipyridamole, cilostazol), and protease-activated receptor-1 inhibitor (vorapaxar). Cilostazol is mostly used in patients with peripheral arterial disease. Similarly, there is not much evidence regarding the use of vorapaxar in addition with DAPT in patients of coronary artery disease (Table 1).

Timing of platelet transfusion or discontinuation of DAPT will be decided after having the knowledge of pharmacokinetics and pharmacodynamics about various antiplatelets.

TABLE 1: Antiplatelets

	Administration route/mode of action	Onset/elimination half-life	% inhibition of platelet function	Recovery after discontinuation
Aspirin	Oral/irreversible cyclooxygenase-1 inhibitor	20–45 min/2–4 h	60–70%	5 days
Clopidogrel	Oral/irreversible P2Y12 inhibitor	12–24 hr/4–6 h	60–70%	5–7 days
Prasugrel	Oral/irreversible P2Y12 inhibitor	0.5–4 hr/7 h	90%	7–10 days
Ticagrelor	Oral/reversible P2Y12 inhibitor	0.5–4 hr/7 h	90%	3–5 days
Cangrelor	Intravenous/reversible P2Y12 inhibitor	Immediate/3–5 min	>90%	30–60 min
Abciximab	Intravenous/reversible glycoprotein IIb/IIIa inhibitor	Immediate/10–30 min	~100%	12 h
Tirofiban	Intravenous/reversible glycoprotein IIb/IIIa inhibitor	Immediate/2–2.5 h	~100%	4 h
Eptifibatide	Intravenous/reversible glycoprotein IIb/IIIa inhibitor	Immediate/2–2.5 h	~100%	4 h

PREVENTION OF BLEEDING

Assessment of Bleeding Risk

“DAPT score” may be useful for decisions about whether to continue DAPT in postangioplasty patients. In patients treated for 1 year with DAPT without significant bleeding or ischemic events, the patients with high DAPT score (≥ 2) have a favorable benefit-risk ratio with prolonged DAPT because prolonged DAPT reduces both ischemic and bleeding complications when compared with nonprolonged DAPT.¹⁰

The 2017 Focused Update on DAPT provides a comprehensive set of recommendations for the routine use of DAPT after coronary artery stenting, with perhaps the underlying message being that an individual assessment of high bleeding [e.g., predicting bleeding complication in patients undergoing stent implantation and subsequent dual antiplatelet therapy (PRECISE-DAPT) score ≥ 25] or ischemic risk (e.g., DAPT score ≥ 2 and/or complex PCI) may justify a shorter or longer DAPT duration, respectively, than the hitherto accepted standard of 6 months (clopidogrel) in stable or 12 months (ticagrelor or prasugrel) in ACS patients (Table 2).

Bleeding Risk According to Types of Surgery

Surgery can be divided into low, intermediate, and high-risk categories, with estimated 30-day cardiac event rates for major adverse cardiac events of less than 1%, 1–5%, and more than or equal to 5%, respectively (Table 3).^{20,21}

TABLE 2: Risk scores validated for dual antiplatelet therapy duration decision making¹¹⁻¹⁹

^aFor the PRECISE-DAPT score, use the score nomogram: mark patient's value for each of the five clinical variables of the score and draw a vertical line to the 'point' axis to determine the number of points obtained for each clinical variable. Then summate the points obtained for each clinical variable to the total score.

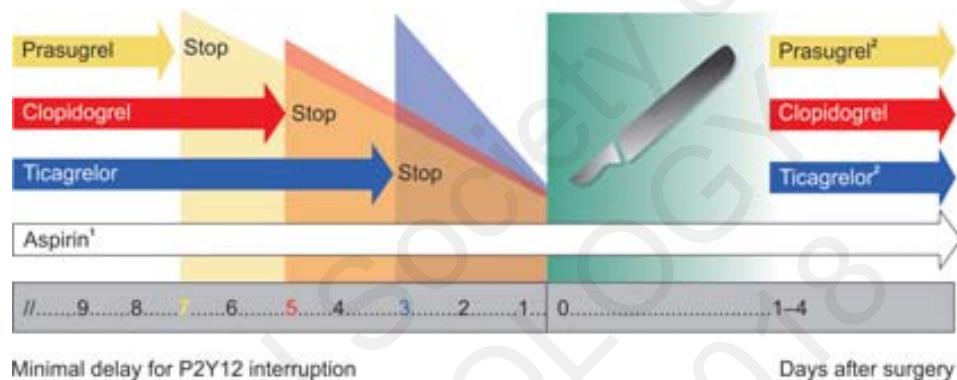

For the DAPT score, summate positive points for each value and subtract values for age to the total score

CHF, congestive heart failure; CrCl, creatinine clearance; DAPT, dual antiplatelet therapy; LVEF, left ventricular ejection fraction; MI, myocardial infarction; PCI, percutaneous coronary intervention; WBC, white blood cells.

TABLE 3: Types of surgery

Low risk (<1%)	Intermediate risk (1–5%)	High risk (>5%)
Superficial surgery	Intraperitoneal: Splenectomy, hiatal hernia repair, cholecystectomy	Aortic and major vascular surgery
Breast	Carotid symptomatic (CEA or CAS)	Open lower limb revascularization or amputation or thromboembolectomy
Dental	Peripheral arterial angioplasty	Duodenopancreatic surgery
Endocrine: Thyroid	Endovascular aneurysm repair	Liver resection, bile duct surgery
Eye	Head and neck surgery	Esophagectomy
Reconstruction	Neurological or orthopedic: Major (hip and spine surgery)	Repair of perforated bowel
Carotid asymptomatic (CEA or CAS)	Urological and gynecological: Major	Adrenal resection
Gynecology: Minor	Renal transplant	Total cystectomy
Orthopedic: Minor	Intrathoracic: Nonmajor	Pneumonectomy
Urological: Minor (Transurethral resection of the prostate)		Liver or pulmonary transplant

CEA, carotid endarterectomy; CAS, carotid artery stenting.

▲ = Expected average platelet function recovery.

¹Decision to stop aspirin throughout surgery should be made on a single case basis taking into account the surgical bleeding risk.

²In patients not requiring oral anticoagulant.

FIG. 1: Time frames of minimal discontinuation and reimplementation of dual antiplatelet therapy for patients undergoing elective noncardiac surgery.^{25,26}

Guidelines for the Timing of Noncardiac Surgery in Relation to Newer Generation Drug-eluting Stent

In the era of new antiplatelet agents, there has also been continuous development in the efficacy of DES. The previous guidelines were mostly based on first-generation sirolimus- or paclitaxel-eluting stents. But, now the ACC/AHA (American College of Cardiology/American Heart Association), 2016, guidelines give data regarding the use of newer generation DES (with elution of everolimus or zotarolimus). Clearly, newer generation DES shows less thrombogenicity and better ischemic protection, thus requiring a shorter period for re-endothelialization.²⁷ Hence, the necessary duration of DAPT after DES placement has been shortened in the new guidelines. Compared with prolonged DAPT, short-term DAPT is associated with similar rates of MACE but lower rates of bleeding after DES placement.²⁸ The updated 2016 ACC/AHA guidelines recommended elective noncardiac surgery to be performed 6 months after newer generation DES placement, and if the risk-benefit ratio of delaying the required surgery versus risk of stent thrombosis is more, then surgery could be considered at least 3 months after DES placement²⁹ in contrast to a year with first-generation stents as some of studies also hypothesized that myocardial

ischemia is the leading cause of postoperative mortality and morbidity in patients undergoing major vascular surgery as platelets have been implicated in the pathogenesis of acute thrombotic events (Flowchart 1).³⁰

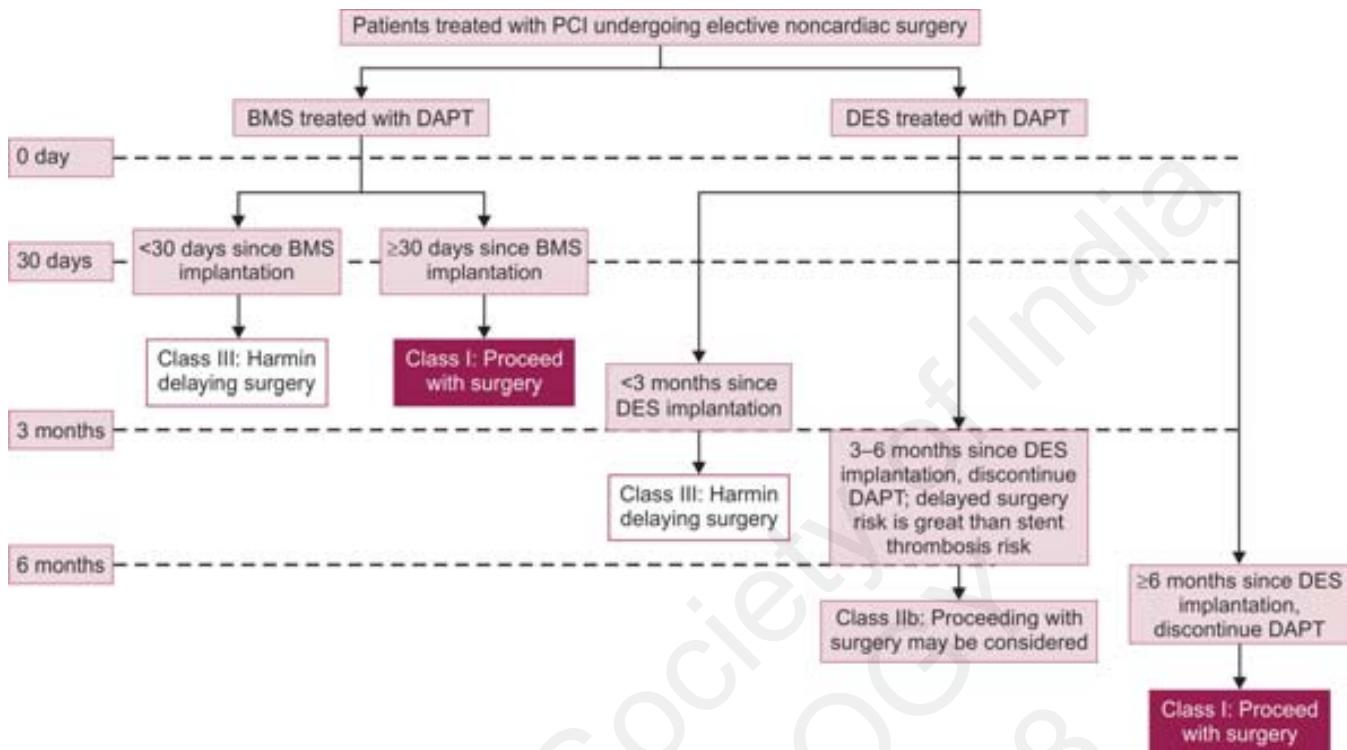

However, if emergency or urgent noncardiac surgery is required, then a decision to continue aspirin or DAPT should be individualized with consensus of the cardiologist, anesthesiologist, and surgeon, with the risk weighed against the benefits of continuing DAPT.³¹

Dual Antiplatelet Therapy versus Single Antiplatelet Therapy

According to the European Society of Cardiology (ESC), 2017, guidelines, DAPT discontinuation is recommended in the form of stopping P2Y12 inhibitors at least 3 days before surgery for ticagrelor, at least 5 days for clopidogrel and at least 7 days for prasugrel.

Single antiplatelet therapy (SAPT)—if the bleeding risk is not very high, then it is recommended to continue aspirin and DAPT is to be started as early as possible postoperatively. This is primarily based on expert opinions.

However, patients undergoing elective noncardiac surgery within first month of treatment with PCI should not discontinue DAPT.

BMS, bare-metal stent; PCI, percutaneous coronary intervention; DAPT, dual antiplatelet therapy; DES, drug-eluting stent.

FLOWCHART 1: Recommendations for the timing of elective noncardiac surgery in patients with coronary stents.

TREATMENT OF BLEEDING

Bleeding complications such as major hemorrhages do not occur very frequently with the use of DAPT; however, minor bleeding complications can occur which can be managed with various pharmacological and nonpharmacological measures described below. In case of minor bleeding in which hemostatic agents were used, once hemostasis is achieved, consider the starting of antiplatelets as early as possible.³²⁻³⁴

In case of emergent surgery, reversal of the antiplatelet effect by platelet transfusion may be considered which carries the risk of significant arterial thrombosis.

General Measures to Stop Bleeding

Nonpharmacological Measures

In cases where bleeding is not significant, general nonpharmacological measures and discontinuation of DAPT are sufficient to treat the bleeding (Box 1). Some techniques like plasmapheresis or hemofiltration can reduce plasma concentration of antiplatelets in some cases and these are also not easily accessible in all emergency settings.

General Hemostatic Agents

There is no specific antidote available to reverse DAPT. However, few prohemostatic agents are available which can be useful for reversal of the effect of antithrombotic drugs in some situations. For example, recombinant activated factor VII (rFVIIa), prothrombin complex concentrates (PCC), and activated PCC [APCC; e.g., factor VIII inhibitor bypass activity

BOX 1 General nonpharmacological measures

- Stop DAPT
- Timing and dose of drug
- Presence of associated comorbidities
- Look for bleeding site
- Send complete blood count, prothrombin time, activated partial thromboplastin time, thrombin time, fibrinogen concentration, creatinine concentration
- Intravenous fluids and red cell transfusion to make patient hemodynamically stable and also apply mechanical pressure, if possible
- Use endoscopic, radiological, or surgical measures wherever applicable

DAPT, dual antiplatelet therapy.

(FEIBA)] are often considered. Antithrombotic effect reversal with rFVIIa is not approved,³⁵ but it is still considered as a last option when all other attempts have failed and when the risks and benefits are carefully explained.

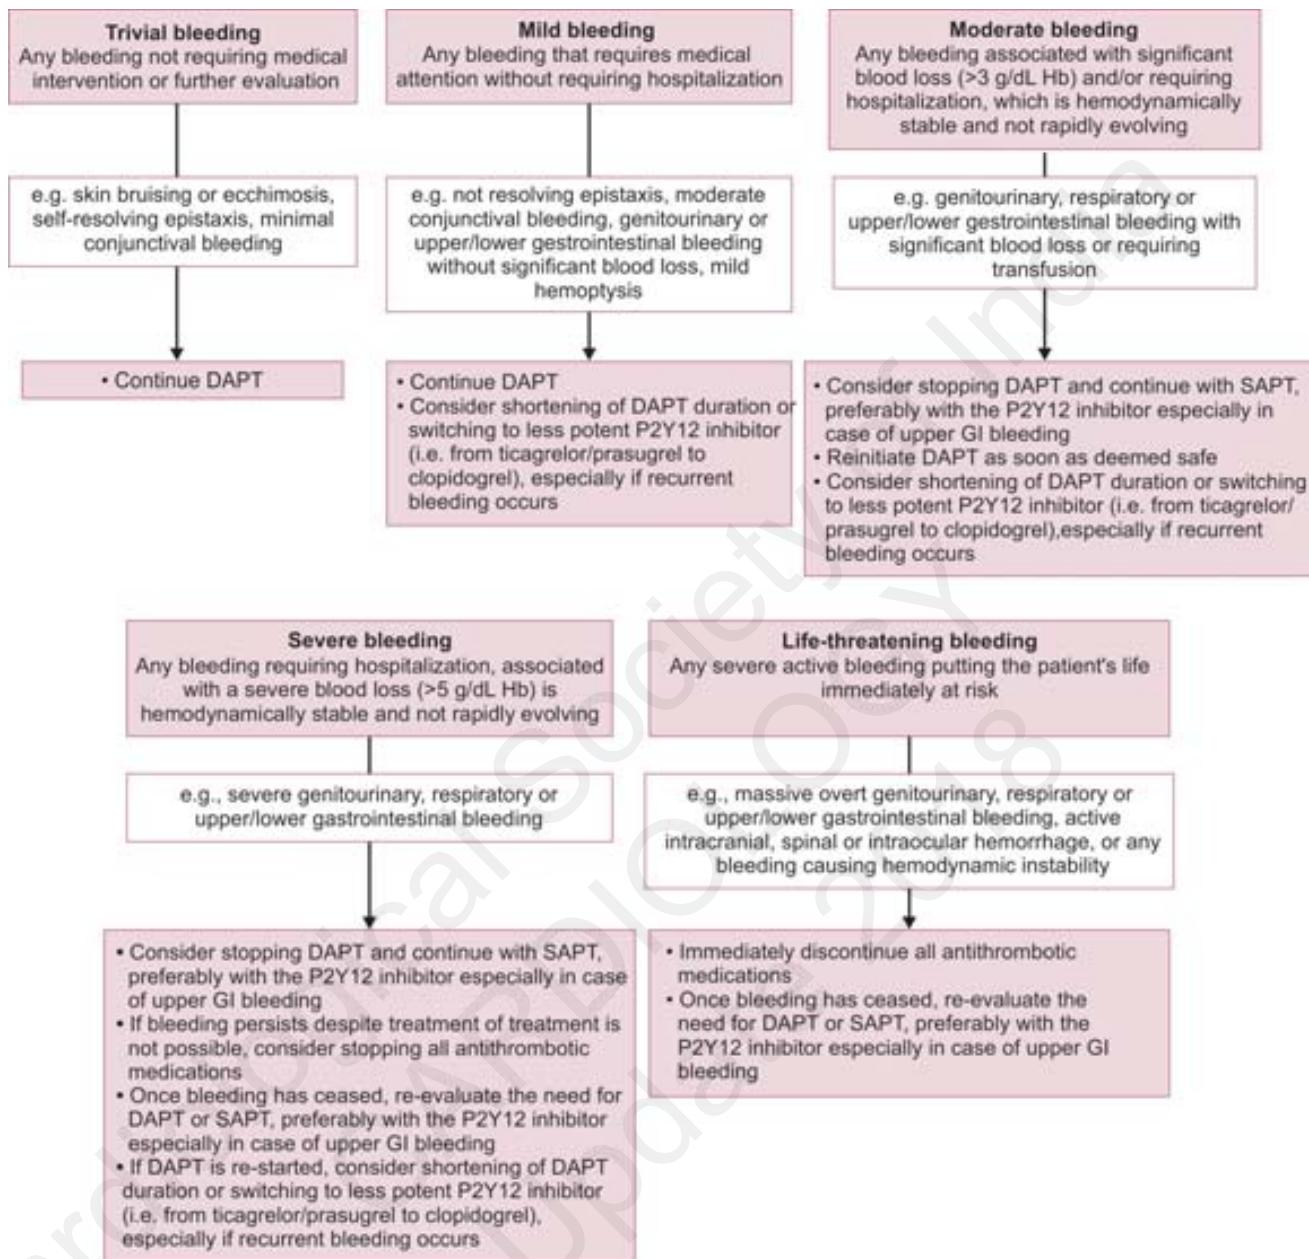

PCC and fresh frozen plasma (FFP) are used to reverse vitamin K antagonists (VKAs), but their role as a reversal agent for DAPT is doubtful (Box 2).³⁶

Practical Recommendations for Management of Bleeding

Flowchart 2 shows practical recommendations for management of bleeding.

SECTION 8

Dual Antiplatelet Therapy

DAPT, dual antiplatelet therapy; GI, gastrointestinal; SAPT, single antiplatelet therapy.

FLOWCHART 2: Management of bleeding.

BOX 2	Pharmacological and blood component prohemostatic measures
	<ul style="list-style-type: none"> • Tranexamic acid • Desmopressin • Fresh frozen plasma • Cryoprecipitate • Platelet transfusion • Fibrinogen concentrate • Prothrombin complex concentrate • Activated prothrombin complex concentrate • Recombinant factor VIIa

CONCLUSION

While balancing risks of bleeding versus thrombotic events, the relative adverse events must be considered. Rarely, the bleeding is life-threatening in comparison with the potential consequences of stent thrombosis.

Sudden discontinuation of DAPT can lead to a rebound effect marked by an excessive thromboxane A2 activity and inflammatory prothrombotic state, increased platelet adhesion, and aggregation.

Surgery further increases the prothrombotic and inflammatory state, which, combined with incompletely

endothelialized DES, can lead to stent thrombosis and, consequently, myocardial infarction and/or death.³⁷

In a patient treated with DAPT after coronary stent implantation, who must undergo surgical procedures that mandate the discontinuation of P2Y12 inhibitor therapy, it is recommended that aspirin be continued if possible and P2Y12 platelet receptor inhibitor be started as soon as possible after the surgery. There are no clinical evidence-based trials or studies that have shown benefits of IV antiplatelet agents used as bridging therapy in patients who require to stop DAPT temporarily before noncardiac surgery—class 1 recommendation of ACC guidelines.

An elective noncardiac surgery should not be performed within at least 1 month after bare-metal stent (BMS) implantation or within 3 months after DES implantation in patients in whom DAPT will need to be discontinued perioperatively—class 3 recommendation of ACC guidelines.

After coronary stent implantation, elective surgery requiring discontinuation of P2Y12 inhibitor should be considered after 1 month irrespective of the stent type if aspirin can be maintained throughout the perioperative period—*Class 2a recommendation of ESC guidelines*.

Discontinuation of P2Y12 inhibitors should be considered at least 3 days before for ticagrelor, at least 5 days for clopidogrel and at least 7 days for prasugrel—class 2a recommendation of ESC guidelines.

It is not recommended to discontinue DAPT within the first month of treatment in patients undergoing elective noncardiac surgery—class 3 recommendation of ESC guidelines.

If emergency or urgent noncardiac surgery is required, then a decision to continue aspirin or DAPT should be individualized with consensus of the cardiologist, anesthesiologist, and surgeon, with the risk weighed against the benefits of continuing DAPT.

Coronary Intervention

History and Evolution of Coronary Intervention

Dev B Pahlajani, Akshay Mehta

INTRODUCTION

Coronary angiography and intervention are the most common invasive and interventional procedures performed all over the world. It is estimated that more than 3 million coronary interventional procedures are performed annually across various countries with India contributing half a million of them.

Evolution of coronary intervention is the result of curiosity to know the physiology and anatomy of the cardiovascular system, ingenuity of the earlier researchers, with the aim to provide relief to the victims of cardiac ailments. While to the contemporary practitioner of intervention cardiology, the procedure may appear very simple with a comment “after all what is so big about it?”, one must not forget the challenges of unknown, ethics, primitive technological, and engineering material at disposal to these scientists of the earlier era. The evolution to the present state should be credited to the courage and daring with coordination among physicians, physicists, engineers, technologists and in the modern era with the pharmaceutical and device industry.

History of coronary intervention is incomplete without acknowledging the early work performed in animals, and cardiac catheterization and coronary angiography in humans that ultimately laid the firm foundation of coronary intervention as we perform today.

Phases of evolution: One could divide the evolution of coronary intervention in four phases:

1. Early animal experiments to understand the physiology of cardiovascular system
2. Development of X-ray systems
3. Cardiac catheterization and coronary angiography in humans
4. Coronary intervention.

Early animal experiments: While Greeks and Romans used to perform “medical procedures” by introducing needles and tubes during early era, the subsequent experiments in

humans were performed only in cadavers by introducing needles and pipes in vascular system.

Credit for understanding the cardiac physiology can be attributed to Claude Bernard, a French physiologist (1813-1878). He performed several invasive experiments in dogs. He introduced a small glass tube in the jugular vein of a dog and measured intracardiac pressures by connecting it to “cardiodynamometer” and showed that the right ventricular pressure was lower than the arterial pressure. He can be given the credit for detailed description of cardiac catheterization in animals.

Auguste Chauveau (1827-1917) a veterinary physician and Étienne Marey (1830-1904) an engineer, technologist and physician, again a French physiologist, described the simultaneous pressure tracings in left ventricle and aorta in awake horse and gave account of intracardiac pressure recordings in various cardiac chambers. They commented that “one can be reassured of the innocuity of this method by examining the horse who is scarcely disturbed with the procedure!!”

In late 19th century, cardiac catheterization became routine in physiology laboratories. However, its application in humans remained elusive for few decades.

X-rays: The soul of cardiovascular invasive and interventional procedures:

One wonders what would have been the face of diagnostic and therapeutic cardiovascular intervention had there been no discovery of X-rays !

Credit for the development of coronary angiography and cardiovascular intervention squarely rests on the serendipitous discovery of X-rays by German physicist, Wilhelm Röntgen in 1895. On November 8, 1895 while experimenting, he observed that certain rays were emitted during passing of current through discharge tube. Not knowing the significance of these rays he called them X-rays. He recorded the first X-ray pictures of the hand of his wife with wedding ring. On January 18, 1896 an X-ray machine was

FIG. 1: Wilhelm Röntgen with the first X-ray of his wife's hand with the wedding ring.

formally displayed by Henry Louis Smith and fully functional unit was introduced at the World Fair by Clarence Daily in 1904 (Fig. 1).

Subsequently several refinements, like live fluoroscopy, cine angiography have made it possible to perform the invasive procedures.

Cardiac catheterization in humans: Werner Forssmann, a German Urologist, can be given the credit for performing the first cardiac catheterization in human. No doubt there were some earlier attempts to perform human catheterization which either failed or did not provide the desired outcome. Born on August 29, 1904, it is reported that he performed several experiments on himself. Fascinated by the work of Claude Bernard, Chauveau, and Marey who had performed cardiac catheterization in animals, he desired to perform the cardiac catheterization through the cubital vein. He discussed the plans with his chief, Dr Schneider, and his colleagues. There was strong resistance from academic community. However, with the chief's encouragement he

performed the initial animal experiment to assess the safety of the procedure. In his first attempt, he opened his left cubital vein and inserted the lubricated catheter with help of his colleague Peter Romeis and pushed the catheter for about 35 cm. However, the catheter could not be pushed further and had to be abandoned since Romeis thought that the experiment was dangerous. Later, Forssmann with the help of his surgical nurse Gerda Deisen, could open his left arm vein and introduced the catheter for 30 cm. Initially, the nurse thought that the experiment was supposed to be performed on her. With her help he went to the X-ray department, one floor below and advanced the catheter upto 60 cm in the region of the right atrium. He was criticized intensely. However, the chief Snuger authorized the second catheterization to be performed in a woman dying of puerperal sepsis with shock. The aim was to administer intracardiac adrenaline and strophanthin. It may appear ironical that this case could indeed, might have been the first "therapeutic cardiac catheterization". In November 1929 paper entitled "DIE SONDIERUNG DES RECHTEN HERZENS" (Catheterization of the right heart) was published. Forssmann moved to Berlin to work in Charite hospital in Berlin. However, was fired from his work which was not considered to be ethical by chief Ferdinand Sauerbruch proclaiming "he could lecture in a circus but never in a respectable German University". He joined Eberswalde and carried out at least 6 additional safe catheterizations. In October 1956, he was awarded Nobel Prize in medicine, physiology which he shared with Andre Cournand and Dickinson Richards. At the awarding ceremony Professor Lil Hestrstrand commented that Forssmann was working in a milieu that did not clearly grasp the great value of his idea. Subsequently, the procedure was adapted in various institutions with variously designed catheters and material (Fig. 2).

Andre Cournand and Dickinson W Richards worked together in New York and performed various studies on the hemodynamics and relationship between the heart and the lungs. They also reported on the cardiac output measurements and published several papers on the techniques and

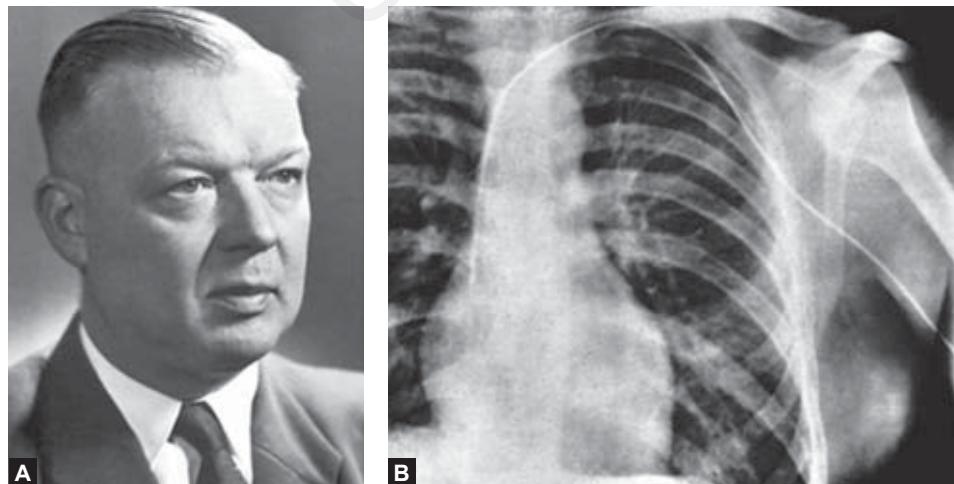

FIG. 2: A, Dr Werner Forssmann; B, Catheter through left cubital vein in right atrium.

advances like new catheters, new pressure recorders which resulted in better and safer intravascular recordings. In 1942 they dared to advance the catheter in right ventricle and pulmonary artery. They also studied hemodynamics in shock with measurement of arterial blood pressure, cardiac output, blood gases, and other biochemical parameters.

ARRIVAL OF CORONARY ANGIOGRAPHY

While indirect visualizations of the coronary arteries by injecting into the ascending aorta had been practiced by Charles Dotter who suggested that one could occlude the ascending aorta with a balloon and then dye could be injected into the ascending aorta to temporarily arrest the heart so as to visualize the coronary arteries; however, it was left to the keen observation of Mason Sones in Cleveland clinic who observed that 40 cc of contrast which got injected into the right coronary artery could be tolerated without any untoward side effects except bradycardia. This particular case could be considered as the path breaking case for the futuristic treatment of coronary artery disease. This first selective coronary arteriogram performed by Dr Mason Sones in Cleveland Clinic on October 30, 1958 could be considered as serendipitous discovery. A young man of 26 years of age, was undergoing cardiac catheterization for evaluation of his rheumatic disease of mitral and aortic valve. After completing left ventricular angiogram, Dr Sones intended to perform aortic root shoot. Dr Sones was observing 11 inch image intensifier while sitting underneath in the pit to monitor the injection. A 50 cc of contrast was inadvertently delivered directly into the right coronary artery. Fearing the worst, Dr Sones as he described, grabbed the scalpel to open the chest and perform open cardiac massage. However, he was astonished to find the patient had brief period of bradycardia which recovered after coughing and injection of atropine. This was indeed a serendipitous event which heralded the beginning of new era in cardiology to selectively opacify coronary arteries (Fig. 3). This will open up the flood gates for the accurate diagnosis of coronary arteries, to judge its prognosis and appropriately tailored scientific treatment.

FIG. 3: Dr Mason Sones in his cardiac catheterization laboratory.

Needless to say that without selective visualization of coronary arteries subsequent coronary artery bypass graft surgery and percutaneous transluminal coronary angioplasty (PTCA) would not have been light of the day. As a matter of fact before Sones's work, attempts were made to image coronary arteries by Radner in 1945, to use trans-sternal puncture to inject contrast. However, this was associated with too many complications and therefore the procedure had to be abandoned. The selective opacification by contrast medium was fraught with fear and some of the skeptics felt that introducing oxygen-free medium into the coronary circulation which is already compromised by atherosclerosis could be dangerous and lead to sudden death.

Subsequently, Sones designed the catheters which had a relatively thick shaft (8F) which tapered to soft and flexible tip of small diameter (5F). He was also instrumental in coordinating with Philips North America to develop 5 inch image intensifier which was better suited for coronary artery visualization than earlier larger intensifiers. It was only 4 years later in 1962 that Sones published his paper on 1,000 coronary angiography cases since Sones wanted to acquire complete knowledge and experience before publishing. It may appear news to many practitioners of cardiology that Sones was dyslexic (and reluctant to write and read). Sones also advocated the importance of visualization of coronary arteries in multiple views. It is surprising that as late as 1996, a leading article which appeared in Lancet wrote "as an aid to ischemic heart disease it seems at present to offer little that cannot be more easily obtained by methods such as good history taking and electrocardiography." However, clinicians all over the world realized that there was no equivalent test to coronary arteriography.

While Sones technique was performed through the brachial cutdown route an important path changing modification occurred when Dr Melvyn Judkins designed his preshaped catheters which could be introduced through transfemoral approach. Because of the simplicity of the procedure and no cutdown the Judkins catheter technique became widely popular.

Development of Coronary Balloon Angioplasty

Dr Andreas Roland Gruentzig could rightfully be called as the father of coronary angioplasty (Fig. 4). Born in Dresden, Germany on June 25, 1939 and having obtained his training in Zurich in the University Hospital of Zurich, Switzerland, he was fascinated with the work of balloon angioplasty in the peripheral arteries by Dotter. He performed the dilatation of the superficial femoral artery with the help of Eberhard Zietler and started following the technique of Dotter on his own, together with Meira Schlumpf his personal assistant and was instrumental in designing several balloon catheters for dilating peripheral arteries. While designing various catheters he had to approach several plastic experts to get the appropriate shape of the balloon. This involved trying various forms of polyvinyl chloride (PVC) or rubber so as to form the appropriate and safe pressure resistant cylindrical balloons.

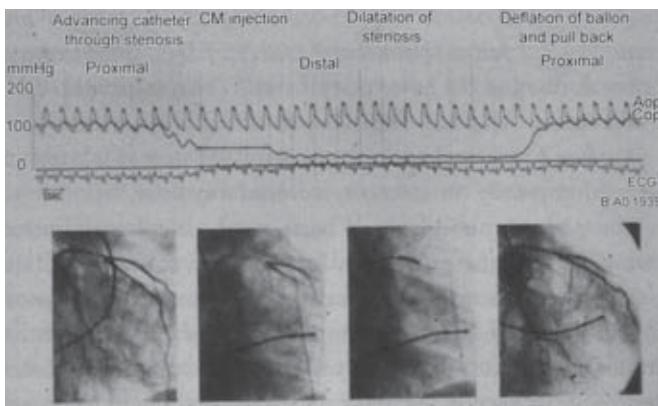

FIG. 4: First coronary angioplasty by Dr Andreas Gruentzig.

In the beginning, the entire designing and the construction was conceived on his kitchen table in his apartment. He even assumed that silk stocking would be required to prevent PVC balloon from turning in the spherical shape with increasing pressure. In his own recounts he mentions the developments of the balloon catheter by writing "I spent the next two years contacting manufacturing plants in an attempt to solve this problem. Especially fruitful was the cooperation of a factory that produced shoe laces and which provided me with silk meshes which I planned to wrap around the balloon, thus limiting its outer diameter. I then needed a very thin balloon to insert within the mesh. It was at that time that I met a retired chemist, Dr Hopff, a Professor emeritus of chemistry of the Technical University of Zurich. He introduced me to PVC compounds. I started to experiment with this material and studied his book on organic chemistry. I acquired some small thin PVC material used as insulation for electrical wires. Following the description in his book, I heated a localized segment of the tubing and applied compressed air pressure resulting in a localized aneurysm of the tubing. I used a second outer tubing measuring 4 mm in diameter to confine the diameter of the segment. After hundreds of experiments most of which were performed in my own kitchen I was able to form a sausage-shaped distensible segment which I tried to reinforce with the silk mesh. When I mounted the material on normal catheter tubing and applied pressure to distend the aneurysmal segment, I suddenly realized that the strength of this material was so great that the silk mesh was not necessary. This was a great breakthrough and enabled me to reduce the size of the catheter."

There were severe criticisms especially by the surgeons and particularly by the internists as regards to the safety of his procedure. However, Dr Ake Senning, a well-known cardiovascular surgeon, in his institute supported him to further develop the methods to remove the blocks in the occluded arteries. The earlier designs were of single lumen catheters. However, he was in search of technique to produce double lumen catheters and ultimately could get help from Schneider Medintag Company. On October 22, 1975, he performed the first canine coronary angioplasty after cardiac surgeon Marko Turina had produced coronary stenosis with silk ligature and in about years "time several dogs"

angioplasty was performed and he was ready to perform coronary angioplasty in the clinical use, since the double lumen catheter had been produced by Schneider Medintag. However, he found it difficult to get the first patient. Though according to the historical records it is mentioned that the first angioplasty was performed intraoperatively, actually attempt to perform angioplasty in Catheterization Laboratory was attempted earlier to intraoperative procedure. On March 22, 1976, a 63-year-old man was referred to Gruentzig with several myocardial infarctions, unstable angina, severe triple vessel disease, left main stenosis, and peripheral vascular disease and was turned down by cardiac surgeons. After some initial hesitations he attempted to perform the procedure from left brachial artery. However, he could not engage coronary ostium due to bulky 10F guiding catheter. The procedure was abandoned. The patient expired after few days. However, Dr Richard K Myler from San Francisco, USA was impressed by Dr Gruentzig's presentation of dog experiments during the annual convention of the American Heart Association in Miami in November 1976 (Fig. 5). He invited him to perform the procedure intraoperatively during open heart surgery by a team of Elias Hanna. The team consisted of Hanna, Myler, and Gruentzig.

However, Dr Gruentzig was keen to perform the procedure in the cardiac catheterization laboratory. He had to wait until September 1977 when Dr Bernhard Meire referred 38 years old patient who had unstable angina pains of several weeks duration and the angiography had shown discrete left anterior descending (LAD) lesion. As a matter of fact patient was advised CABG surgery and to the good luck of Dr Gruentzig and the future interventional cardiology community, patient agreed to undergo the LAD dilatation procedure. The procedure was performed in the University Hospital of Zurich. Postprocedure angiography has been performed which revealed patent LAD. The first patient became friend of Andrea Gruentzig and used to participate as a popular delegate in live teaching course of angioplasty.

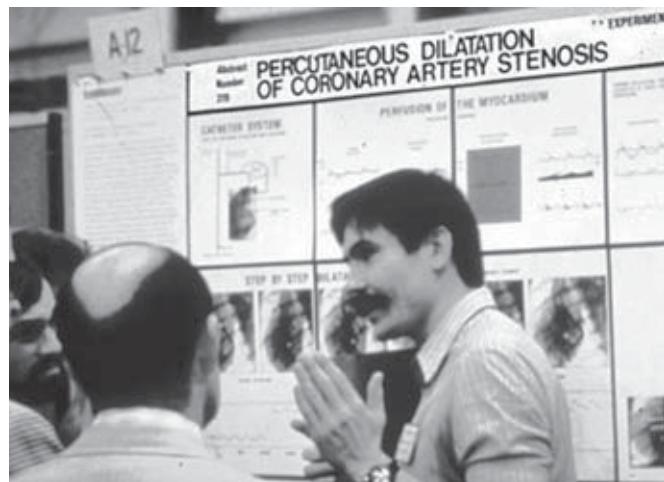

FIG. 5: Dr Andreas Gruentzig at American Heart Association meeting with his presentation.

In addition to developing balloon angioplasty technique, it was to the credit of Dr Gruentzig that he started live demonstration courses. Four such courses were held in Zurich before he moved to USA. During these courses some of the stalwarts and who is who of cardiovascular specialty would be the ones who would be attending these courses. One could meet Dotter, Gruentzig, Mason Sones and Judkins under one roof. Unfortunately all of them died in 1985. Angioplasty thus proved to be a small step for Gruentzig, but a huge leap for percutaneous treatment of coronary artery disease. The numbers slowly tended to grow and it was not surprising that angioplasty numbers have now outnumbered the surgical numbers.

In the beginning, the procedure was recommended for some selective cases. However, the next major step was by John Simpkins who proposed removable of guide wire which would allow the torque control. He named it "steerable guide wire". He designed the wire which had solid core which was tapered toward the distal end to increase flexibility. The guide wire could be moved independently and facilitate the negotiation of the vessel by the balloon. However, these were over the wire systems and maneuvering was little more cumbersome. The next was monorail system developed by Bonzel. The term monorail was coined by Bernhard Meire.

NEW DEVICES

Subsequent to balloon angioplasty acceptance as a definite procedure for treating obstructive coronary artery disease, several problems were encountered by the angioplasters. Some of them were (A) calcified and bulky lesions, (B) small diameter vessels, (C) restenosis, and (D) of course the greatest challenge that would jeopardize the life of the patient, was the acute reclosure after balloon angioplasty due to dissection of the artery and impending acute myocardial infarction. In the early era of angioplasty, it was mandatory to have stood by surgical back up. The interventional cardiologists, engineers, technologists worked together to address some of these problems so as to make the procedure accepted by the patients easily and match the results of coronary artery bypass graft surgery. The result was development of several new adjunctive devices.

Directional Atherectomy

This was one of the first new devices and John Simpson in 1985 was instrumental in developing this device with Flexicut Device Company. The technique could cut huge bulky or calcified plaques giving a larger lumen diameter. However, the procedure later became unpopular since the device was bulky needing large guide catheter, with risk of dissection and arterial closure and myocardial infarction. Moreover, it failed to show reduction in rates of restenosis.

Transluminal extraction catheter (TEC) was designed by Starr. It was over the wire conical system with two stainless steel cutters which cut and aspirated the atheromatous material. Its use was largely defined in the saphenous vein grafts.

Rotational Atherectomy

This high-speed rotational atherectomy device was developed by Auth, a Biomed Engineer who started to investigate the rotational atherectomy as an alternative to debulking with directional coronary atherectomy (DCA) or TEC. The burr spins at 160,000–200,000 p/m pulverizing plaque and calcium in tiny particles. After several experiments the first case of rotational atherectomy in humans was performed by Zaka in Houston and the first coronary rotational atherectomy on January 06, 1988 by Fourrer Bernard in a 68-year-old woman with stable angina. Apart from stents, rotational atherectomy has withstood the test of time. The frequency of its use varies from operator to operator and probably its use is in the range of 5–10%. However, its use is limited to severely calcified lesion.

Laser Angioplasty

It was introduced in interventional cardiology during the beginning years of 1980s and was used in patients with total occlusion and became popular procedure in early 80s. However, the earlier data indicated higher restenosis rate and failed to show benefit of laser and comparable techniques.

Brachytherapy

Several autopsy specimens and animal experiment showed that restenosis occurred due to neointimal proliferation. To reduce the risk of neointimal proliferation, brachytherapy with gamma and beta radiation obtained through different sources and devices was explored. Several post-brachytherapy patients developed stent thrombosis. With the advent of drug-eluting stents, brachytherapy was removed from the market.

Coronary Stents

Stents have been the most important innovation in the field of coronary angioplasty after balloon angioplasty. Stents were able to address two major challenges of balloon angioplasty: (1) acute closure during the angioplasty procedure could be handled effectively since, it provided scaffold to the dissected intima and (2) reduced the risk of restenosis.

The word stent is named after Charles Stenting, an English dentist, who used the dental impression in 1856. The history of first coronary artery stenting started with meeting of two Swedish individuals at a gathering. Wallsten was a designer of a revolutionary machine intended to manufacture paper and Senning one of the most popular surgeon from Switzerland. Dr Senning explained to Wallsten the difficulties of treating aortic dissection. Wallsten agreed to design endovascular prosthesis and created the Wallstent. Subsequently, Puel implanted the first coronary stent on March 28, 1986 and subsequently Sigwart and Puel continued to carry on with their work on stents. Subsequently, new designs like Palmas Schatz, Wiktor, Gianturco-Roubin, NIR, and Multilink flooded the market. These stents tackled the issue of acute reclosure and reduced the incidence of restenosis, but not to a large numbers. There was need to reduce neointimal proliferation. In 1999, Cordis introduced rapamycin-coated

stent called CYPHER. Rapamycin and its analogs decrease neointimal proliferation and thus would reduce the chances of restenosis. First implantation and data was published in First In Man (FIM) trial by Patrick Serruys and Eduardo Sousa from Rotterdam and Sao Paulo. Subsequently, several large scale trials have shown favorable results of drug-eluting stents. Currently, several analogs of rapamycin have been used on cobalt-chromium platform. The field is ever expanding with newer metallic bioabsorbable stents under trial.

HISTORY OF FRACTIONAL FLOW RESERVE, INTRAVASCULAR ULTRASOUND, AND OPTICAL COHERENCE TOMOGRAPHY

Fractional Flow Reserve

Like present times, the quandary faced by clinicians at the beginning of invasive coronary angiography in the seventies was to determine which lesions were important, and which were not. There were very few techniques for measuring human coronary blood flow. In 1974, Dr K. Lance Gould demonstrated that coronary flow reserve (CFR) or hyperemic maximal to basal flow ratio could be related to stenosis severity, and perhaps overcome the limitations and ambiguity of the coronary angiogram for detection of ischemia.

In animal experiments, he showed that CFR began to decline when stenoses were more than 60% narrow and resting flow decreased when stenoses were more than 90% narrowed. Hence, it was thought that coronary physiology could predict anatomy and vice versa. However, it was realized that in human patients, unlike in the experimental dogs, CFR was poorly related to the angiographic percentage narrowing, because of two factors: (1) the inability of the angiogram to precisely determine the stenosis area and length, and (2) the fact that some patients had microvascular disease and an impaired coronary flow reserve, even with normal coronary arteries.

However, Dr Andreas Gruentzig's coronary angioplasty balloon catheter changed cardiology history on July 12, 1979, when it used a small pressure lumen to measure translesional gradients.

He reported the first "nonoperative dilatation of the coronary artery stenosis"; that is, percutaneous coronary balloon angioplasty, in the New England Journal of Medicine. This paper showed the method and results of the dilating Gruntzig catheter inflating in a stenosis. The measurement of the pressure gradient before and after the balloon inflation and deflation was used to guide the procedure, and overcome the very poor angiographic image quality at that time. However, pressure measurements during PTCA were questioned, because of the technical difficulty of measuring pressure through a large 4.5F catheter with a small, fluid-filled pressure lumen.

Over the next few years, coronary angiography improved dramatically and many like Dr Jeff Hartzler, did not feel the need for measurement of pressure to do angioplasty.

Nico Pijls from Eindhoven, the Netherlands, and Bernard De Bruyne in Aalst, Belgium, were the first to begin using a

0.014-inch hollow sensor angioplasty guide wire to measure pressure across a stenosis. With this invention, the evolution of the pressure-only flow reserve theory could be tested, which culminated in the derivation and application of the fractional flow reserve (FFR) concept. FFR is the percent of stenotic flow to normal flow across a stenosis. The flow ratio is computed from the distal or aortic pressure measurements at maximal hyperemia. One important aspect in the development of the FFR was the incorporation of venous pressure to account for collateral flow, making the validation successful in both the animal lab as well as in clinical outcome studies.

In 1996 the validation of FFR, published in the New England Journal of Medicine by Nico, Bernard, and others, demonstrated a strong relationship of myocardial ischemia to an FFR value of 0.75. The sensitivity of FFR in the identification of reversible ischemia was 88%, the specificity 100%, the positive predictive value 100%, the negative predictive value 88%, and the accuracy 93%.

The rest, as they say, is history!

The future of coronary physiology over the next decade is the validation and application of noninvasive imaging-based FFR such as FFRCT (computed tomography-derived FFR), using 3D reconstruction of the arterial imaging scan and applying computational fluid dynamics.

Another development is the resting pressure ratio of the instantaneous wave-free ratio which obviates the use of vasodilator injection for hyperemia.

Quantitative flow ratio (QFR) does away with both pressure wires and induction of hyperemia. It is based on computation of standard invasive coronary angiographic imaging and is derived from fluid dynamic equations incorporating vessel geometry, assumptions on flow through a stenosis, and vessel tapering.

Thus, these are exciting times for coronary physiology and interventional cardiology.

Intravascular Ultrasound

Tremendous advances have occurred during the last 40 years in the field of medical imaging of the heart and the coronary vasculature, triggered by the increasing need to reduce or prevent coronary artery disease.

Although in 1960s and early 1970s, noninvasive method was the most preferred method for the clinical use of heart and great arteries, with increased understanding of coronary artery diseases, noninvasive method alone could not have sufficient resolution and penetration depth to give a direct image of smaller size vessel like coronary arteries.

Due to these limitations of noninvasive method, intravascular imaging route led to the development of X-ray angiography in the 1960s, balloon angioplasty and related techniques in the late 1970s and early 1980s. Meanwhile, in the early 1970s, academic research programs focused on developing two-dimensional real-time ultrasound imaging of the heart, transferring in particular knowledge from underwater acoustics to medicine. This noninvasive route led to echocardiography, an imaging modality acclaimed for its

radiation-free nature but lacking the resolution to image the coronary vasculature.

The first trial of using ultrasound invasively to make image of mammalian lumen was done by Cieszynski in 1956, where a single-element echo catheter was used to measure a dog's cardiac chamber dimensions. In 1969, the cross-section image of an animal's cardiac chamber was first reconstructed and reported with ultrasound by Eggleton et al. In the same year, the first design of cylindrical transducer was first designed by Carelton et al.

From the time of the first implantation of coronary stent in human in 1986, cardiologists were trying to find ways how to investigate coronary vessels *in vivo* from inside. The first method used for this purpose was angioscopy, a method that allows only surface assessment of the vessel.

A need was felt in the early 1990s to provide high-resolution images of diseased coronary artery wall structures, referred to as vulnerable plaques and primarily responsible for myocardial infarctions, when false-negative coronary angiography cases became evident. Intravascular ultrasound (IVUS) is a catheter-based echocardiography modality that was patented by Bom in 1972 and further developed to investigate the status of the coronary artery wall.

Twenty years after its introduction in the clinic in the early 1990s, IVUS technology continues to bring scientific insight into the pathophysiology of the coronary artery disease and not only helps guiding percutaneous coronary interventions, but also research into plaque growth and regression.

Optical Coherence Tomography

Predicting the risk for future acute cardiovascular events requires knowledge of plaque composition, which is not yet provided by conventional IVUS, although several IVUS signal processing techniques have been developed at research level to augment IVUS capabilities in detecting and characterizing coronary artery plaques at risk.

Optical coherence tomography (OCT) was first described more than two decades ago when it was used to image the peripapillary area of the human retina *in vitro*. Eleven years later, OCT was used to image atherosclerotic plaques in human coronary arteries. The image resolution achievable with OCT (axial: 10 µm, lateral: 20–40 µm) far surpasses that of IVUS (100–200 µm). Histological studies have shown that certain adverse plaque phenotypes are associated with the onset of an acute coronary syndrome (ACS). With its excellent spatial resolution, OCT is ideally placed to identify vulnerable plaque that could result in ACS.

While IVUS offers an improved imaging depth for the assessment of lipid or necrotic plaques, intravascular OCT offers better penetration and enhanced imaging of calcific tissue. Intravascular OCT requires a short injection of contrast (e.g., 2–3 seconds) in a similar way to obtain an angiographic image. IVUS does not require a contrast injection as ultrasounds can penetrate through blood.

Since, its first clinical application reported by Huang and coworkers in 1991, suggesting the principle of its use both in ophthalmology and interventional cardiology, the method

has developed rapidly and is now used in increasing number of cases, both in routine clinical situations and research projects. Its detailed intravascular imaging ability, providing real-time information of the intracoronary pathology has benefited interventional cardiology tremendously.

Future of Optical Coherence Tomography in Interventional Cardiology

Optical coherence tomography imaging technique is constantly developing and opening new horizons in the coronary interventions. One is development of the software for the 3D reconstruction of the OCT image. In the near future, introduction of the micro-OCT system is expected which should provide extreme image resolution (up to 1 µm). With this level of resolution cellular structure of endothelial tissue should be assessable. One can only imagine its application not only in the evaluation of disease process but also in its prevention.

Bifurcation Stenting: Optimal Strategy in 2018

Ashwin B Mehta, Nihar Mehta

INTRODUCTION

Coronary artery bifurcations are prone to develop atherosclerotic plaques due to turbulent blood flow and high-shear stress. Bifurcation lesions are commonly accounting for approximately 15–20% of all percutaneous coronary interventions (PCIs).^{1,2} Bifurcation stenting in 2018 is still complex, since it is associated with a high risk of stent thrombosis and significant restenosis. With the use of drug-eluting stents (DESs) there has been reduction in the rate of restenosis and reintervention as compared to bare-metal stents (BMSs).³ This subset of coronary artery disease intervention poses unique challenge of obtaining optimal result in the main vessel (MV) while maintaining the side branch (SB) patency. Understanding the anatomy and physiology of the coronary bifurcation lesions is essential to achieve this goal. While stenting of the MV and stenting of the SB to salvage it if flow is impaired (provisional strategy) is preferred, there are instances where upfront elective two-stent strategy needs to be used. The carina and SB ostium are central to the bifurcation anatomy and several strategies can be used to ensure the optimal results.

DEFINITIONS AND CLASSIFICATIONS

A coronary bifurcation lesion is defined as a coronary artery narrowing occurring adjacent to, and/or involving, the origin of a significant SB (Fig. 1). A significant SB is a branch, closure of which could lead to important adverse sequelae to the patient. Usually these are SBs more than 2.0 mm in diameter.

A bifurcation lesion involves three distinct anatomical segments; the proximal MV, the distal MV, and the SB. The bifurcation carina is the transition zone between the MV and the SB and is the core of the bifurcation anatomy.

In an attempt to simplify classifications, Medina et al. proposed a classification which is easier to remember in comparison to older ones. However, the Medina classification has shortcomings. It does not relate to angulation of the distal main branch (MB) and SB, length of the SB, plaque

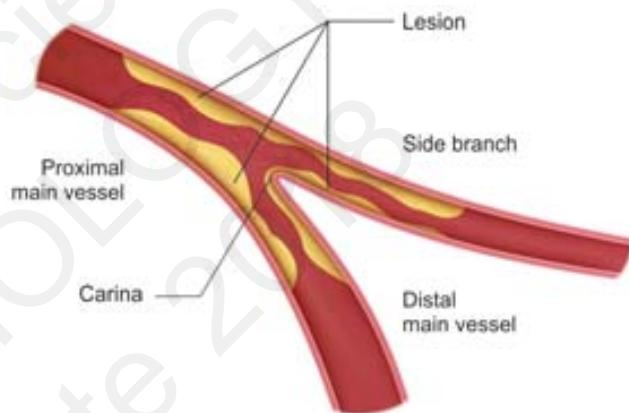

FIG. 1: Anatomy of a coronary bifurcation.

distribution, and the size of the proximal healthy segment which all affects the strategy and decision making (Fig. 2).⁴

A “true bifurcation lesion” is one in which both the MV and the SB have more than 50% stenosis (Medina types 1,1,1 or 1,0,1 or 0,1,1). A “pseudo bifurcation lesion” is one which does not have significant disease at the ostium of the SB (Medina types 1,1,0 or 1,0,0 or 0,1,0).

ANATOMICAL CONSIDERATIONS

Angle assessment in bifurcation lesions is used to measure two angles: (i) The “Take-off Angle” or proximal angle or angle A (Access angle) between the proximal MV and the SB and (ii) The “Carina angle” or angle B (Between) between the distal MV and the SB (Fig. 3). The angle A gives a measure of difficulty in accessing the SB. The acuteness of Angle B increases the risk of carina displacement and SB occlusion (SBO) after stent placement. The angles between the distal MV and SB (angle B) affect the outcome of PCI pertaining to ease of wire access and stent deliverability, plaque shift or “snow-ploughing” effect and complete coverage of ostium of SB.⁴

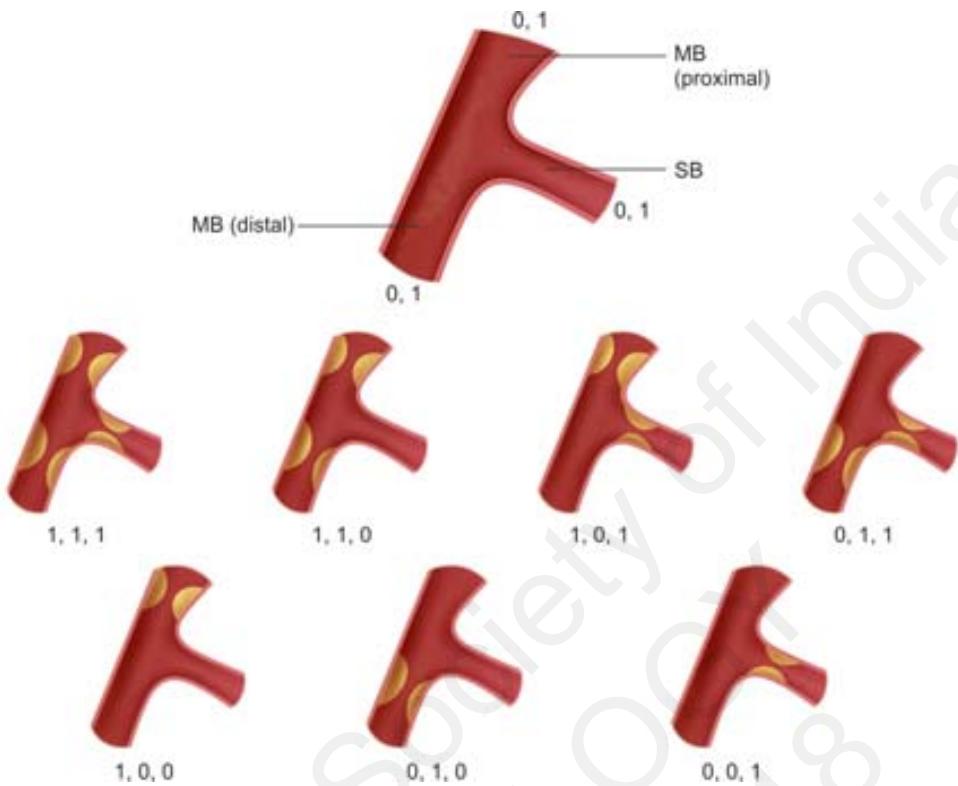

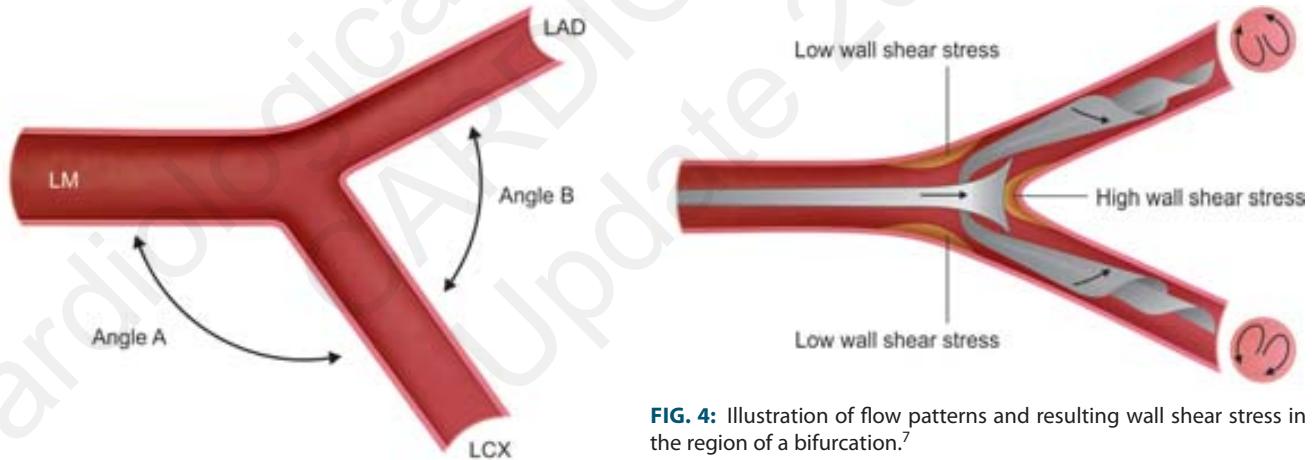

FIG. 2: Medina classification of bifurcation lesions.⁵

LAD, left anterior descending artery; LCX, left circumflex artery; LM, left main.

FIG. 3: Anatomy of the bifurcation angle.

- Angle B when less than 70°, it is called a “Y-angulation” and allows easy wire access to the SB, but plaque shifting is potentially more pronounced and precise stent placement with complete ostial coverage is often difficult or geometrically impossible.
- Angle B when more than 70°, it is called a “T-angulation” and wire access to the SB is usually more difficult. However, plaque shifting is less frequent and precise stent placement with complete ostial coverage is technically easier and more likely.

FIG. 4: Illustration of flow patterns and resulting wall shear stress in the region of a bifurcation.⁷

Plaque distribution in bifurcation lesions is localized exclusively to the outer wall of one or both daughter vessels where the wall shear stress (WSS) is low. The term “WSS” refers to the stress on the arterial wall due to the friction associated with the viscous fluid flowing past the arterial wall (Fig. 4). Atherosclerosis occurs early in areas of nonuniform and low WSS. On the other hand, areas of uniform, high WSS are protected. Thus, the carina is usually protected and the plaques develop in both branches opposite to the carina.^{6,7} In studies done using intravascular ultrasound (IVUS), this theory has been supported showing sparing of the carina.⁸

RELATION BETWEEN SIZES OF VESSELS: MURRAY'S LAW⁹ AND FINET'S LAW¹⁰

In the bifurcation anatomy, it is important to understand the relationship between the sizes of the vessels. The fact that the MV is larger than the MB is frequently forgotten during procedures.

There is an important mother daughter mathematical relationship first described by Murray, based on the principle of minimum work.⁹ Murray's law states that the size of the proximal MV (D_{MV}) and the size of the daughter vessels (D_{MB} and D_{SB}) are represented by the following formula:

$$D_{MV}^3 = D_{MB}^3 + D_{SB}^3$$

This formula has been proven in normal and diseased vessels by IVUS study.¹¹ It, however, was incorrect in calcified vessels and in the culprit lesions of acute coronary syndrome. The following implications can be derived from this formula.

- The difference in the diameter (size discrepancy) between the proximal MV and distal main branch (MB) is dependent on the size of the SB. The larger the SB, the more is the size discrepancy. Therefore, it is imperative to perform the proximal optimization technique (POT) in bifurcation lesions with a large SB (details of POT are described later)
- When kissing balloon inflation is performed with balloons sized according to the two branches—MB and SB, the balloons would always be oversized for the proximal MV. According to Murray's law, the sum of the cross-sectional areas of the balloons of the two branches would be larger than the cross-sectional area of the proximal MV. Therefore, it would be advisable to be conservative in balloon inflation pressures, going up to only moderate pressures during kissing balloon inflation (kissing balloon inflation is described later).

Finet et al. modified this to derive the simple formula:¹⁰

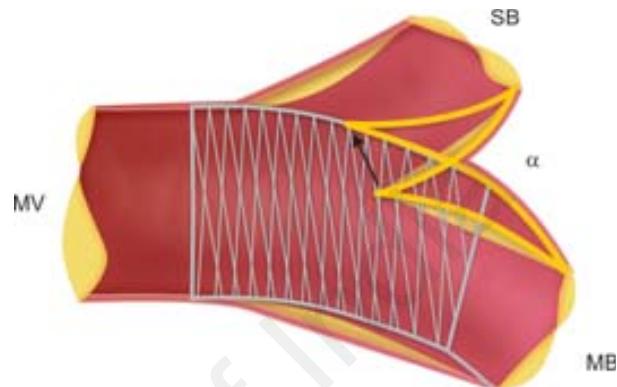

$$D_{MV} = 0.678 (D_{MB} + D_{SB})$$

This formula can be used to calculate the size of one vessel if the sizes of the other two vessels in the bifurcation are known. However, this relationship can be quite variable according to the vessel size. For example, if the SB is small, the calculated value of the MV is smaller than the MB, which cannot be true!¹²

To summarize, the relationship between the size of the MV, MB, and SB are the key to select the optimal strategy of POT and kissing balloon inflation. Considering the variation in the size of the branches and the inadequacy of the Murray's and Finet's laws, IVUS should be used for optimal sizing and improved cardiovascular outcomes.¹³

PLAQUE SHIFT VERSUS CARINA SHIFT

The most common complication of bifurcation stenting is the closure of the SB. The major mechanism for SBO was assumed to be plaque shift from the MV to the SB. However, the carina was found to be spared of atherosclerotic plaque burden due to high WSS (Fig. 4).⁷ Scanty plaque at the carina

MB, main branch; MV, main vessel; SB, side branch.

FIG. 5: Carina shift during stenting according to size of MV.¹⁴

could not be the cause for major plaque shift. Carina shift is a major contributor to anatomical SBO, which has been proven by IVUS study of the MV and SB (Fig. 5).¹⁴

Conversely, functional studies using fractional flow reserve (FFR) showed opposite results. Kang et al. evaluated the MV and SB using FFR and IVUS in a study of 40 patients and showed that carina shift was mostly not associated with a significant drop in FFR. Abnormal FFR in the SB was almost always associated with plaque shift.¹⁵ Angiographically, carina shift can look exaggerated but is often functionally insignificant.

The main causes of SBO due to plaque shift were identified as proximal MV disease, SB ostial disease, and acute coronary syndrome.¹⁶ An IVUS study showed that plaque shift mainly comes from proximal MV disease.¹⁴ The bifurcation angle was not a major predictor of SBO which suggested that carina shift was not the main reason for SB compromise.

To summarize, the compromise of the SB after provisional MV stenting is usually due to carina shift and is functionally not significant. Significant SBO usually results from plaque shift, for which the main predictor is proximal MV disease burden.

THREATENED SIDE BRANCH MORPHOLOGIES: PREVENTING SIDE BRANCH OCCLUSION

The major cause of complexity during bifurcation stenting is the occlusion of the SB. The main goal is identifying the SB at risk and preserving it.

The concept of "threatened SB morphologies" needs special consideration as regards to the incidence of SBO. In studies done comparing the incidence of SBO based on threatened versus nonthreatened SB morphologies, the incidence of SBO was significantly higher in threatened morphologies (80%) as compared to nonthreatened morphologies (7.9%) (Fig. 6).⁴

The COBIS (Coronary Bifurcation Stenting) II registry of 2,227 patients who were treated with provisional stenting identified the following predictors of SBO:¹⁶

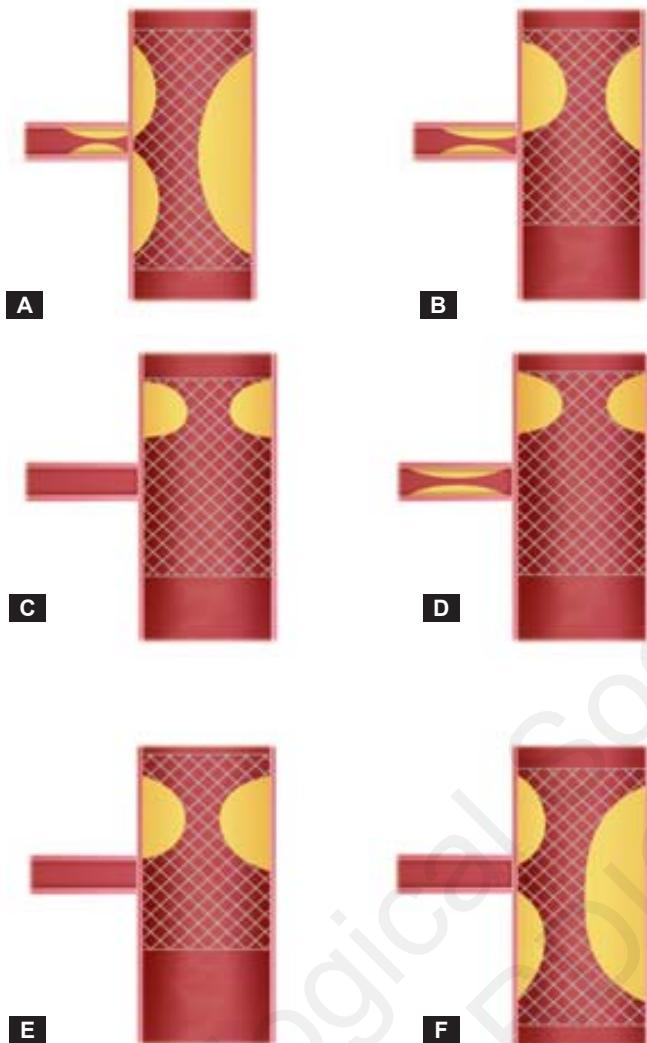

FIG. 6: Threatened side branch morphologies.⁴ A, Side branch (SB) with more than 50% ostial narrowing where the origin is completely spanned by either the diseased segment or the index lesion; B, SB arises adjacent to or is partially contiguous with the diseased index lesion. Nonthreatened SB morphologies includes: C, SB without ostial narrowing; D, SB with ostial involvement; E, Disease-free SB arising adjacent to diseased segment of the parent vessel; F, SB without ostial disease arising from parent vessel lesion spanning the entire origin of the SB.

- Side branch ostial disease
- Side branch lesion length
- Diseased MB
- Non-left main bifurcations
- Acute coronary syndrome.

On the other hand, SB predilatation, jailed wire technique, and IVUS guidance were not predictors of SBO.

STENTING STRATEGY IN BIFURCATION LESIONS—ONE OR TWO STENTS?

The strategy to use one stent (in the MV) or two stents (one in the MV and one in the SB) for the treatment of bifurcation lesions has been long debated.¹⁴⁻¹⁶ The most important

initial questions are whether the SB is large enough (>2.25 mm diameter) and whether the SB supplies a large enough territory to justify its intervention. In the provisional SB stenting strategy, the MV is stented first and the SB is stented through the MV stent, only if necessary. Thus, the use of the second stent is provisional.

The primary reason why the PCI of bifurcation lesions has been a challenge is the risk of SBO or compromise after treating the MV. Hence, understanding the anatomic attributes characterizing the lesion including the bifurcation angle, the size of SB, myocardial territory supplied by the SB, lesion length in SB, and distribution of MV disease are essential. Thus the approach of “one for all” is not practical in all bifurcations. Hence, provisional stenting should not be used as a default strategy in “high-risk bifurcations” that involve a large SB. In some patients, elective double stenting (EDS) strategy is opted for to reduce the risk of large SB compromise.⁴

Provisional Side Branch Stenting Strategy

This strategy involves stenting the MV first. If necessary, a second stent is delivered to the SB through the MV stent in a classic T, T-stenting and protrusion (TAP) (T and small protrusion), inverted culotte or internal crush technique. Use of the second stent is only provisional.

Steps

- *Wiring both the branches:* Wiring starts with the most difficult branch. The second wire is inserted into the easier branch by limited rotation manoeuvres to avoid wire wrap. The wire inserted in the SB should be without hydrophilic or polymer coating because the coating may get peeled off during removal of the jailed wire. The advantage of securing the SB with a wire is that it serves as a marker to find the SB lumen, if an occlusion occurs
- *Predilatation:* Predilatation of the MB is left to the operator’s discretion. Predilatation of the SB does reduce the risk of SB compromise after MV stenting and also relieves ischemia in the SB territory. It can, however, produce a dissection in the SB. The subsequent step of rewiring the SB through the distal strut of the MB stent may be difficult in presence of dissection. Therefore, predilatation of the SB is reasonable to reduce SB compromise in a high-risk lesion, but the operator should avoid dissections in the SB¹²
- *Stenting the MV across the SB:* The selection of the stent is important. The cell area should allow access to the SB ostium. The diameter of the stent should be selected according to the distal MB (not the proximal MB) in order to avoid excess carina shifting (Fig. 5). Ideally, the stent size should be selected using IVUS. The proximal part of the stent prior to the bifurcation may be dilated with a short 0.5 mm bigger balloon. This is called “POT technique”. This results in optimal diameter of the proximal part of the stent and allows the struts of the stent to face the SB which allows subsequent rewiring of the SB (Fig. 7).¹⁷ The POT technique has been shown to reduce

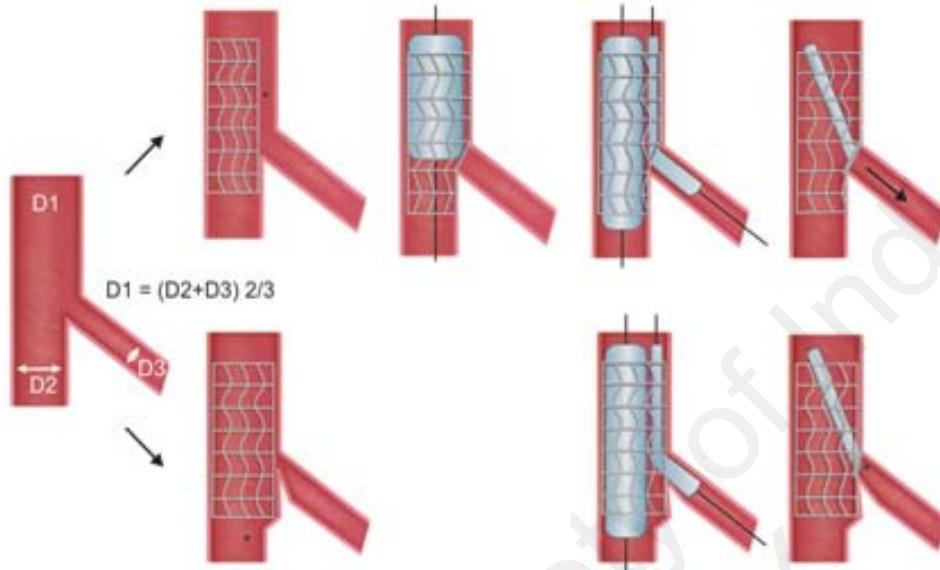

FIG. 7: Consequence of choice of diameter of main vessel (MV) stent. Up—selection according to the diameter of the distal MV followed by proximal optimization technique technique. Down—selection according to the diameter of the proximal MV.

the restenosis rates in the MV when the size of the SB is more than 2.5 mm.¹⁶ An interesting finding was that there was no benefit of POT if final kissing inflation (FKI) was performed, probably due to the effect of two balloons expanded in the proximal MV¹⁶

- **Side branch rewiring or guide wire exchange:** This step starts with removal of the wire in the MB and inserting it into the SB. Alternatively, a third wire can be used to go through the struts of the MB stent into the SB so that MB position of the initial wire is not disturbed. The SB jailed wire is then removed or passed into the MB if MB wire was removed. The maneuvering of the wire through the MB stent strut should be done carefully, such that the wire enters the distal most strut of the stent. Final kissing balloon inflation performed after this “distal cross” of the guide wire allows correction of the MV stent deformation, allows better scaffolding to the SB ostium, and facilitates better future access to the SB. On the other hand, FKI performed after “proximal cross” of the guide wire results in MV stent deformation and poor SB ostium scaffolding (Fig. 8).¹⁸
- **Final kissing balloon inflation:** Two short balloons are selected based on the diameter of the distal vessels. They are inflated simultaneously to perform the FKI. For the optimal result of FKI, distal crossing of the wire is preferable.

A subanalysis of the CACTUS trial showed that FKI was associated with a lower major adverse cardiac event (MACE) rate and better angiographic result.¹⁹ However, the Nordic-Baltic Bifurcation III Study randomized 477 patients to FKI versus no FKI in patients treated with MV stenting. This study showed no difference in the MACE rate or event free survival at 6 months. FKI resulted in better angiographic results, especially in true bifurcation lesions. FKI resulted in longer contrast use, angiography, and procedure times.¹⁸ Koo et al.

advocated the use of FFR guided jailed SB intervention. Their study of 110 patients showed no difference in the clinical outcomes at 9 months between the groups with or without FFR guided SB angioplasty.^{20,21}

The conclusion drawn from these studies does not support routine balloon dilatation of the SB, but advocates use of FFR to guide intervention in a jailed SB. However, after SB ballooning, FKI is mandatory since SB ballooning deforms the MV stent.

- **POT-side-POT (re-POT):**^{12,22} The main goal in coronary bifurcation stenting is optimal expansion of the MV and MB stent. Although, the key issue is preserving the SB patency, but clinical outcomes are highly dependent on the MV stent expansion, particularly in the provisional stenting strategy.¹² Therefore, FKI can be replaced by a second POT. In case the SB needs to be treated, it is rewired and ballooned. This will lead to MV stent deformation which can be corrected by a second POT or a re-POT instead of a FKI. This simplifies the procedure.

The most challenging part of re-POT is precise location of POT balloon. It should cover the proximal edge of stent carina, which can be done by aligning the proximal edge of distal balloon marker with the tip of stent carina (Fig. 9).^{12,22} The impact of this technique needs to be evaluated in clinical trials.

- **Provisional SB stenting:** In about 70–80% of cases, the procedure ends at the previous step. In about 20% results in the SB were unsatisfactory after FKI:²⁰
 - More than 75% residual stenosis
 - Dissection in SB
 - Thrombolysis in myocardial infarction (TIMI) flow grade less than 3 in a SB more than 2.5 mm diameter
 - Fractional flow reserve less than 0.75
 - Persistent intraprocedural angina or electrocardiogram (ECG) changes.

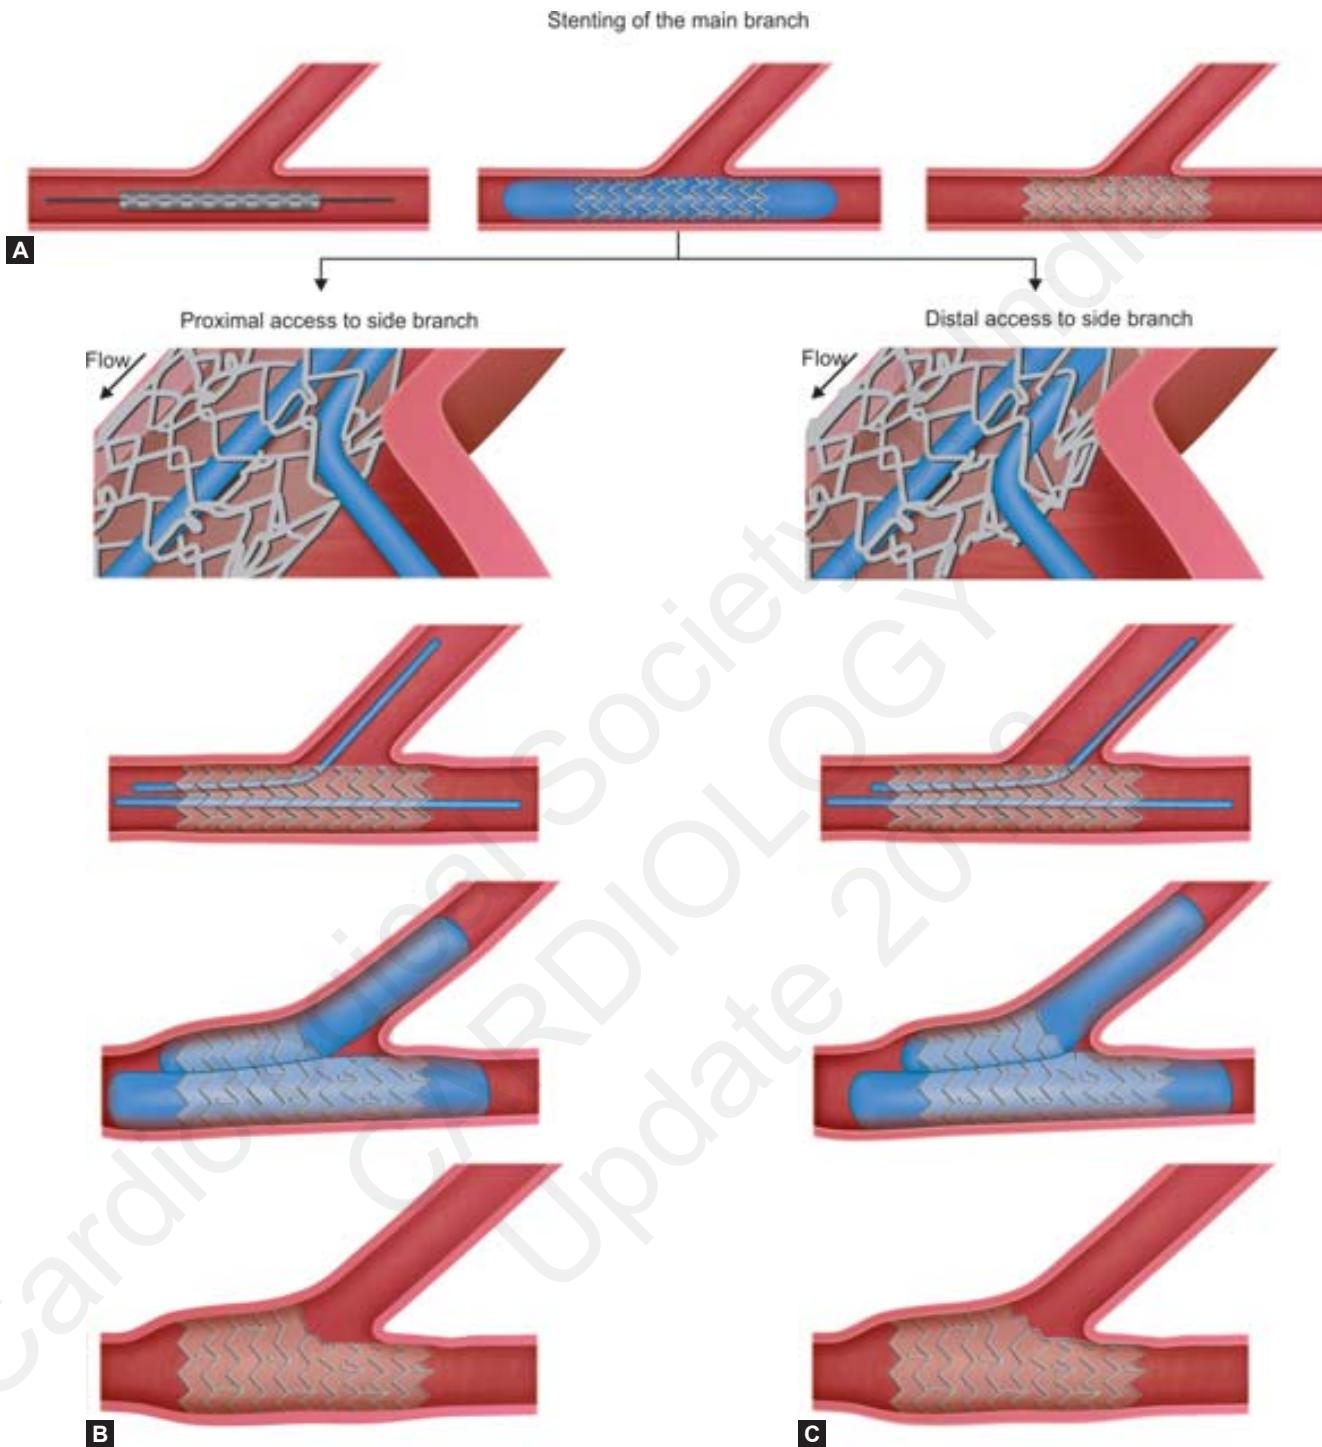

FIG. 8: Proximal versus distal cross during guidewire recrossing and result after final kissing balloon inflation.¹⁸

In these situations, stenting of the SB is done using reverse T technique, TAP technique, reverse crush or inverted culotte technique.

Evidence for Provisional Stenting Strategy and Indications for Side Branch Stenting

The current evidences favor the provisional stenting strategy as the preferred strategy for bifurcation stenting. The results of several randomized studies and prospective

registries were pooled into meta-analyses.²³⁻²⁶ Overall, the meta-analyses did not reveal any differences at 6–7 month follow-up in terms of mortality, MACE, and target lesion revascularization (TLR), although there was a significant difference in favor of the single-stent group in the Bifurcation Coronary Study (BBC) One study.²⁷

The Nordic Baltic Bifurcation Study IV randomized 450 patients to compare provisional SB stenting versus two-stent strategy in treatment of true bifurcation lesions with a

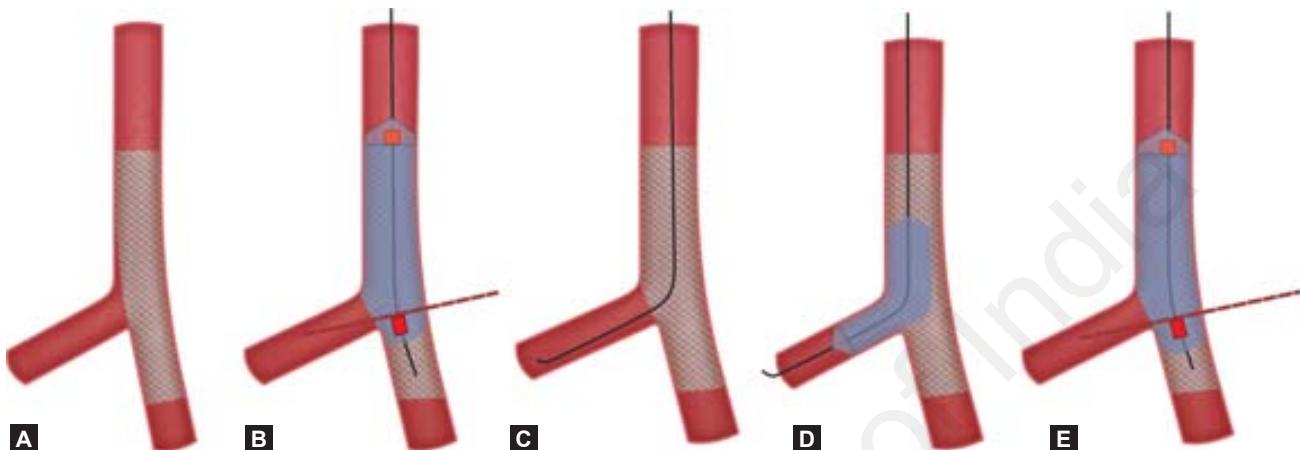

FIG. 9: The POT-side-POT technique. A, Stenting the main vessel and main branch (MB) according to the distal MB size; B, Proximal optimization therapy (POT); C, Re-wiring the side branch; D, Side branch balloon dilatation; E, Re-POT (second POT).²²

large SB. After 2 years, two-stent techniques for treatment of true bifurcation lesions with a large SB showed no significant difference in MACE rate compared to provisional SB stenting.²⁸

To determine the indication for SB stenting in a provisional stenting strategy, the SMART-STRATEGY (Smart Angioplasty Research Team-Optimal Strategy for Side Branch Intervention in Coronary Bifurcation Lesions) trial divided patients into a conservative group and a aggressive group. In the conservative group, SB stenting was indicated if TIMI flow less than 3 in non-left main bifurcation or if the diameter stenosis was more than 50% or dissection occurred in left main bifurcation. In the aggressive group, SB stenting was indicated if diameter stenosis more than 50% or dissection in non-left main or if the diameter stenosis was more than 30% or dissection occurred in left main bifurcation. Target vessel failure (TVF), the primary endpoint was similar between two groups (9.4% vs. 9.2%, $p = 0.97$). The mortality was numerically lower (0.8% vs. 2.3%, $p = 0.62$) in conservative group, although not statistically significant. Periprocedural myocardial infarction (MI) was significantly lower in conservative group (5.5% vs. 17.7%, $p = 0.002$).²⁹

The European Bifurcation Coronary TWO (EBC TWO) trial compared provisional one-stent technique with elective two-stenting in the large caliber true bifurcation lesions (SB diameter ≥ 2.5 mm) and significant ostial disease length (≥ 5 mm), but MACE was not different between two groups.³⁰

Based on these data, current opinion favors provisional SB stenting with placement of DES in the MV. One should be conservative in stenting of the SB.

Elective Double Stent Strategy

Although provisional stenting has been a preferred option according to many randomized controlled trial, in situations where the SB is large or severely diseased, or supplies a large area of myocardium, the two-stent strategy is still often preferred because of its superior acute angiographic result and lower risk of SB compromise.

Indications

- True bifurcation lesions—MV and SB have more than 50% stenosis (Medina classification 1,1,1 or 1,0,1 or 0,1,1)
- Side branch supplies a large area of myocardium
- Side branch has a diameter appropriate for stenting; more than 2.25 mm
- Side branch lesion is severe and/or long
- Wide angle between the MV and SB that would lead to difficulty in recrossing the SB after MV stenting.

Amongst the various two-stent strategies, the operator should select the strategy which is most familiar to him. Several trials have evaluated the best two-stent strategy, but the results are quite variable. The BBK II trial³¹ found culotte technique had a reduced restenosis rate compared to T stenting, whereas the NORDIC II trial³² showed culotte technique has similar results compared with crush technique. Conversely, the double kissing (DK) Crush III trial³³ showed that culotte was inferior to the DK Crush technique in the left main bifurcation lesions.

The DKCRUSH I bifurcation study by Chen et al. showed that the DK Crush technique reduced the incidence of stent thrombosis, TLR, and cumulative MACE rate at 8 months when compared to classical crush technique.³⁴ The DKCRUSH II study showed that the DK Crush technique reduced the restenosis rate and thus the TLR and target vessel revascularization at 12 months as compared to provisional stenting.³⁵ DKCRUSH-V study³⁶ showed that DK Crush technique showed a lower rate of target lesion failure at 12 months when compared to provisional stenting in the left main bifurcation lesions.

In the light of these trials with varying results, the optimal result in terms of stent apposition and expansion are more important than the stenting strategy. Currently, popular techniques are the T stenting, TAP technique, mini-crush, DK Crush, and mini-culotte techniques.

TIPS AND TRICKS³⁰

- *Guide catheter:* The 7F or 8F guide catheters are preferred to reduce friction among the hardware and allow easy

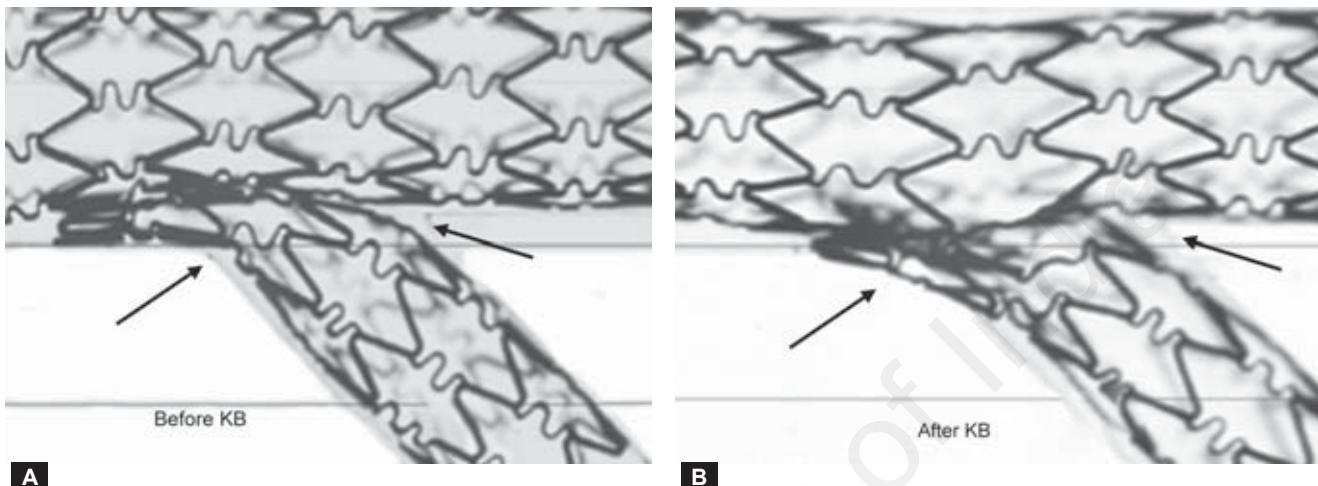

FIG. 10: DK crush technique: The distal cross may lead to a gap in stent coverage at the carina after kinal kissing balloon inflation. In this technique, proximal or mid cross is preferred.³⁷

manipulation. They also provide better support for stent delivery

- **Wiring the vessel:** Wire the branch which seems more difficult first, where manipulation and rotation are expected. This will minimize wire crisscrossing. During insertion of the second wire, minimal rotation should be done. Both wires should be kept separate on the table
- **Lesion preparation:** Lesions in proximal MV, distal MV, or SB should be adequately prepared before stent deployment. In case of severely calcified lesions, rotational atherectomy may be used. Cutting balloons may be used in fibrotic lesions. The main problem with aggressive balloon dilatation is dissection
- **Stent selection and deployment:** When using EDS strategy, drug eluting stents have proven to be more effective than BMSs.^{18,19} Sizing of the stent is also essential for optimal results. IVUS should be used to choose the optimal stent size and to assess the adequate stent deployment or requirement for post dilatation of the stents.
- **Jailed guide wire:**
 - When a stenting strategy involves jailing the guide wire, a nonhydrophilic guide wire should be used. This is because the coating on the hydrophilic guide-wires may get peeled off when pulling it back
 - During deployment of the stent which jails the guide wire (jailing stent), nominal pressure should be used so that retrieval of the jailed wire is easier
 - During forceful removal of the jailed wire, the guide catheter may get deep throated. To avoid this, the guide catheter should be pulled back into the aorta before removing the jailed wire. In case the “jailed wire” cannot be pulled back easily, a balloon can be advanced over the jailed wire
- Stents used should have ideal stent strut expansion for optimal SB crossing. Hence, stents with “open cell” design are preferred

- **Side branch re-crossing:** Distal crossing close to the carina is preferred to ensure adequate geometry of the carina, correction of the MV stent deformation, and scaffolding of the SB ostium (Fig. 8). An exception to this rule is in case of the DK Crush technique where proximal or mid-cross is preferred to distal cross. This is based on bench testing which shows that after crushing, a trough is created between the MV and SB stent struts on the side opposite to the crushed part. If the wire recrosses distally, it may cross this trough, before entering the SB stent. After kissing balloon inflation in this case, there could be a potential gap in the coverage of the stents at the level of the carina (Fig. 10)³⁷

- **Final kissing balloon inflation:** Using noncompliant balloon is an essential step to optimize results. Balloon pressures during FKI should be nominal
- **Hemodynamic support:** May be necessary, especially with left main PCI. Intra-aortic balloon pump may be needed urgently or may be used electively in some cases
- **Dual antiplatelet therapy:** should continue for 12 months after the procedure at least, to reduce the risk of stent thrombosis.

CONCLUSION

In the current era of PCI, coronary bifurcations still remain a complex subset. Despite the favorable results shown by multiple trials on coronary bifurcations, achieving success of these interventions requires a learning curve. Understanding of the anatomy of the coronary bifurcation with regards to MV and SB involvement, the carina, angulations, and myocardial territory supplied are of crucial importance. IVUS is extremely useful to determine the sizes of the vessels and selection of the stent sizes in bifurcation anatomy.

As SBO is a serious complication, anatomical risk stratification of threatened SBs is useful to preserve the SB.

However, the most important predictor of clinical outcomes is the MV stent expansion. Using techniques like proximal optimization therapy, FKI or re-POT are important steps to ensure that the geometry of the stent and carina are preserved.

As per the current evidence, provisional strategy using one stent is the strategy of choice where the risk of the loss of SB by SBO is small or not consequential. In case of a SB narrowing during provisional stenting, FFR guided angioplasty may be performed. In most instances, angiographic SB pinching is due to carina shift rather than plaque shift and does not show any functional significance.

It is sensible to resort to the strategy of EDS when the loss of SB is undesirable like in presence of a large SB (>2.25 mm), severe ostial and/or long segment involvement and wide angle (angle B) with anticipated difficulty in recrossing into SB. Out of all the available techniques for elective double vessel stenting, a choice has to be made on the basis of anatomy, feasibility, operator preference, and experience to deliver a good short-term and long-term results.

Left Main Coronary Artery Stenting in 2018

DS Gambhir

INTRODUCTION

Significant left main coronary artery (LMCA) disease, defined as 50% diameter stenosis, corresponding to 75% of area stenosis is observed in approximately 5–10% of patients who undergo coronary angiography for symptomatic coronary artery disease (CAD).^{1,2} When treated medically, significant LMCA disease carries a mortality of 50% within 3 years after diagnosis.^{3,4} With the advent of coronary artery bypass surgery (CABG) and availability of its long-term follow-up results^{5,6} which established its superiority over medical therapy, CABG was accepted as the gold standard for the treatment of significant LMCA stenosis. In its initial publication on the results of balloon angioplasty by Gruntzig et al.,⁷ this procedure was considered unsuitable, and in fact contraindicated, in patients with LMCA disease. However, after the introduction of drug-eluting stents (DESs) resulting in significant reduction in need for repeat revascularization, there was resurgence of enthusiasm in the role of stenting for LMCA disease.

This chapter will focus on the results of comparison between stenting using DES with CABG, very long-term results of stenting, strategies for left main (LM) bifurcation stenting, and the role of adjunct modalities in the treatment of unprotected LMCA disease.

STENTING VERSUS BYPASS SURGERY FOR LEFT MAIN CORONARY ARTERY DISEASE

Both US and European guidelines have recommended CABG in most patients with LMCA disease.^{8,9} However, the widespread availability of DES associated with improvement in techniques of coronary stenting has lowered the threshold for performing percutaneous coronary intervention (PCI) instead of CABG for LMCA disease. Also, several large registries and randomized controlled trials have demonstrated that results of LMCA stenting are comparable to CABG.^{10–12} This

chapter will focus on the results of four recent prospective, randomized trials, comparing long-term results of PCI using DES with CABG (Table 1).

SYNTAX trial.¹³ Subgroup analysis of patients with unprotected LMCA stenosis comparing PCI using DES with CABG on 705 patients and publication of 5-year follow-up results, there was no difference in major adverse cardiac and cerebrovascular events (MACCEs) between the two modalities of treatment (36.9% vs. 31.0%; p = 0.12). On further analysis, stratified according to the SYNTAX score, MACCE was significantly higher with PCI (46.5% vs. 29.7%; p = 0.003) in the high-risk group (SYNTAX score ≥33). Repeat revascularization rate were found to be higher in the PCI-treated patients regardless of SYNTAX score (26.7% vs. 15.5%; p <0.01). There was, however, no difference in the mortality between two groups, while the lower incidence of stroke rate after PCI persisted at 5 years (1.5% vs. 4.3%; p = 0.003). These findings were confirmed by the smaller LE MANS study¹⁴ and PRECOMBAT trial.¹⁵

The MAIN COMPARE registry¹⁰ enrolled 2240 patients undergoing CABG or PCI with stents [bare-metal stents (BMSs) in early phase and DES in the subsequent period]. There was no difference between the two groups with regard to composite end point of death, Q-wave myocardial infarction (MI), or stroke at minimum follow-up of 3 years. However, target vessel revascularization (TVR) was significantly higher in the PCI group as compared to CABG (p <0.001).

The greatest limitation of these studies^{10–15} was the use of either BMS or first generation of DES leading to higher rate of TVR. Recent meta-analysis^{16,17} have shown progressive decline in TVR, after the introduction of newer generation of DES. More recently, two large randomized trials using relatively current generation of DES and contemporary surgical techniques have been reported with somewhat conflicting results.^{18,19}

The NOBLE trial¹⁸ is a prospective, non-inferiority trial which randomized 1201 patients to PCI of LMCA stenosis with BIOLIMUS-eluting stent (n = 598) or CABG (n = 603).

TABLE 1: Major trials comparing percutaneous coronary intervention (PCI) versus coronary artery bypass grafting (CABG) for left main coronary artery disease, depicting the results of end points at long-term follow-up (values indicate hazard ratio, PCI vs. CABG; p value in brackets)

Trial (year)	No. of patients		Maximum FU (Years)	End points			References
	PCI	CABG		All-cause mortality	Repeat revascularization	MI	
SYNTAX (LM subgroup) (2013)	351	348	5	0.88 (NS)	1.82 (p = 0.001)	1.67 (NS)	11
PRECOMBAT (2015)	300	300	5	0.73 (NS)	1.86 (p = 0.020)	1.20 (NS)	29
NOBLE (2016)	598	603	5	1.07 (NS)	1.50 (p = 0.03)	2.88 (p = 0.004)	18
EXCEL (2016)	948	957	3	1.34 (NS)	1.72 (p <0.001)	0.93 (NS)	19

CABG, coronary artery bypass grafting; FU, follow-up; LMCA, left main coronary artery; MI, myocardial infarction; PCI, percutaneous coronary intervention; NS, not significant.

LM bifurcation stenting was performed in 88% of patients with two-stent techniques in 35% of these patients. The primary endpoint—composite of MACCE (death from any cause, nonprocedural MI, repeated revascularization or stroke) occurred in 28% of patients after PCI and 15% in the CABG group which exceeded the prespecified noninferiority margin. At 5-years, there was no significant difference between the two groups in all-cause mortality or stroke. Repeat revascularization rates were higher in PCI versus CABG group (15% vs. 10%; p = 0.03), as were nonprocedural MI (6% vs. 2%; p = 0.004). Treatment with BMS in 8% patients, along with higher strut thickness of BIOLIMUS-eluting stent compared to new generation everolimus-eluting stent could have adversely influenced the incidence of TVR, non-procedural MI and stent thrombosis in the PCI group.

The EXCEL trial.¹⁹ This trial was designed to assess the previous observations that patients with low or intermediate (≤ 32) SYNTAX score had similar outcomes after PCI or CABG. In this randomized trial, 1,905 patients with unprotected LMCA disease were randomized to PCI (n = 948) treated with XIENCE stent versus CABG (n = 957). The primary end point—composite of death, stroke or MI at 3 years, occurred in 15.4% of patients in the PCI group and 14.7% in the CABG group (p = 0.02, for noninferiority). However, ischemia-driven revascularization remained higher in the PCI group (12.6% vs. 7.5%; p <0.001). This trial, therefore, confirmed that PCI using new generation stents and CABG have similar outcomes with regard to mortality, stroke, and MI at 3 years follow-up in patients with low-to-intermediate risk coronary anatomy and SYNTAX score of less than or equal to 32.

The conflicting outcomes between NOBLE and EXCEL trials could be explained by: (1) use of different generation of stents, (2) inclusion of repeat revascularization in the composite primary endpoint in the NOBLE trial, and (3) inclusion of patients with low or intermediate SYNTAX score in the EXCEL trial.

Meta-analysis

Several meta-analysis have been performed to compare the long-term efficacy and safety of PCI using DES versus CABG in patients with LMCA disease.²⁰⁻²³ However, these included, both observational and randomized studies, different types of stents including BMSs and did not incorporate the results of

two recent randomized trials—NOBLE¹⁸ and EXCEL.¹⁹ These meta-analysis were further limited by assessment of short- and midterm outcomes.²⁰⁻²⁵ To overcome the limitations of previously published meta-analysis, Giacoppo et al.²⁶ published the results of meta-analysis of four randomized clinical trials, which included 4,394 patients,^{11,15,18,19,27-29} all of whom were treated with DES and were followed up for three or more years with an objective to compare the long-term safety and efficacy of PCI with DES versus CABG in patients with significance LMCA disease. The primary endpoint was a composite of all-cause death, MI or stroke at the longest available follow-up. Secondary end points included repeat revascularization and composite of all-cause death, MI, stroke or repeat revascularization. Among 4,394 patients included in the primary analysis, 2,197 patients underwent PCI with DES and 2,197 were treated by CABG. All studies except EXCEL¹⁹ reported a follow-up of 5 years. Both modalities of treatment showed comparable outcomes with regard to all-cause death, MI or stroke at long-term follow-up. Kaplan-Meir analysis did not show significant differences between two treatments over time with a cumulative incidence of 18.3% in the PCI group and 16.7% in the CABG group at 5 years follow-up. PCI had numerical advantage over CABG during the first 2 years, which, however, reversed over the next 3–5 years, with nonsignificant benefit of CABG over PCI. Overall, MACCEs were similar for the two modalities [hazard ratio (HR) 1.05, 95% confidence interval (CI) 0.90–1.23; p = 0.53].

Influence analysis in this meta-analysis revealed that heterogeneity was mainly due to the NOBLE trial¹⁸—the only study which showed superiority of CABG over PCI. The results remained consistent after including patients with low to intermediate SYNTAX scores (1–32) (HR 1.02; 95% CI 0.74–1.41; p = 0.89). The grouping of trials according to generation of DES used for PCI did not show any significant differences in the primary endpoint between patients who underwent PCI with first-generation or second-generation DES.

In another recently published meta-analysis³⁰ of six randomized trials including 4,686 patients with a median follow-up of 39 months, there were no significant differences between PCI versus CABG in the risk of all-cause mortality or cardiac mortality. However, the relative risk of mortality tended to be lower with PCI compared to CABG among patients in the lower SYNTAX score tertile, similar in the

intermediate tertile, and higher in the upper-SYNTAX score tertile. The long-term composite risk of death, MI or stroke was similar between PCI and CABG. However, PCI was associated with greater rates of unplanned revascularization compared with CABG (HR 1.74; 95% CI 1.47–2.07). The authors concluded that both procedures resulted in similar long-term outcomes. While PCI offers an early safety advantage, CABG demonstrates greater durability for treatment of LMCA stenosis.

All the meta-analyses^{20–23} have consistently shown that need for repeat revascularization was significantly higher after PCI compared to CABG. There was no significant influence of DES generation on the incidence of repeat revascularization.²⁶ The second-generation DES and first-generation DES groups showed a similar risk of repeat revascularization.²⁶

VERY LONG-TERM FOLLOW-UP AFTER LEFT MAIN CORONARY ARTERY STENTING

While comparing LMCA stenting with CABG, one of the most important limitations is the nonavailability of very long-term (10 years or more) follow-up results after LMCA intervention. In the ASAN-MAIN registry,³¹ 10-year results after implantation of BMS for unprotected LMCA stenosis highlighted the safety of procedure with cardiac mortality similar to CABG (6.9% vs. 11.0%; p = 0.1). However, repeat revascularization (43.1% vs. 6.7%; p < 0.001) and TLR (24.9% vs. 4.9%; p < 0.001) were higher in BMS group compared to CABG. LE MANS RCT³² was the first study which reported 10-year results of LMCA intervention, compared to CABG. Although the number of patients included was very small in both groups: PCI (n = 52) and CABG (n = 53), the survival rate was close to 70% in the PCI group and MACCE-free survival was numerically better for PCI. The rate of repeat revascularization was comparable between PCI and CABG groups (p = 0.46), mainly due to an increase in repeat revascularization in the CABG group 2 years after the operation. The study thus demonstrated durability of PCI for LMCA stenosis in the short-, long- and very long-term follow-up.³²

These preliminary findings of LE MANS study should be regarded as mere observations rather than definitive and conclusive in the absence of large-randomized controlled trials such as SYNTAX¹³ or PRECOMBAT.¹⁵ Moreover, the analysis of SYNTAX score revealed that all patients included in this study had SYNTAX score less than 32 (low and middle groups). Therefore, excellent results observed in LE MANS study³² may not be applicable to patients with more complex lesions. More data from large, prospective and randomized studies should be available before any definite conclusions can be drawn with regard to long-term durability of PCI for LMCA disease.

CURRENT GUIDELINES FOR LEFT MAIN CORONARY ARTERY STENTING

The current PCI guideline for the treatment of LMCA stenosis was recently updated to a class IIb indication with a B level of

evidence from the American College of Cardiology/American Heart Association and European Society of Cardiology.³³ In addition, the European Society of Cardiology and European Association for Cardio-Thoracic Surgery reported the following indications of LMCA stenting relative to CABG:³⁴ (1) isolated or single vessel disease, ostium/shaft, class IIa B; (2) isolated or single vessel disease, distal bifurcation, class IIb B; (3) LM plus two- or three-vessel disease, SYNTAX score 32 or less, class IIb B; (4) LM plus two- or three-vessel disease, SYNTAX score 33 or more class III B. Therefore, DES implantation is currently considered as an alternative option for selected patients with unprotected LMCA disease.

SELECTION OF LEFT MAIN BIFURCATION STENTING STRATEGY

There is no consensus with regard to optimal strategy for LM bifurcation stenting. Although several techniques have been described, the provisional one-stent approach has been considered as the most preferred strategy in comparison to elective two-stent strategy for PCI of LM bifurcation stenosis.

Provisional One-stent Technique

This consists of deploying a single stent from LM to left anterior descending (LAD) across the ostium of left circumflex (LCx). It is preferred in patients with insignificant focal stenosis at the ostium of LCx or nondominant left coronary system. In contrast, a large dominant LCx (≥ 2.5 mm in diameter) with significant long stenosis at the origin of LCx which has a narrow angle of origin with LAD, often requires elective two-stent strategy. Evaluation by fractional flow reserve (FFR) for LCx stenosis provides valuable information for need to intervene.

Several studies have reported that, compared to two-stent strategy, this approach is associated with more favorable outcome including lower risk of major adverse cardiac events (MACE),^{35–37} death,³⁷ MI,^{36,37} and TVR.^{36–38} The incidence of stent thrombosis is also lower with one-stent approach.^{37,38} Based upon several observational studies, the provisional one-stent approach is preferred for the treatment of LM bifurcation stenosis³⁹ and more than 60% of patients in the real world get treated by this approach.³⁶ However, this strategy remains to be evaluated in randomized controlled studies.

Final Kissing Balloon Inflation (FKI) in Provisional Stenting

Although, this step is frequently performed in patients undergoing provisional one-stent approach, its role is unclear and controversial. Out of 413 patients who underwent provisional single-stent treatment, 96 received FKI after main vessel stenting.⁴⁰ During a 2-year follow-up, the rate of composite death, MI and TLR did not differ significantly between groups with or without FKI (12.5% vs. 8.5%; p = 0.82), regardless of angiographic side branch (SB) stenosis. Although statistically insignificant, there was a trend toward more frequent TVR in the FKI group (8.1% vs. 4.8%; p = 0.83). Another small study

showed similar results.⁴¹ It seems, therefore, that FKI may not provide improvement in long-term clinical outcomes after main vessel stenting in provisional one-stent approach for LM bifurcation stenosis.

Side Branch Stenting in Provisional Stenting

Stenting of LCx after main vessel stenting in provisional stenting approach is often required in patients who develop compromise in LCx flow leading to ischemic symptoms or signs. It is also indicated in patients who develop flow-limiting dissection of LCx origin following FKI. Two small pilot studies evaluated the benefit of FFR in decision-making for LCx stenting after main vessel stenting in LM bifurcation treatment.^{42,43} These studies observed that only one-third of angiographically significant LCx ostial stenoses were found to have FFR less than 0.80. It is, therefore, suggested that FFR provides useful information in guiding treatment of LCx ostial stenosis. An FFR of more than or equal to 0.80 is a strong predictor of favorable survival and low event rates in patients with intermediate disease.^{44,45}

Stenting of LCx in provisional stenting can be performed by using one of the following techniques: (1) provisional T stenting, (2) the T-and-protrusion (TAP) technique, (3) reverse crush, and (4) provisional culotte. Each of these techniques have their advantages and limitations.

Elective Two-stent Approach

A planned two-stent strategy is used if there is significant stenosis of distal LMCA extending into both LAD and LCx branches, and possibility of acute hemodynamic collapse or periprocedural MI in the event of abrupt occlusion of LCx. A large number of elective two-stent techniques and their modifications have been proposed for LM bifurcation stenting. These include: TAP technique, crush and its variants—mini crush and double kissing and crush (DK crush), culotte, and simultaneous kissing stent (SKS technique). Since all LM bifurcations are not the same, selection of an appropriate technique depends upon consideration of several variables such as relative size of LM and its main branches (MBs), the bifurcation angle and the severity and length of stenosis at LCx origin. Equally important criteria are the experience and expertise of the operator in performing a particular technique.

Crush Techniques

The classical crush technique provides complete lesion coverage for SB ostium and generally used in patients with LM bifurcation angle of less than 70°. However, covering the SB ostium with three layers of stents can make the FKI technically difficult and even failure in approximately 15–20% of cases. The Mini-Crush technique avoids a large area with three layers of stent struts, and thereby improves the success of FKI, and minimizes residual metallic stenosis at the SB ostium.⁴⁶ Another modification called DK crush technique comprises additional kissing balloon inflation between SB crushing and MB stenting. It has been reported to facilitate FKI and enhances stent apposition.⁴⁷

Culotte Technique

It consists of sequential implantation of two stents in both the branches, with the MB stent implanted through the SB stent, and thus forming a double layer of stents in the main vessel. This technique is suitable for all angles of bifurcation and provides near-perfect coverage of SB ostium.

Simultaneous Kissing Stent Technique

In this technique, both the stents—LM to LAD and LM to LCx are delivered and implanted together, thereby forming a double-barrel, metallic carina in LMCA. SKS is preferred in emergency situations of LMCA occlusion with a narrow angle of bifurcation and diameter of LMCA much bigger (at least two-thirds) compared to the combined sizes of LAD and LCx. This technique, though simple and easy to perform, is rarely used because of difficulty in placing a stent proximal to the double barrel, if required to seal a dissection, the formation of a new diaphragmatic metal membrane, difficulty in wiring for PCI of restenosis, and treatment of distal vessel stenosis.

Need for Proximal Optimization Technique

Since the LMCA diameter is often much larger than the distal MB diameter, proximal optimization of stent deployment is very important for adequate stent apposition in the LM bifurcation intervention.⁴⁸ This facilitates recrossing the SB through a distal stent cell and avoid abluminal rewiring by a second wire. The choice of stent diameter should be based upon the distal MB reference diameter to minimize carina shifting.⁴⁹ The stent selected for LM to LAD should be such that it should be expandable to the reference diameter of LMCA.

ROLE OF ADJUST DEVICES

Intravascular Ultrasound

It is a useful adjunct imaging modality which can provide valuable information including lesion morphology and dimensions during LMCA stenting.⁵⁰ It enables interventionist to provide adequate information on stent apposition and adequate coverage of lesions, after implantation.^{51,52} Recent meta-analyses have demonstrated that intravascular ultrasound (IVUS)-guided PCI is associated with lower risk of death, MI, TVR, and stent thrombosis after DES implantation.^{53,54} In patients with unprotected LMCA stenosis, the beneficial effects of IVUS-guided stenting on clinical outcomes were reported by the MAIN COMPARE multicenter registry which enrolled 975 patients with LMCA stenosis who underwent PCI under IVUS guidance or angiography alone.⁵⁵ In the propensity score matched comparison, IVUS guidance showed a trend toward lower rates of mortality at 3 years (6% with IVUS vs. 13.6% in angiography group; $p = 0.063$). Andell et al.⁵⁶ investigated the clinical outcomes of IVUS guidance on composite end point of all-cause mortality, restenosis or definite stent thrombosis in patients undergoing unprotected LMCA-PCI in a nationwide population-based observational study using SCAAR registry. After adjusting for potential

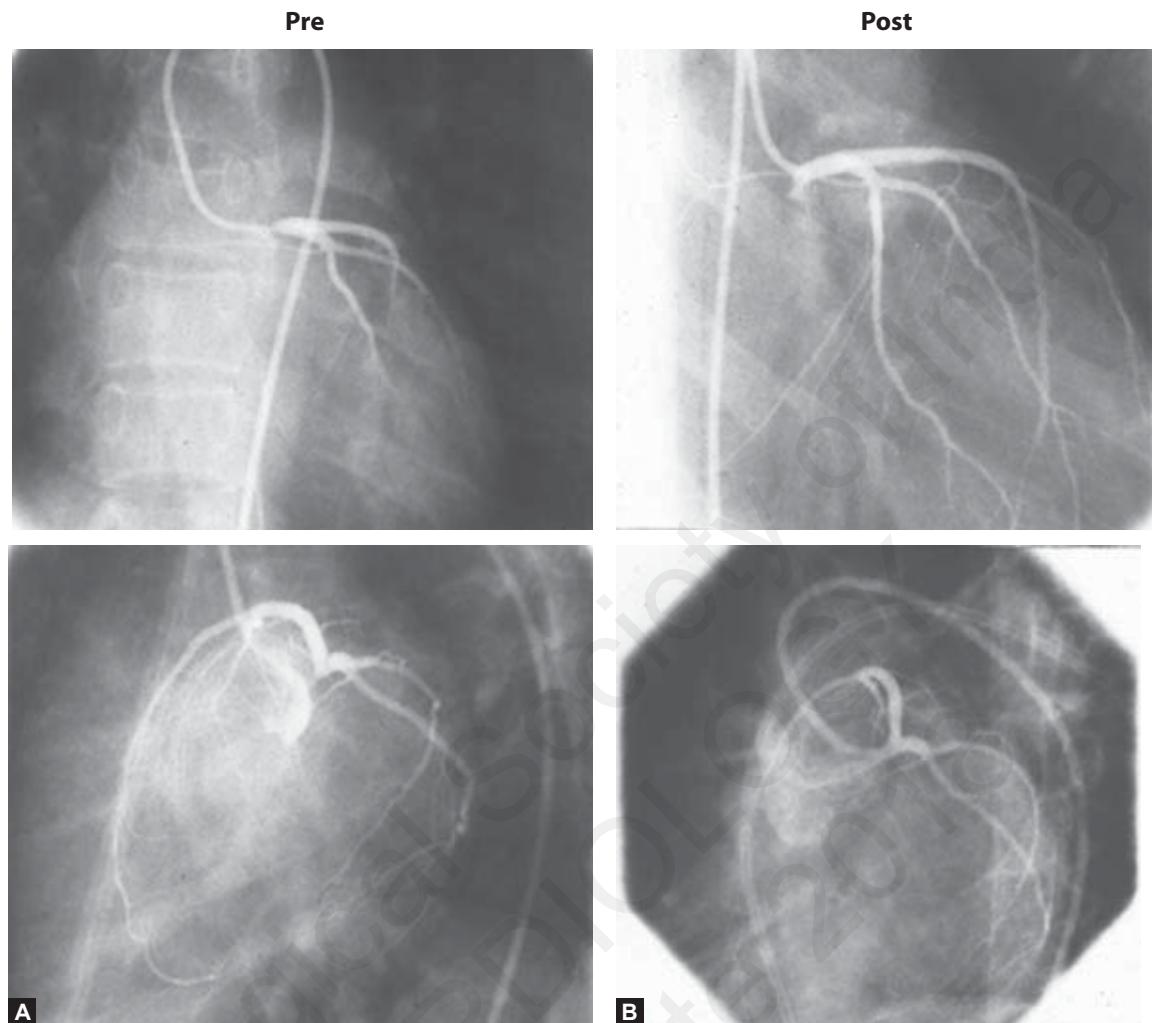

FIG. 1: Left main ostial stenting using Palmaz Schatz coronary stent under cardiopulmonary support (the first case performed by the author).

cofounder, IVUS-guided approach was associated with significantly lower incidence of primary composite endpoint of all-cause mortality, restenosis or definite stent thrombosis ($p = 0.003$).

Although large, prospective studies and registry data suggest improved outcomes with IVUS-guided DES implantation for LMCA stenosis, randomized trials are underpowered to assess the clinical utility of this approach.

Malapposition with underdeployment of stent increases the risk of stent thrombosis and restenosis. Kang et al.⁵⁷ studied the optimal IVUS-derived minimal stent cross-sectional area (MSA) for prevention of in-stent restenosis (ISR) in 403 patients undergoing DES implantation for LMCA stenosis. The best IVUS-derived MSA which predicted angiographic ISR on segmental basis were: 5.0 mm² for LCx ostium, 6.3 mm² for the LAD ostium, 7.2 mm² for the polygon of confluence (POC), and 8.2 mm² for the proximal LMCA above the POC. The operator should, therefore, attempt to achieve these values by using high pressure post-stent balloon dilatation.

Role of Optimal Coherence Tomography

Optimal coherence tomography (OCT) can provide accurate information of the arterial wall, including LMCA disease. Preprocedure OCT can be used to assess the lesion morphology-fatty, fibrofatty, calcific, or thrombotic. It can assess the thickness of calcium in the vessel wall, and thereby helps to decide the strategy for lesion modification before stenting. It enables precise online measurement of length and diameter of LMCA for selection of appropriate size of stent. Dissection resulting from predilatation can be easily detected, and taken into consideration while deciding the stent length. After deployment of stents, OCT can be used to verify that the guidewire recrosses into SB through the distal stent cell to ensure optimal scaffolding and minimal metal carina.⁵⁸ Post-stent deployment, OCT helps to assess the stent expansion, and occurrence of edge dissection. Three-dimensional evaluation with OCT ensures evaluation of LCx ostium and carina, and enables to detect any strut protruding at the ostium of LCx.

Hemodynamic Support

Although intra-aortic balloon pump is not routinely required during LMCA stenting, it should be used selectively to prevent hemodynamic collapse in patients with severely depressed LV function.

PERSONAL EXPERIENCE

The author performed the first case of LM stenting 20 years ago in a young pregnant patient who presented with recurrent episodes of syncope and found to have 90% ostial stenosis of LMCA (Fig. 1).⁵⁹ From 2004 to 2017, I have performed LMCA stenting in 463 patients of whom 310 (67%) were distal LM bifurcation stenosis. Single-stent approach was used in 130 (28%), two-stent strategy in 322 (69%), and LM-triple stenting in 11 (2.5%) of cases.

The various two-stent techniques for LM bifurcation stenting used were: SKS (30%), V-stenting (20%), DK crush (20%), TAP (16%), Mini-Crush (9%), T-stenting (4.6%), and culotte (1%). Use of adjunct devices included rotablation in 58%, IVUS in 28%, IABP in 21%, and OCT in 2.2% patients. Angiographic success was achieved in 460 (99%) and clinical success in 452 (97.5%). Major in-hospital complications included death (1%) and reintervention (0.6%). No patient required emergency CABG. Our experience highlights the safety of LM bifurcation stenting using DES.

CONCLUSION

Considering all the data available in the literature, the optimal management of unprotected LMCA disease is still a subject of debate. Most studies have suggested that, whereas there is no difference in mortality between the two treatment strategies, a recent meta-analysis²⁵ shows no difference in safety end points. In patients with LM associated with complex multi-vessel disease, CABG is superior to stenting with better long-term results. For patients with low or intermediate risk (SYNTAX score ≤32), both therapies are comparable but PCI is associated with less morbidity, shorter hospital stay and lower incidence of stroke when compared to CABG. However, repeat revascularization rates are higher despite using the latest generation of DES. Given the lack of mortality difference between the two treatment modalities, the focus should shift at improving the outcomes for both PCI and CABG in the treatment of LMCA stenosis.

Current Update in the Treatment of Calcified Lesions

Matthew I Tomey, Samin Sharma

INTRODUCTION

Calcification is a defining feature of advanced coronary atherosclerotic plaque¹ and remains a challenge to optimal percutaneous coronary intervention (PCI). Calcified lesions are more difficult to cross and dilate. They are also more likely to be associated with suboptimal stent deployment, angiographic complications, and adverse clinical outcomes. Severe calcification often accompanies other complex lesion features such as chronic total occlusion, tortuosity, diffuse disease, or lesion location at a bifurcations or arterial ostium. With aging of the population and, in particular, management of coronary artery disease (CAD) in older adults undergoing transcatheter aortic valve replacement, the challenges of managing calcified coronary plaque have grown only more common in the contemporary cardiac catheterization laboratory. At one time, moderate or severe calcification conferred a 60–85% likelihood of success and a moderate risk of procedural complications.^{2,3} Today, calcified lesions can be treated with an extremely high likelihood of success, with rates of angiographic and procedural success exceeding 99% in the drug-eluting stent era.⁴ In this updated review, we provide our perspective on the present landscape of options for managing calcified plaque in 2018.

IDENTIFICATION AND CLASSIFICATION OF CALCIFICATION

A key principle in the successful interventional management of calcified CAD is that calcification should be recognized and characterized before the start of intervention. Anticipation of challenges posed by calcification permits appropriate preparation, device selection, and strategic planning and may help to avoid complications.

The primary method for recognition and qualification of lesion calcification continues to be fluoroscopy. In addition to being ubiquitous, fluoroscopy is highly specific for coronary calcification. As mineral content within coronary plaque

accumulates, coronary artery calcium becomes progressively radiopaque (like bone) and visible by fluoroscopy. Current angiographic criteria for calcification of coronary plaque define moderate calcification as densities evident during the cardiac cycle before injection of contrast medium and severe calcification as radiopacities evident without cardiac motion before injection of contrast medium, typically involving both sides of the arterial wall (similar to “tram tracks”).⁵

Yet as interventional cardiologists have long appreciated, fluoroscopy can be insensitive for detection of fibrocalcific plaque and inaccurate in discrimination of calcification as severe versus not severe and superficial versus deep. Growth in experience with advanced intravascular imaging modalities including intravascular ultrasound (IVUS) and optical coherence tomography (OCT) has confirmed this and today offers interventional cardiologists with additional options to refine diagnosis of coronary calcification in preparation for PCI. Using IVUS, plaque calcification appears as shadowing of deeper arterial structures with an acoustic signature that is brighter than the reference adventitia.⁶ IVUS permits description of the arc, length, distribution, and depth of coronary calcium. On IVUS examination, calcification graded as severe by fluoroscopy is typically associated with a large arc of superficial calcium involving at least three quadrants.⁶ Using time domain⁷ and frequency domain⁸ OCT examination, plaque calcification appears as a well-delineated signal-poor region with sharply defined borders. Variable attenuation of light by plaque lipid content can interfere with accurate measurement of calcium on OCT examination.

In our practice, we do not routinely use IVUS or OCT for the purpose of grading lesion calcification. These tools can be useful, however, in equivocal cases. In our experience, findings on intravascular imaging in such cases have underscored the need for a high-index of suspicion for fibrocalcific plaque in patients with high-risk clinical features such as advanced age, chronic kidney disease, and prior history of coronary artery bypass graft surgery (CABG).

PATIENT AND LESION SELECTION

Prerequisite to lesion-specific interventional management of calcified CAD is global assessment of the patient and appropriateness of PCI. Updated appropriate use criteria for coronary revascularization in stable ischemic heart disease provide guidance on the recommended role of PCI in different clinical and anatomic scenarios.⁹ Calcification can influence this calculus in several ways. Lesion calcium can confound angiographic estimation of obstruction, leading to either over- or underestimation of diameter stenosis.¹⁰ Both in isolation and in conjunction with other complex lesion features, calcification contributes to the SYNTAX score, influencing consideration of PCI versus CABG.

In our clinical experience caring for patients with calcified CAD, scenarios arise not infrequently in which coronary revascularization is indicated and coronary anatomy is favorable for CABG, but overall assessment of the patient by a heart team leads to recommendation against surgery. Examples include patients requiring reoperative heart surgery; older patients with severe aortic stenosis assigned to transcatheter aortic valve replacement; patients with severe left ventricular dysfunction; and patients with multiple comorbidities conferring high surgical risk. As a consequence of this selection process, patients undergoing PCI for calcified CAD often have multiple high-risk features and limited reserve to tolerate complications.

WIRE SELECTION

Standard “workhorse” guidewires are usually sufficient for PCI of calcified lesions. When severe calcification is accompanied by significant angulation or arterial tortuosity, the properties of a chosen guidewire may have greater impact on the performance of PCI. In such cases, guidewires with hydrophilic coating may help to facilitate wire manipulation and delivery of interventional devices. If device delivery across calcified segments is impossible despite use of a hydrophilic guidewire, other options may include addition of a second “buddy” wire or deep coronary intubation with a child-in-mother catheter.

When an atheroablative strategy is planned, a specialty guidewire is required for compatibility with the chosen atheroablative device. Manipulation and lesion crossing with these finer wires are possible but can be more challenging, with risks of wire kinking and dissection. In most cases, we primarily wire with a hydrophilic guidewire within a microcatheter,

such as the FineCross[®] MG (Terumo Interventional Systems, Tokyo; Japan) or Threader[™] (Boston Scientific, Natick; MA). In addition to supporting wire manipulation and permitting subsequent exchange for an 0.009" RotaWire[™] (for rotational atherectomy; Boston Scientific, Natick; MA) or 0.012" ViperWire[™] (for orbital atherectomy; Cardiovascular Systems, Inc., St Paul; MN), the use of a microcatheter provides an additional gauge of stenosis severity and likelihood of crossing with an atheroablative device. As a rule of thumb, if our microcatheter does not cross, we will instead primarily wire with and proceed directly to atheroablation using a smallest size burr or crown.

MODIFICATION OF CALCIFIED LESIONS

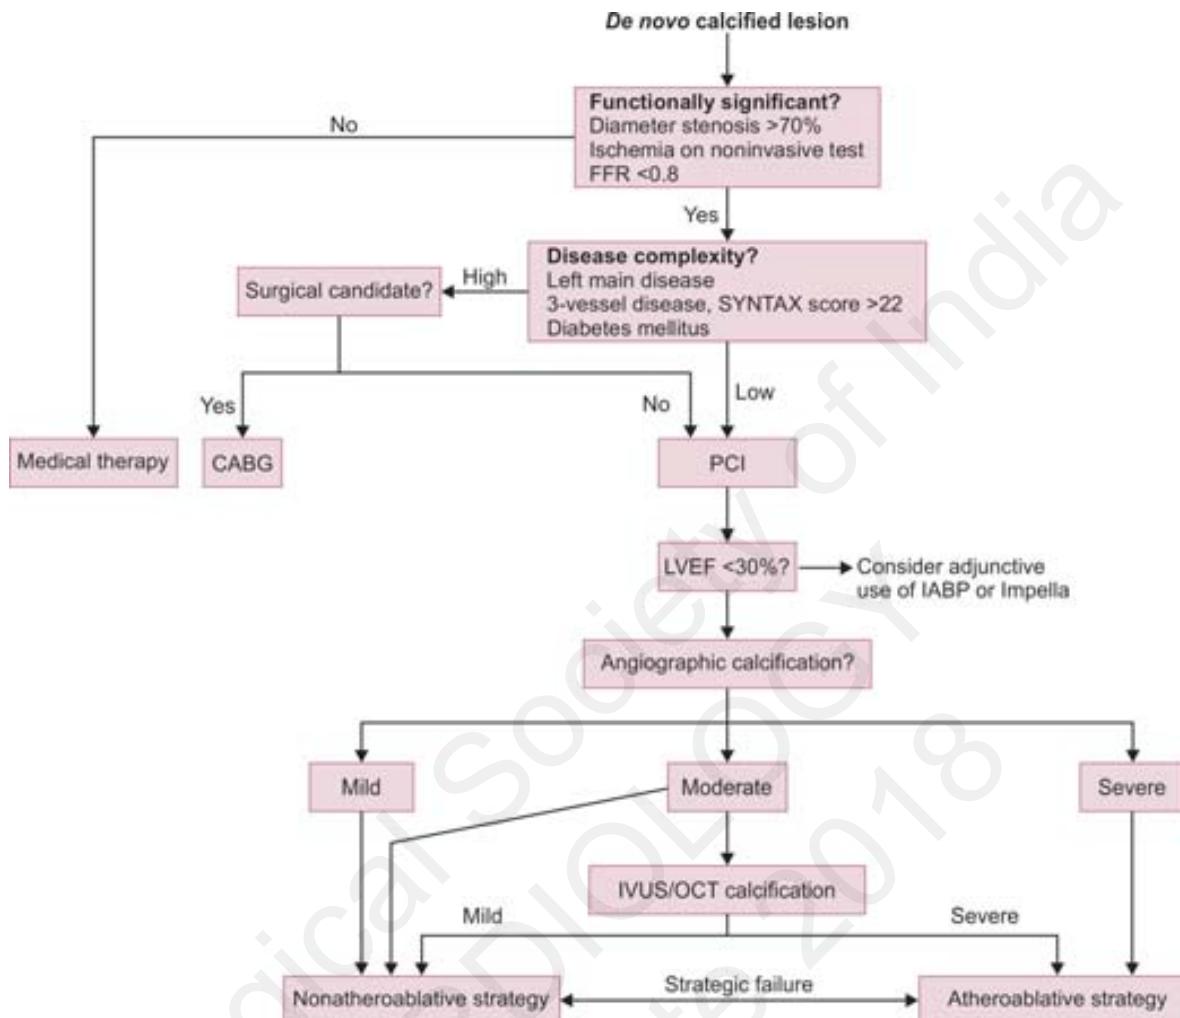

Whereas emphasis in an earlier era of PCI was placed on “debulking” of calcified plaque, focus today is instead placed on modification of lesion properties to facilitate subsequent balloon angioplasty and stenting. Multiple devices for this purpose are available today (Table 1),¹¹ which can be loosely divided into techniques based on balloon inflation and techniques based on atheroablation: rotational atherectomy, orbital atherectomy, and excimer laser coronary angioplasty (ELCA). In our practice, we favor an up-front strategy of atheroablation for target lesions associated with moderate or severe calcification (Flowchart 1). Although the largest randomized trial of an atheroablative strategy in the drug-eluting stent era (the Rotational Atherectomy Prior to Taxus Stent Treatment for Complex Native Coronary Artery Disease study, ROTAXUS) did not show reduction in major adverse cardiac events (MACEs),¹² strategic success was indeed superior with rotational atherectomy as compared with traditional balloon angioplasty for moderately or severely calcified lesions, as has been our experience.

Both rotational and orbital atherectomy can be highly effective for facilitating PCI of calcified lesions and we continue to incorporate both tools in our practice. For many calcified lesions, either device can be used effectively and safely and device selection is influenced predominantly by operator and laboratory preference and comfort. In some cases, however, details of coronary anatomy can favor preferential use of one device or the other. Here, we will compare and contrast the two techniques (Table 2).

Rotational and orbital atherectomy share common principles. Both exploit the material properties of calcium to selectively ablate calcified plaque and to facilitate device

TABLE 1: Interventional adjuncts to balloon angioplasty for modification of calcified lesions

Approach	Example
Scoring balloon angioplasty	AngioSculpt [®] (AngioScore, Inc., Fremont; CA)
Cutting balloon angioplasty	Wolverine [™] (Boston Scientific, Natick; MA)
Constrained semicompliant balloon angioplasty	Chocolate [®] (TriReme Medical, Pleasanton; CA)
Rotational atherectomy	Rotablator [™] (Boston Scientific, Natick; MA)
Orbital atherectomy	Diamondback 360 [®] (Cardiovascular Systems, Inc., St Paul; MN)
Excimer laser coronary angioplasty	CVX-300 [®] (Spectranetics, Colorado Springs; CO)

CABG, coronary artery bypass graft surgery; FFR, fractional flow reserve; IABP, intra-aortic balloon pump; IVUS, intravascular ultrasound; LVEF, left ventricular ejection fraction; OCT, optical coherence tomography; PCI, percutaneous coronary intervention.

FLOWCHART 1: In patients with *de novo* calcified lesions for whom PCI is indicated clinically, lesion modification via atheroablation is appropriate in order to facilitate procedural success when calcification is severe. If calcification severity is intermediate or indeterminate by angiography, intravascular imaging with IVUS or OCT may be useful for reclassification.

Source: Adapted from Tomey et al.¹³ with permission from the author and Publisher.

advancement through jagged calcified segments.¹³ Rapid rotation of the rotational atherectomy burr (differential cutting) and rapid orbiting of the orbital atherectomy crown (differential sanding) preferentially ablates hard, inelastic tissue which, unlike healthy arterial wall, cannot stretch away from the ablative device. High speed of device rotation or orbit displaces friction orthogonally and facilitates forward motion of the device across plaque. Diamond chips on the surface of the burr or crown ablate calcified plaque into microscopic particles which traverse the coronary microvasculature and eventually undergo phagocytosis within the reticuloendothelial system.¹⁴

Shared complications of rotational and orbital atherectomy include clinical complications common to PCI, including bleeding, vascular complications, stroke, myocardial infarction,

urgent CABG and death and angiographic complications, including dissection, perforation, acute closure, side branch loss, and slow-flow/no-reflow.¹⁵ Incidence of slow-flow/no-reflow during atheroablation is significantly lower today, down from as high as 15% in early series of rotational atherectomy¹⁶ to as low as 0.0–2.6% in more recent series.¹³ It is our belief that this reduction derives from iterative improvements in operator technique, optimal antiplatelet therapy, incorporation of a continuously infusing flush cocktail, and careful attention to maintaining adequate coronary perfusion pressure.¹³ Very low observed rates of slow-flow/no-reflow using the orbital atherectomy may relate to design features that provide for higher flow of flush cocktail (18 mL/min) and an orbiting crown less likely to obstruct the lumen,¹⁷ promoting clearance of debris and reducing microvascular obstruction.¹⁸

TABLE 2: Comparison of rotational atherectomy and orbital atherectomy

	Rotational atherectomy	Orbital atherectomy
Wire	0.009" RotaWire™	0.012" ViperWire™
Lubricant	RotaGlide™	ViperSlide™
Ablative device	"Burr"	"Crown"
Diamond chips	Anterior only	Anterior and posterior
Sizes	Multiple (1.25, 1.5, 1.75, 2.0, 2.25, 2.38, 2.5 mm), interchangeable	Single (1.25 mm), with larger path carved by higher speed
Guide catheter size	6 Fr: for 1.25, 1.5, 1.75 mm burrs 7 Fr: for 2.0 mm burr 8 Fr: for 2.25, 2.38, 2.5 mm burrs	6 Fr
Axial motion	Rotational	Elliptical
Longitudinal motion	Pecking, intermittent	Gradual, continuous
Direction of ablation	Forward only	Forward and backward
Maximum run	20 s	25 s
Difficulty of setup	Higher	Lower
Learning curve	Longer	Shorter
Body of experience	Decades	Years
Effect on plaque	Shallower dissections	Deeper dissections

PERFORMANCE OF ATHEROABLATION

Vascular Access and Guide Catheter Selection

Selection of vascular access approach, sheath, and guide catheter for a given patient should balance simultaneous goals of reducing bleeding and vascular complications and providing adequate support for atheroablation. For most patients, a 6 French system is adequate to support atheroablation, accommodating the orbital atherectomy crown and rotational atherectomy burr sizes up to 1.75 mm, and readily permitting either a transfemoral or transradial approach. Indeed, it is important to note that atheroablation is feasible from the radial approach with comparable procedural success.^{19,20} Support can be further enhanced by use of a long sheath; selection of a guide catheter shape associated with extra back-up; and use of a child-in-mother catheter. The 7 French or larger systems may be desired or needed for cases in which complex bifurcation PCI is anticipated or requirement for a 2.0 mm or larger rotational atherectomy burr. In such cases, transfemoral access may be preferred, although some patients may be eligible for transradial access using sheathless guide catheters with internal diameters up to 7.5 French or 7 French glide sheaths with a 6 French profile. Coaxial guide placement is essential to facilitate burr or crown passage and avoid dissections.

Wiring

Prior to beginning atheroablation, it is necessary to position a device-specific wire (RotaWire™ or ViperWire™) across the target lesion with its radiopaque tip positioned as far distally as possible within the target vessel, avoiding small branches and eliminating any distal loops, bends, or kinks. This

will reduce risk of wire fracture and coronary perforation. Although this can be accomplished by wiring primarily with the RotaWire™ or ViperWire™, the properties of lesions selected for atherectomy can make this challenging and predispose to wire kinking. Instead, it can be easier to first wire with a workhorse or specialty 0.014" coronary guide wire and then exchange for the RotaWire™ or ViperWire™ using a microexchange catheter or over-the-wire balloon.

Properties of a chosen wire influence its tendency to wire bias, with stiffer wires conferring greater wire bias and preferential ablation at the lesser curvatures of angulated segments. This is particularly relevant to rotational atherectomy as the path of atheroablation tracks coaxially with the path of the central guidewire. This property of stiffer wires (e.g., the extra support RotaWire™) can be exploited deliberately to enhance modification of plaques predominantly localized to the lesser curvature, although significant care is required in treatment of highly angulated segments to avoid dissection and perforation. The stiffer extra support RotaWire™ is also preferred for treatment of ostial lesions. Otherwise, in our practice, the floppy RotaWire™ remains suitable for most lesions treated with rotational atherectomy, and the ViperWire™ is used for all cases of orbital atherectomy.

Both as preparation for subsequent angioplasty and stenting and as a safety precaution in case device delivery is required urgently, as in cases of dissection and perforation, we recommend preparing a standard workhorse wire with an appropriate curve in advance of beginning atheroablation.

Burr and Crown Selection

In rotational atherectomy, the ultimate cross-sectional area of atheroablation approximates that of the largest burr size used.

Although larger burrs (with a burr:artery ratio >0.7) effect greater plaque debulking, smaller burrs (with burr:artery ratio <0.7) permit equivalent angiographic and procedural success with fewer angiographic complications, reduced periprocedural creatine kinase (CK)-MB release, smaller sheaths and guide catheters and, in turn, lower vascular and bleeding complications.^{21,22} Accordingly, as procedural goals have shifted from plaque debulking to lesion modification, the optimal final burr:artery ratio is 0.5–0.6. In many cases, this can be accomplished with a single appropriately sized burr (Table 1). For epicardial vessels less than 3 mm in diameter, a 1.5 mm burr is usually appropriate. For epicardial vessels larger than 3 mm in diameter, a 1.75 mm burr is generally sufficient. In some cases, a stepped burr strategy may be preferable; factors favoring this approach include inability to cross the target lesion with a microexchange catheter or balloon and severe angulation, tortuosity or eccentricity. In such cases, initial rotational atherectomy using a 1.25 mm burr is preferred. Analogously, in cases in which an initially selected 1.5 mm or larger burr fails to crack a lesion or encounters excessive decelerations, downsizing the burr can be useful to facilitate lesion modification and reduce risk of procedural complications. Conversely, if attempted balloon dilatation is not successful after initial ablation with a 1.25 mm burr, upsizing to a 1.5 mm or 1.75 mm burr may be required to effect sufficient lesion modification.

The Diamondback 360° Coronary Orbital Atherectomy System currently uses a single 1.25 mm “classic crown.” Unlike rotational atherectomy, with orbital atherectomy, the ultimate cross-sectional area of atheroablation is larger than the crown and dependent upon the speed of lesion crossing, the rotational speed, and the number of passes. Larger luminal areas are associated with slower lesion crossing, faster rotational speed, and increased numbers of passes. In a carbon block model, using a 1.25 mm crown and 20 forward and backward passes over approximately 5 minutes of treatment time, a rotational speed of 80,000 rpm was associated with a maximum luminal diameter of 1.64 mm and a rotational speed of 120,000 rpm was associated with a maximum luminal diameter of 1.84 mm. Of note, whereas rotational atherectomy tends to generate a mostly cylindrical lumen in treated areas after atheroablation, in clinical practice, orbital atherectomy can produce lumina of irregular shapes with variable degrees of guttering. In our practice, we have found that the slower rotational speed of 80,000 rpm is safe and effective for the vast majority of treated lesions.

Flush Solution

A pressurized, continuous flush solution is essential with both rotational and orbital atherectomy to lubricate the atheroablative device, to minimize thermal injury and to promote microvascular clearance of debris.

For rotational atherectomy, the traditional composition of the flush solution included heparinized saline, vasodilators, and RotaGlide™ lubricant, a especially designed solution comprised of olive oil, egg yolk, phospholipids, sodium deoxycholate, L-histidine, disodium ethylenediaminetetraacetic acid (EDTA), sodium hydroxide, and water.

In comparison with heparinized saline alone, addition of RotaGlide™ lubricant is associated with reduced heat generation. Due to its composition, RotaGlide™ is contraindicated in patients with allergies to egg or olive oil; use of flush solutions omitting RotaGlide™ have been reported with comparable procedural success.²³ Vasodilators incorporated in flush solutions, included for the purpose of preventing slow-flow/no-reflow, have included nitroglycerin, verapamil, nicardipine, adenosine, and nicorandil, in varied combinations.^{16,24–28} As rotational atherectomy technique has improved, many users have found it possible to diminish or eliminate inclusion of vasodilators in the flush solution,²⁹ maintaining low rates of slow-flow/no-reflow while avoiding hypotension and bradycardia. Today, we recommend a standard rotational atherectomy flush solution composed of heparinized saline and RotaGlide™ only, reserving vasodilators for provisional use.

In the case of orbital atherectomy, flush solution is comprised of normal saline and ViperSlide™, a proprietary lubricant especially designed for the orbital atherectomy system. No additional vasodilators are required to be added to this cocktail and we again favor only provisional use of intracoronary vasodilators during performance of orbital atherectomy. Of note, a safety mechanism in the orbital atherectomy system prohibits device activation in the absence of continuous pressurized flush solution.

Adjunctive Pharmacology

Patients undergoing atheroablation should receive optimal anticoagulation and antiplatelet therapy for PCI in accordance with standard practices. Glycoprotein IIb/IIIa inhibitors (GPI) were associated with reduction in periprocedural CK-MB release and slow-flow/no-reflow phenomenon in earlier series of rotational atherectomy, reflecting the integral role of thrombosis to these complications.³⁰ With advances in anticoagulant and antiplatelet therapies and recognition of bleeding complications associated with routine GPI use, however, GPI should today be reserved for only provisional use.

Temporary Pacing

Transient microvascular ischemia of the cardiac conduction system and associated atrioventricular block can occur during atheroablation of the right coronary artery, dominant left circumflex artery, or, in the setting of chronic total occlusion of the dominant vessel, atheroablation of a vessel providing major collateral circulation.³¹ In anticipation of that possibility, insertion of a transvenous pacemaker historically was considered prerequisite to atheroablation for such a vessel.

More recently, preemptive insertion of a transvenous pacemaker in this situation has become less uniform, with some operators preferring provisional use and initial management with atropine, aminophylline or antivagal maneuvers. Reasons for this transition include recognition of risk of ventricular perforation and cardiac tamponade; reduced severity of distal microembolization and microvascular ischemia with optimal technique; and

recognition of the usually transient and remediable nature of atrioventricular block during atheroablation.

Mechanical Circulatory Support

Atheroablation in and of itself is not an indication for mechanical cardiac support. When temporary mechanical circulatory support is otherwise indicated for high-risk PCI, however, such support may permit more complete revascularization and greater operator comfort and possibly safety using atheroablative devices. In a randomized study comparing the Impella Recover LP 2.5 versus intra-aortic balloon counterpulsation for support of elective high-risk PCI, rotational atherectomy was employed more extensively at operator discretion in subjects assigned to Impella support with higher periprocedural CK-MB release but no increase in death or large (clinically-relevant) myocardial infarction and, in fact, a significant reduction in major adverse events at 3-month follow-up.³²

Preparatory Steps

Once optimal anticoagulation and antiplatelet therapy have been confirmed, and the RotaWire™ or ViperWire™ is positioned appropriately across the lesion, key steps are taken to ensure readiness for atheroablation and swift response to potential complications. We recommend preemptively opening and preparing a noncompliant balloon sized 1:1 to the reference vessel diameter. Once the chosen device has been opened and assembled, outside of the body, the operator must verify free flow of flush solution through the distal end of the device; free movement of the advancer knob, and, once loaded on the back end of the wire, device rotation at the appropriate speed. For the great majority of lesions, we favor a set rotational speed of 140,000–160,000 rpm for rotational atherectomy and 80,000 rpm for orbital atherectomy.³³ The device is then advanced over the wire through and just beyond the tip of the guide catheter. It is not necessary to activate rotation of the device during advance through the guide. As the device advances, an assistant withdraws the wire at an equal pace in order to maintain stable wire position within the vessel. We favor active use of fluoroscopy at low magnification during this process to verify stability of wire position. Finally, before beginning atheroablation, three steps are taken to remove tension from the system in order to prevent the device from jumping forward and, potentially, causing dissection, perforation or entrapment. First, unlock and gently advance and retract the device. Second, disengage the hemostatic valve on the guide catheter and gently advance and retract the drive shaft. Third, transiently activate the device at a low rotational speed. In the case of rotational atherectomy, this is accomplished by tapping on the foot pedal while in Dynaglide mode. In the case of orbital atherectomy, this is performed by briefly toggling the device on and then off.

Device Motion and Ablation Speed

Proper technique in device motion plays an important role in the efficacy and safety of rotational and orbital atherectomy,

and it is important to recognize that optimal motion differs for the two devices.

For rotational atherectomy, technique has improved iteratively over decades of use with less excessive deceleration and stalling, less distal thromboembolization, and less thermal injury.³⁴ In addition to appropriate burr sizing, fundamental elements of optimal rotational atherectomy technique today include (1) a rotational speed of 140,000–160,000 rpm, (2) gradual burr advancement with a slow, pecking to-and-fro motion, (3) short ablation runs lasting no more than 15–20 seconds, pausing between runs, and (4) avoidance of decelerations greater than 5,000 rpm. Visual, tactile, and auditory feedback provides additional signals concerning resistance to burr advancement. Once the lesion has been fully crossed, rotational atherectomy is completed with a final polishing run, which should be smooth and without resistance. For lesions that cannot be crossed despite optimal technique, options to be considered include higher speeds, downsizing the burr, upgrading support using a more supportive guide catheter or adding a child-in-mother catheter. Of note, whereas early literature associated higher rotational speeds with risk of slow flow due to increased platelet aggregation, higher speed ablation may today be safe when combined with other elements of optimal technique. In recent randomized comparison of low-speed (140,000 rpm) versus high-speed (190,000 rpm) rotational atherectomy, there was no difference detected in incidence of slow flow.³⁵

For orbital atherectomy, in contrast, the optimal device motion¹⁷ entails not pecking but rather slow and steady advance. The crown should be brought to approximately 5 mm proximal to the target lesion and then advanced, initially with low rotational speed (80,000 rpm), at a rate of approximately 1 mm/second, monitoring on fluoroscopy to ensure 1:1 movement of the crown and advancer knob. A run of orbital atherectomy, not to exceed 30 seconds in duration, consists of multiple passes at this speed forward and backward through a target lesion, maintaining continuous movement and finally returning to a proximal resting point outside the lesion. Multiple runs may be required to completely treat a lesion, with a total treatment time not to exceed 5 minutes. As with rotational atherectomy, we advocate concluding orbital atherectomy with a final polishing run.

Procedure Completion and Device Removal

At the conclusion of atheroablation, the rotational atherectomy burr is removed by activating Dynaglide™ mode, pressing the brake defeat button, and manually withdrawing the burr while stepping on the foot pedal at low-rotational speed. As the burr is withdrawn, an assistant advances the RotaWire™ at an equal pace in order to maintain stable wire position within the vessel. Mechanics of device removal are similar for orbital atherectomy, noting that a new GlideAssist™ mode (akin to Dynaglide™) has recently been added to permit activation of

the device at slow rotational speed (5,000 rpm) to facilitate device tracking and removal.

Once the device is out of the body, cineangiography is indicated to assess the effects of atheroablation and to exclude incident complications. Safe performance of atheroablation without use of contrast has been described, but pending additional data, this approach remains exploratory and should be limited to highly experienced operators skilled with both atheroablative devices and intravascular imaging.³⁶

POSTATHEROABLATION ANGIOPLASTY AND STENTING

In the absence of complications, the prepared workhorse guide wire is advanced across the lesion and balloon angioplasty and stent implantation proceed in standard fashion. Due to the calcific nature of lesions treated, noncompliant balloons are the standard of care for postatheroablation balloon angioplasty. In the current era, noting high rates of restenosis and repeat revascularization in calcified lesions with or without adjunctive use of atheroablation,³⁷ contemporary drug-eluting stents should be considered the treatment of choice, sized 1:1 to the reference vessel diameter. In a series of 1,176 *de novo* coronary lesions treated with rotational atherectomy from 2002 to 2013, drug eluting stents were associated with a more than 50% reduction in MACES [hazard ratio 0.42, 95% confidence interval (CI) 0.26–0.67, $p <0.001$.³⁸ In target vessels for which reference vessel size is angiographically ambiguous, postatherectomy IVUS or OCT may be a useful guide for optimal stent sizing.

COMPARATIVE EFFICACY

To date, no trial has compared orbital and rotational atherectomy with respect to efficacy endpoints. Early insights from plaque imaging after atheroablation suggest that there are differences between the two techniques in their effects on plaque. In a series of 20 patients with OCT imaging before and after orbital atherectomy ($n = 10$) or rotational atherectomy ($n = 10$), orbital atherectomy was associated with deeper dissections, especially in plaques with comparatively less calcium and more lipid content.³⁹ Orbital atherectomy was associated in this small series with improved stent expansion and lower incidence of stent strut malposition (4% vs. 8%, $p = 0.038$). Additional comparative data on procedural outcomes, 30-day and 1-year clinical outcomes after rotational and orbital atherectomy are anticipated from the Multicenter Prospective Study to Evaluate Outcomes of the Moderate to Severely Calcified Coronary Lesions (MACE; ClinicalTrials.gov Identifier: NCT01930214), which was completed in June 2017.

OTHER DEVICES

An effective alternative to rotational or orbital atherectomy for modification of calcified or fibrocalcific plaque is photoablation with ELCA.^{40–45} ELCA works by directing

pulses of ultraviolet light to coronary plaque via optical fibers. These pulses cause vaporization of water, dissociation of carbon–carbon bonds, and molecular vibration leading to plaque destruction. Appropriate eye protection is required with use of ELCA. Unlike rotational and orbital atherectomy, which require placement of a RotaWire™ or ViperWire™, ELCA is compatible with a standard coronary guidewire. This feature can be quite useful for severe lesions and chronic total occlusions through which an exchange catheter cannot cross and exchange to or primary writing with a RotaWire™ or ViperWire™ is not possible. In our practice, ELCA serves a specialty role for such lesions, as well as selected recalcitrant undilatable lesions and in-stent restenosis within calcified lesions.

Atheroablation is not required for treatment of all calcified lesions, and in particular those with less than severe calcification. Indeed—with some effort—comparable results can be achieved with “plain old balloon angioplasty”,⁴⁶ cutting and scoring balloon angioplasty.⁴⁷ No significant difference in clinical outcomes was observed in the randomized ROTAXUS trial with a primary strategy of rotational atherectomy,³⁷ and additional data are awaited from the randomized ECLIPSE trial comparing orbital atherectomy versus conventional balloon angioplasty, currently enrolling (ClinicalTrials.gov Identifier: NCT03108456). Should these approaches fail to effectively prepare a lesion, however, secondary conversion to an atheroablative strategy may be required. Should complications of balloon angioplasty occur, such as dissection, secondary application of atheroablation may be relatively contraindicated. Operators should practice within the scope of their training and comfort. We strongly advocate that operators who treat calcified and complex lesions should gain proper training in and comfort with use of atheroablative devices so that patients can be offered the benefit of atheroablation as an up front strategy when appropriate.

CONCLUSION

The availability and maturation of multiple techniques for atheroablation today makes effective interventional management of calcified CAD possible and safe in the overwhelming majority of cases. Comfort in diagnosis and management of calcified coronary plaque has become ever more important as our population ages. The subset of older adults undergoing evaluation for transcatheter aortic valve replacement constitutes an important and growing population of patients who benefit from optimal interventional management of calcified CAD. In 2018, it is incumbent upon interventional cardiologists who treat these patients to develop proficiency in a full spectrum of tools for interventional management, including atheroablative devices. We strongly advocate the establishment of centers of excellence for interventional management of calcified CAD that will serve both as leaders in patient care and education.

Protected Percutaneous Coronary Interventions: Treating the Complex Higher-risk Indicated Patients

Mathew Samuel Kalarickal, Ramachandran Paramasivam

INTRODUCTION

Treatment of complex and high-risk procedure is not a new invention or technology. High risk patients were treated even in the 80s and 90s with balloons even when the stents were not available. Those days even dual antiplatelet treatment was not in practice. Aspirin alone was the main stay.

Coronary artery disease (CAD) is the leading cause of mortality not only in the developed world and also in the developing countries. The enormous disease burden underscores the importance of prompt identification and appropriate treatment of these patients to improve outcomes. In patients with CAD, extent and severity of coronary ischemia remains the major determinant of mortality and hence, medical treatment alone may not be adequate in those subset of patients with large ischemic burden. The benefit of revascularization is directionally proportional to the extent of ischemia and the completeness of revascularization.

With increasing life-expectancy and extensive prevalence of coronary risk factors, the number of patients with CAD

presenting at an advanced age and with high-risk clinical presentation is on the rise. At the same time, better understanding of the disease, accumulating experience, and availability of better hardwares have led to increasing competence among interventional cardiologist dealing complex lesion subsets. This resulted in the birth of a new subspecialty in interventional cardiology called “Complex High-risk Indicated Patients (CHIP)—interventions”.¹

COMPLEX HIGH-RISK INDICATED PATIENTS

There is no universal definition for CHIP (Table 1). Current risk assessment incorporates the following three important areas: (1) patient comorbidities (advanced age, frailty, chronic obstructive pulmonary disease, etc.) decides patient's physical ability to withstand the procedure; (2) adverse coronary anatomical features (calcification, chronic total occlusion, last surviving vessel, degenerated vein graft, etc.) determines the complexity of the intervention; and (3) unfavorable

TABLE 1: Complex High Risk Indicated Patients

Patient comorbidities	Clinical presentation	Complexity of coronary anatomy	Adverse hemodynamics
<ul style="list-style-type: none"> • Age >70 years • Frailty • History of cerebrovascular accident • Diabetes mellitus • Chronic kidney disease • Peripheral vascular disease • Chronic lung disease • Severe aortic stenosis 	<ul style="list-style-type: none"> • STEMI • ACS with unstable hemodynamics, dysrhythmia, or refractory angina • Mechanical complications of AMI • Cardiogenic shock • Congestive cardiac failure • Coronary intervention after resuscitated cardiac arrest • Severe left ventricular dysfunction 	<ul style="list-style-type: none"> • Intervention to unprotected left main vessel or left main equivalent • Distal left main bifurcation intervention • Multivessel disease • Degenerated vein graft intervention • Last remaining coronary conduit vessel • Chronic total occlusion with J-CTO score >2 • SYNTAX score >33 	<ul style="list-style-type: none"> • Low cardiac output (Cardiac Index <2.2 L/min/m²) • Elevated LV filling pressure (PCWP >15 mm Hg) • Elevated pulmonary artery pressure (mean >50 mm Hg)

ACS, acute coronary syndrome; AMI, acute myocardial infarction; STEMI, ST-elevation myocardial infarction; J-CTO, Multicenter Chronic Total Occlusion Registry of Japan; LV, left-ventricular; PCWP, pulmonary capillary wedge pressure.

hemodynamics, poor left-ventricular (LV) function, and associated valve disease determines hemodynamic stability during procedure.

During the procedure, contrast injections, balloon dilatations, atherectomy device passes, and stent manipulations transiently disturb the blood flow to the target coronary vessel which results in negative inotropic effect.² High-risk patients have limited ability to withstand the adverse hemodynamic effects of dysrhythmia, ischemia-reperfusion injury, or no-reflow associated with percutaneous coronary interventions (PCI) and these type of patients may have significantly low cardiovascular reserve and are increasingly susceptible to postischemic stunning.

CHIP PCI HOSPITAL

For running a successful CHIP program, the hospital must possess following basic facilities:

- At least two CHIP qualified physicians and a team of interventionists, trained nurses, and technical staff offering 24 × 7 emergency PCI services
- Catheterization laboratory with capabilities of atherectomy, intravascular imaging, and physiology, and hemodynamic support devices
- Cardiothoracic surgery facilities with 24 × 7 availability
- Intensive care physician and nurses trained in handling high-risk cardiac patients
- Administrative and economic support from the management for the program.

CHIP PHYSICIAN

Complex high-risk indicated patients' interventions are different from routine coronary interventions. Physician performing CHIP interventions should have specific skill sets to handle complex anatomical subsets and complications during procedure. CHIP operator should be a high volume operator with significant proportion of them being complex interventions involving left main coronary artery and bifurcation lesions requiring double stent strategy, chronic total occlusion recanalization—both antegrade and retrograde techniques and calcified lesion intervention involving atherectomy devices. They should also possess good knowledge of intravascular imaging and physiology. In addition, he should be competent to handle procedure complications such as coronary perforation, access site complications and device embolization and entrapment.

PATIENT EVALUATION AND PROCEDURE PLANNING

Preprocedure evaluation and planning are the cornerstones of the CHIP interventions. Maximum possible information regarding the patient's past medical and surgical history has to be obtained from the case records and treating primary care physician. Reviewing all previous procedure records is essential. For example, number of bypass grafts implanted

during previous coronary artery bypass graft surgery, type of stents implanted and complications happened during previous procedure. During the assessment, it is also important to decide on the requirement of pulmonary artery pressure monitoring and hemodynamic support at the time procedure.

Once evaluation is completed, the whole information regarding the patient has to be discussed in the heart team meeting and appropriate consensus to be arrived.

In addition, it is prudent to involve experts from specialties such as heart failure, electrophysiology, and cardiac intensive care in the management of patients with other associated cardiac illnesses.³

The pros and cons of the procedure have to be explained in detail to the patient and the relatives and informed consent to be obtained.

HEMODYNAMIC SUPPORT DEVICES

Hemodynamic support devices are the cornerstone of CHIP procedures. They stabilize patient's hemodynamics during procedure to facilitate the procedure. There are various types support devices with different levels of back up support available for clinical use.

Intra-aortic Balloon Pump

Inflation of the balloon in early diastole augments diastolic pressure that leads to increased coronary perfusion pressure whereas deflation of balloon at end diastole decreases the aortic systolic pressure which decreases the LV afterload. Intra-aortic balloon pump (IABP) support provides up to 0.5 L/min of cardiac output.

In BCIS-1 trial, patients undergoing high-risk PCI [left ventricular ejection fraction (LVEF) <30% and extensive CAD] were randomized to either routine IABP or no planned IABP prior to PCI. There was no difference in the primary endpoint of major adverse cardiac and cerebrovascular events (MACCEs) at 28 days although there was a marked reduction in procedural complications. Bleeding and access-site complications trended higher toward routine IABP use. Although, there was no difference in 6-month mortality, it was significantly reduced at 51 months follow up. The IABP-SHOCK II study randomized 600 patients presented with acute myocardial infarction (AMI) complicated by cardiogenic shock (CS) to routine IABP versus no IABP.⁴ By 30 days, the primary endpoint of all-cause mortality (39.7% vs. 41.3%, p value 0.69), and secondary endpoints of bleeding, sepsis, and stroke were similar between the groups.

The CRISP AMI trial⁵ evaluated the role of prophylactic IABP insertion in patients undergoing primary PCI (PPCI) for anterior wall STEMI without CS in reducing the mean infarct size measured by cardiac MRI imaging between 3 days and 5 days of post-procedure. The primary endpoints were not statistically significant between the two groups. Secondary cardiac MRI imaging measures of mean LVEF and LV systolic volume were also similar.

Advantages

- Readily available in catheterization laboratories
- Small access size comparing to other devices (8F)
- Ease of percutaneous implantation.

Disadvantages

- Increase cardiac output only by 0.5 L/min
- Not reliable in patients with dysrhythmia
- Increase risk of access site complications, hemolysis, aortic dissection, atheroembolism, stroke, and infection.

Although the vast experience exists with the use of IABP, it provides minimal hemodynamic support, which may not be adequate for severe forms of CS. IABP has been studied extensively and has not reduced mortality in patients with CS or high-risk-PCI except in the setting of STEMI patients treated with fibrinolysis.

Impella

Impella recover LP 2.5 (Abiomed) is a microaxial rotatory blood pump that expels the blood directly from LV to the aorta which in turn decreases end-diastolic pressure, end-diastolic volume and end-systolic volume. In this way, Impella directly unloads the left ventricle, increase cardiac output and coronary perfusion⁶. Impella LP 2.5 delivers an output up to 2.5 L/min. Impella CP device provides an output up to 4 L/min and Impella 5.0 device up to 5 L/min. The first two devices are implanted percutaneously and last through surgical cut down.

In PROTECT I study,⁷ enrolling patients with LMCA or sole remaining conduit and severe LV dysfunction, the device was technically successful in all cases with a low complication rate. In PROTECT II trial, 452 patients undergoing elective high-risk PCI were randomized to IABP or Impella 2.5. The primary endpoint of 30-day major adverse events (a composite of 11 end points) in intention-to-treat analysis was not different between the devices, however, it showed a trend favoring Impella in the per-protocol population analysis. At 90 days per-protocol defined major adverse events were significantly lower in the Impella group.

Currently, FDA approves Impella device for patients with CS after AMI or CABG.

Advantages

- Easy to use
- Augment cardiac output by 2.5–5 L/min
- Does not require stable cardiac rhythm.

Disadvantages

- Not universally available
- Requires 12–14 Fr access/surgical access for Impella 5
- Nonpulsatile flow
- Risk of displacement
- Access site complications, increase risk of atheroembolisation, stroke, and infection.

Extracorporeal Life Support

Extracorporeal life support (ECLS), formerly known as extracorporeal membrane oxygenation (ECMO), is a

modified heart lung machine that can be implanted percutaneously. It has a venous cannula (18–21 Fr) that is placed in the right atrium via the femoral vein and an arterial cannula (16–19 Fr) placed either in the iliac artery or descending aorta. The blood drawn from the right atrium is accelerated through a centrifugal pump and oxygenated in a membrane oxygenator before delivered to the arterial system. Depending on the size of the cannula, ECLS delivers an output up to 7 L/min.^{8–10}

Although ECMO provides considerable hemodynamic support, it imposes significant increase in afterload that in turn intensifies LV wall stress and oxygen demand. This may be deleterious to an already compromised left ventricle.

Advantages

- Augment cardiac output by more than 4.5 L/min
- Does not require stable cardiac rhythm
- Can be used to support the circulation up to several weeks.

Disadvantages

- Not widely available
- Nonpulsatile flow
- Possible poor perfusion of coronaries and cerebral circulation
- May require concomitant use of IABP
- Access site complications, limb ischemia, systemic inflammatory response, renal failure, systemic embolization, stroke, and infection
- Need for perfusionist.

Although there are few single center studies that evaluated ECMO in the setting of CHIP PCI, there are no major randomized studies.

TandemHeart

TandemHeart is a percutaneous ventricular assist device which works without the need of external oxygenator or a heat exchanger. In TandemHeart, the inflow cannula (21 Fr) placed in the left atrium via transseptal puncture from the right femoral vein, outflow cannula (15–17 Fr) is implanted at the level of aortic bifurcation via right femoral artery. The device pump cycles the oxygenated blood from left atrium into femoral artery. TandemHeart device provides up to 4 L/min of cardiac output.

This device indirectly unload the left ventricle, reduces the cardiac filling pressures and myocardial oxygen demand. However may paradoxically increase the myocardial demand due to rise in afterload in patients with CS with severe LV dysfunction. In such case scenario additional LV unloading devices like IABP or Impella may be necessary.

In Thiele H et al. study randomized AMI patients complicated by CS to IABP (n = 20) and TandemHeart (n = 21) before revascularization.¹⁰ Although TandemHeart device enhanced hemodynamic and metabolic parameters more effectively, this did not result in a survival benefits.¹¹

Advantages

- Can augment cardiac output by up to 4–5 L/min

- Support the circulation up to 14 days
- Does not require stable cardiac rhythm.

Disadvantages

- Requires transseptal puncture and difficult to use in emergencies
- Right atrial displacement of cannula from left atrium leads to profound desaturation.
- Access site complications, atheroembolism, stroke, infection and hemolysis.

POST-PROCEDURE CARE

Postprocedural care following implantation of support devices consists of transfer of the patient to ICU, continuous monitoring in ICU, weaning, and removal. Qualified staff and own hospital protocol is important. Care should be exercised in transferring the patients to ICU to prevent device displacement and loss of hemodynamic support. Patients should be periodically monitored for anticoagulation levels and hemolysis. It is also important to watch for device migration, bleeding, and limb ischemia.¹²

Hemodynamic support devices weaning may start in catheterization laboratory after the procedure. If an IABP is used, assistance is reduced from 1:1 to 1:2 for 10 minutes, followed by 1:3 for 10 minutes. If hemodynamic parameters are good for 10 minutes, then the device can be removed. For Impella device, the level of support is reduced by two levels every 10 minutes until P-2. If the patient continues to hemodynamically stable on level P-2 for 10 minutes, then the device can be removed. At the time of device removal, the device is turned down to P-1 level and pulled back into the descending thoracic aorta. Once in the descending thoracic aorta, the device can be turned off completely to P-0 and removed.¹³⁻¹⁵

If weaning done in ICU, it should be started immediately in patients who demonstrate hemodynamic improvement with good end organ perfusion and can be carried out over few hours. IABP should be weaned with a stepwise decrease in assisted beats from 1:1 to 1:2 to 1:3 over several hours. If hemodynamics remained stable on 1:3 for 3 hours, then the device is set back at 1:1, heparin infusion is stopped and once the aPTT is less than 50 seconds the device can be removed. Impella should be weaned over hours with reduction in level of support by two levels every 2-3 hours until the level P-2. Once patient is remained stable at level P-2 for 2-3 hours the device can be removed. Arterial access site can be closed with the preclose technique, surgical closure, or manual pressure.

Mechanical support devices are compared in table 2 and recommendations for use during CHIP PCI provided in table 3.

CURRENT EVIDENCE

Complex high-risk indicated patients form a specific subgroup of patients who need an advanced level of care compared to the routine patients undergoing revascularization. The randomized trials evaluating effectiveness of different treatment strategies for patients with CAD hardly represent this subset of patients. Although revascularization appears to be beneficial in CHIP population, it has to born in mind that the procedure involves a higher level of risk to the patient and also has economic implications for the health care system. So, this approach needs to be evaluated in major randomized trials before its wide spread adaptation in clinical practice.^{16,17}

CONCLUSION

Patients undergoing elective high-risk PCI should be transferred to high-volume centers with operators specialized

in treatment of complex higher-risk indicated patients. Collective team based approach is needed for appropriate patient selection, treatment, and subsequent care of these patients. Each institution should familiar with at least two support devices including IABP and Impella or TandemHeart in order to provide safe and efficient delivery of care in patients with high-risk-PCI. Finally CHIP PCI shows great promise in advancing the interventional cardiology but it is not without risk.

Complex high-risk indicated patients terminology is a new but the technology is old. Most of the devices IABP, femorofemoral bypass was in use even in the 1990s itself. ECMO is a modification of femorofemoral bypass. Impella is an addition which is very useful in high-risk patients.

Ostial Coronary Lesions: Tips and Tricks for the Interventionist

Pravesh Vishwakarma, Rishi Sethi

INTRODUCTION

By definition, ostial lesions are the lesions within 3 mm of origin of the vessel from aorta or parent vessel. Ostial lesions continue to challenge the skills of an interventionist despite several advancements in percutaneous coronary intervention (PCI) techniques in last 40 years. Due to unique anatomic and histologic characteristics, these lesions tend to have poor outcomes (short-term as well as long-term) as compared to lesions in nonostial location. And also, for all practical purposes, lesions very close to ostium (up to 5–6 mm) should be considered as ostial due to similar challenges posed by them during PCI.

Depending on the origin, ostial lesions can be categorized into aorto-ostial lesions [e.g., right coronary artery (RCA), left main coronary artery (LMCA), and saphenous grafts arising from aorta] and branch ostial lesions [e.g., left anterior descending artery (LAD) and left circumflex (LCx) ostial lesions; diagonal, obtuse marginal, posterior descending artery (PDA), and posterolateral branch (PLV) ostial lesions].

This chapter will focus mainly on challenges encountered and their solutions for aorto-ostial interventions. Many of these technical considerations apply to branch ostial lesions as well but these lesions are in essence bifurcation lesions (median class—0, 1, 0 or 0, 0, 1) with the plaque often extending to main branch. Hence, intervention at branch ostial junctions should be planned according to bifurcation characteristics with an individualistic approach.

MORPHOLOGY AND HISTOLOGY

Aorto-ostial lesions have a unique three-dimensional funnel-shaped morphology with variable take off angles from aorta. These may be associated with diffuse or focal coronary artery disease at other locations and are usually atheromatous in origin. Isolated aorto-ostial lesions are usually seen in females more commonly involve RCA^{1,2} and are due to nonatherosclerotic causes such as inflammatory aortic disease (e.g., syphilitic, Takayasu arteritis), prior radiotherapy or aortic

valve surgery, congenital arterial hypoplasia or extrinsic compression by a dilated pulmonary artery.³

Ostial lesions tend to have higher fibrous tissue and calcium content and minimal atheromatous plaque.⁴ They have high rigidity and increased recoil tendency causing suboptimal acute luminal gain. There is also increased intimal hyperplasia after stenting leading to increased rates of target lesion revascularization (TLR). Introduction of drug-eluting stents (DES) has led to reduced restenosis and other complication rates as compared to balloon angioplasty and bare metal stents, but results at ostial location still remain inferior to those at nonostial lesions.⁵ Hence, optimal PCI with a well deployed DES remains the only guarantee to best possible long-term outcome. Knowing the tips and tricks to tackle an ostial lesion comes handy in these situations. Various challenges expected and their solutions are discussed in the following text.

DIAGNOSTIC CHALLENGES

- Appropriate evaluation of ostial disease is often challenging. Catheter-induced coronary vasospasm is a close mimic, especially in RCA and should be ruled out before proceeding with PCI. Intracoronary nitroglycerine can help differentiate between spasm and true lesion
- Deep intubation beyond lesion may miss ostial disease. This usually happens with small sized (4 or 5 Fr) diagnostic catheters. Absence of contrast backflow into aortic sinus and pressure damping or ventricularization may be the clues. But pressure damping effect may not be seen in catheters with side holes and also if the catheter is noncoaxial. Stagnant dye (nonclearance or nonwashout of contrast) in coronary should prompt the operator to look for a catheter deep throated into significant ostial-proximal lesion. Failure to recognize it may lead to prolonged coronary ischemia and arrhythmic complications. Catheter needs to be disengaged before next injection to allow the artery to “breath” in between injections. Nonselective

- root injections close to ostium may be helpful but are not sufficient to opacify and characterize coronary lesions. Deep intubation of coronaries can also be prevented by slight clockwise or anticlockwise rotation of catheter, keeping the catheter tip nonaligned to coronary ostial axis. Repeated need to engage and disengage catheter can increase the risk of ostial damage and dissection. Forceful contrast injections should be avoided as it may also cause intimal disruption and coronary dissection
- Accurate assessment of lesion severity by quantitative coronary analysis is not possible because of absence of proximal reference segment. Fractional flow reserve (FFR) can be help in estimating physiological significant of lesion. Of note, for aorto-ostial lesions, pressure equalization needs to be done in aorta with guiding disengaged away from ostium. Continuous intravenous infusion of adenosine is more reliable for inducing hyperemia as compared to intracoronary bolus because of need to engage to inject adenosine and rapidly disengage to do measurements
 - Among imaging modalities, intravascular ultrasound (IVUS) is of particular help. Detailed plaque morphology (plaque burden, lipid core, fibrotic plaque, and calcification) as well as lesion severity [minimum luminal area (MLA)] can be assessed, helps plan adjunctive strategy like cutting balloon for fibrotic plaque and rotablation for calcified lesion. However, noncoaxial course of IVUS catheter with a disengaged guide catheter may lead to overestimated MLA and failure to recognize the severity. Optical coherence tomography (OCT) has limited utility because effective clearance of blood from lumen requires guide catheter to be engaged selectively and this would prevent ostial plaque visualization behind the catheter. Computed tomography coronary angiography (CTCA) may be extremely helpful in cases where a critically narrowed and/or anomalously placed ostium does not allow selective engagement and coronary artery visualization.

SELECTION OF HARDWARES

Radial versus Femoral Access

Considering the unequivocal advantage in terms of bleeding complications and survival benefits, it is impractical to advise against radial access over femoral. Moreover, it is a matter of operator's experience and personal preference. In some cases with challenging anatomy, femoral access can provide better guiding catheter stability and more control over catheter manipulations.

Guiding Catheter Selection

The best guiding catheter for ostial lesion would be a less aggressive one without active support or a tendency to wedge in the diseased ostium occluding the coronary blood flow. An aggressive catheter may repeatedly get deep threated into lesion compromising the blood flow, and need to repeatedly engage and disengage can increase the risk of coronary

dissection. For RCA and saphenous venous grafts, Judkins right, multipurpose, Amplatz right curves are preferred. For ostial LMCA lesions, Judkins left curve with or without short tip can be used (Fig. 1).

Guiding catheters with side holes may be used for ostial chronic total occlusions, but for nonocclusive stenosis, we advise guiding catheters without side holes. Presence of side holes may fail to show warning sign of pressure damping or ventricularization in case of deep wedging, and are never sufficient to maintain blood supply of coronaries. Another drawback is contrast wastage and inadequate opacification of arteries, hence increased contrast burden during the procedure.

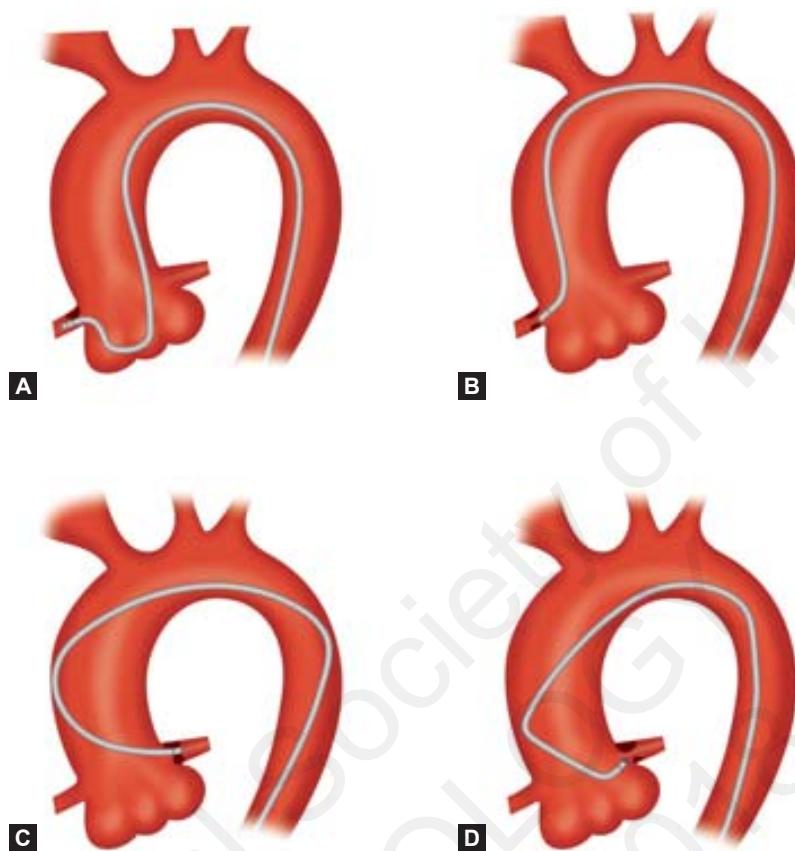

Another very relevant option in those situations where the risk of deep engagement is causing problems is to upsize the guiding catheter. A larger size guide would abut against the outer side of the ostial funnel and thus would have less chances of engaging deep.

Guiding Catheter Maneuvers

The purpose of catheter manipulations is to avoid impeding coronary blood flow due to catheter wedging in lesion, to avoid ostial dissection by catheter due to repeated trauma at diseased segment and to efficiently engage or disengage the catheter for precise stent placement without losing complete access to artery.

As soon as the catheter engages the ostium, pressure waveform changes (damping or ventricularization) are seen. These changes may be used throughout the procedure as a surrogate marker of engagement thus avoiding unnecessary contrast injections. For LMCA, guiding catheter may be gently withdrawn to disengage till the pressure waveform is normalized. For RCA, the guiding catheter is disengaged by giving a gentle counterclockwise torque with a purpose to creating a malalignment between guide and coronary axis. This prevents accidental deep intubation into RCA at the cost of reduced guiding support. Hence, while giving counterclockwise rotation, guide catheter is gently pushed down by a couple of millimeters so that guiding does not flip back completely into ascending aorta. Alternatively, after wiring and guiding, wire may be gently pulled out together as one unit; or wire may be pushed into distal coronary tree thereby pushing the guiding back. During these maneuvers, guidewire must be parked distal enough in coronary bed to support disengaged guiding catheter.

By doing the reverse maneuvers, catheter may be engaged again to increase the guide support while delivering a hardware like percutaneous transluminal coronary angioplasty (PTCA) balloons or stent. Guiding catheter stability may also be improved by using a second guidewire into distal coronary bed as "buddy wire" or into conus or acute marginal branch as "anchoring wire" or with a PTCA balloon over it as "anchoring balloon" technique. Sometimes, guiding catheter's tendency to deep intubation may be controlled by a "floating wire" in aortic sinus where second guidewire, placed free floating into aortic sinus, acts as a barrier between catheter tip and ostium.

EBU, extra back up; LMS, left main stem; RCA, right coronary artery.

FIG. 1: Selecting a guiding catheter shape for aorto-ostial lesion. Choosing a less aggressive catheter avoids deep seating, thereby reducing the risk of flow impediment as well as ostial dissection. **A**, Amplatz catheter—deep engagement of RCA; **B**, Judkins catheter—minimal engagement of RCA; **C**, EBU catheter—deep engagement of LMS; **D**, Judkins catheter—minimal engagement of LMS.

Wire Selection

Standard workhorse wires are usually sufficient for ostial lesions. Even intermediate or extra support wires may be preferred. In general, hydrophilic or light support wires should be avoided for lack of adequate support to guiding catheter and heightened risk of coronary perforations. Additional wires may be used (as buddy wire or anchoring wire) to increase the guide support as described earlier in the text.

In critically stenosed ostial disease where ischemia burden is huge, e.g., in ostial LMCA lesions, it is preferable to preload the guidewire inside the guiding catheter. As soon as the catheter tip engages the ostium, wire is quickly advanced into distal coronary artery and catheter is disengaged promptly, thus significantly reducing ischemia duration.

Lesion Preparation

Optimal lesion preparation is essential not only for adequate stent expansion but also to avoid stent migration. It relieves ischemia and increases time window for catheter and stent manipulation. As the aorto-ostial lesions are rigid and fibrotic, one should have low threshold to predilate. We advise an

aggressive predilatation in almost all cases of aorto-ostial lesions. Predilatation is done with compliant PTCA balloon preferably 0.5 mm smaller than distal normal reference segment (balloon to artery ratio 0.7:0.9), partially hanging in aorta and partially inside coronary artery beyond the ostium and guiding catheter disengaged to avoid balloon damaging the catheter. Satisfactory endpoint is disappearance of balloon waist during inflation and without elastic recoil after the balloon is deflated. Resistant lesions may cause watermelon seeding of the balloon, i.e., balloon slips proximally or distally before it achieves full inflation. This problem can be circumvented by using longer balloons and a very slow inflation (at rate of 1 atm at a time or even less) while simultaneously maintaining a push or pull on balloon catheter shaft. Some of nonyielding lesions can be successfully dilated by using noncompliant balloons at high pressures close to rated burst pressure (RBP). But, very high-pressure predilatation can cause undesirable complications such as intramural hematoma and/or coronary dissection leading to luminal compromise. Forceful injections should be avoided as it can cause dissection at ostium to extend antegradely down the coronaries as well as retrogradely causing aortic root dissections. These problems can be avoided by using

scoring balloon or cutting balloon, which create controlled dissections as compared to noncompliant balloons. If cutting balloon or scoring balloon is not available, a noncompliant balloon over primary wire along with a second wire as buddy wire between balloon and plaque can lead to focused force dilatation of lesion. Intracoronary imaging modalities like IVUS can help plan these adjunctive devices from the outset by characterizing the plaque morphology, e.g., cutting balloon or scoring balloon for fibrotic plaques and rotablation for heavily calcified plaques, especially superficial ring calcium. If rotablation is chosen, maintaining a stable coaxial guide position is a challenge with ostial lesions and burring should start from within the guiding catheter so as not to miss the ostial lesion.

Stent Selection

There is no doubt that DES have an advantage over bare metal stents with respect to lower TLR rates and ostial lesions are no exception. Elasticity and rigidity at aorto-ostial location necessitates a stent with good radial strength to avoid excessive recoil. Slotted tube stents may be preferable over single coil stents. In case of ambiguous ostium, it may be difficult to predict the stent length with certainty so it is better to choose a little longer stent so as to cover the whole lesion up to distal edge.

Stent Positioning

Optimal stent positioning requires entire circumference of the proximal stent edge to be within the aorto-ostial landing zone (AOLZ) which is circumferential area within 1 mm of true ostium (i.e., aorto-ostial plane). Variable ostial location as well as angles of takeoff and suboptimal visualization from a disengaged guiding catheter make the identification of true ostium or AOLZ one of the trickiest jobs by a two-dimensional coronary angiography. IVUS studies have shown geographic miss in 10% of cases⁶ while a CTCA study showed it in 87% of cases.⁷ This is why it is recommended to cover the whole ostium while keeping one or two struts hanging into aorta rather than struggling to visualize AOLZ. Proximal protrusion more than recommended (positive geographic miss) can make the coronary artery “nonengageable” for future interventions, while missing the ostium (negative geographic miss) can lead to increased risk of stent thrombosis as well as stent restenosis.

Optimal Angiographic Views

For an ostial lesion, optimal angiographic view is the one, which demarcates aorto-ostial plane that is to say the view which separates aortic sinus from coronary ostium without any overlap. Owing to variable anatomy, there is no one angulation which suites all. It should be tailored according to individual anatomy. Multiple orthogonal angiographic views should be used to minimize overlap or foreshortening. Flecks of calcium in aortic root close to ostium may also help identify the ostium. For RCA, optimal view is obtained with a left anterior oblique view with or without slight caudal angulation.

TABLE 1: Optimal angiographic views to best delineate ostia of various coronaries

Coronary vessel ostium	Optimal view
Left main coronary artery	AP cranial, LAO cranial, and RAO cranial
Right coronary artery (RCA)	LAO, LAO caudal, lateral view
Aortocoronary grafts	<ul style="list-style-type: none"> • LAO for RCA grafts • RAO for LAD, LCx saphenous grafts
Left anterior descending (LAD) artery	LAO caudal, AP caudal, and RAO caudal
Left circumflex artery (LCx)	LAO caudal, AP caudal, and LAO cranial
Diagonal branches	LAO cranial, LAO caudal
Obtuse marginal branches	LAO caudal, LAO cranial
PDA and PLV	AP cranial, LAO cranial

AP, anteroposterior; LAO, left anterior oblique; RAO, right anterior oblique; PDA, posterior descending artery; PLV, posterolateral branch.

Sometimes, lateral view may give the best demarcation of true ostium. For LMCA ostium, cranial views are best with slight left or right anterior oblique angulation. Caudal (left anterior oblique—caudal, right anterior oblique—caudal) views may supplement and help give better estimate of aorto-ostial plane (Table 1).

Stent Deployment

Stent is loaded in guiding catheter just proximal to the tip. Now, guiding catheter is made coaxial with coronary artery. This allows ostial engagement causing some pressure damping. Stent is quickly delivered into the vessel with proximal stent marker just distal to catheter tip. Guidewire is pushed in distal circulation to provide maximum support. Now all three (guiding catheter, stent, and guidewire) move as one unit. Tightening the Y-connector may help making the assembly act as one. The whole system is gently retracted (in case of RCA, anticlockwise torque on guiding may be used) to bring the proximal stent marker just proximal to true ostium. This in turn automatically disengages the ostium and pressure comes back to normal waveform. Now system layout is like guiding catheter disengaged and just proximal stent balloon freely floating in aortic sinus supported by wire and stent shaft, and proximal stent marker just outside the ostium and proximal stent edge at the ostium. Magnification and StentBoost⁸ can assist in confirming the same. It should be noted that proximal stent marker is not at the stent edge but 0.5–1 mm proximal to stent edge (depending on stent manufacturer). This is important so that proximal stent edge is covering the circumference of ostium. For added safety, stent edge may be kept 1–2 mm hanging into aortic root. As the catheter tip is just proximal to stent marker, contrast injections are able to delineate margins of aortic sinus while partly filling the ostium. Before the stent is deployed, final position must be confirmed in multiple views. If satisfied, stent can be deployed at nominal pressure. After first inflation, balloon is deflated, retracted a few millimeters into aorta and

reinflated to high pressures to ensure complete expansion as well as stent apposition. Pulling on an incompletely deflated balloon can also suck the guiding catheter in and lead to stent deformation, another unrecognized cause of geographic miss. It is very important to allow enough time for balloon to deflate completely before attempting pull back.

Before stent balloon is taken out completely, guiding catheter should be made coaxial and railed-in over the deflated balloon to engage stented ostium. This step is important in case postdilatation is needed and one may not be able to deliver noncompliant balloon in noncoaxial and disengaged guiding catheter. Caution should be taken not to use force as it can cause longitudinal compression and deformation of stent. It may be the reason behind classical teaching of guiding catheter to avoid touching the stent and many of operators advising against this step. High pressure postdilatation should be done at ostial lesions to correct any recoil, underexpansion or malapposition. Higher sized noncompliant balloon can be used at proximal edge of stent to achieve the “funneling” of ostium.

Excessive respiratory or cardiac movement can be hindrance in achieving stable stent position. Respiratory motions can be minimized by asking the patient to hold breath. Some patients may not be able to tolerate it for a long time resulting in deep inspiration at the least desired time. It is better to ask patients to take gentle shallow breaths. Cardiac motions can be difficult to overcome. Beta-blockers, intracoronary adenosine or rapid ventricular pacing may be helpful in reducing stent excursions. Partially inflating the stent at 2–3 atm (partial preinflation technique)⁹ increases the stent weight as well as profile, thus limit stent oscillations and stent can be fully deployed after final position adjustment. This technique can be disastrous if lesion is not prepared well, can result in stent getting stuck at wrong place or stripped off the balloon.

SPECIAL TECHNIQUES FOR OSTIAL STENT PLACEMENT

Floating Wire Technique

Guiding tip is retracted back and a second steerable soft-tipped guidewire is placed into aortic sinus between guiding tip and ostium. Guiding catheter is advanced over primary wire till its forward movement is stopped by second floating wire (Fig. 2). This technique also described as “sepal wire technique” for ostial LMCA stenting¹⁰ works 2-fold—prevents guiding from jumping into ostium and simultaneously marks the junction of ostium to aortic sinus. It can really help when true ostium is ambiguous and cannot be defined by traditional angiographic views.

Tail Wire Technique (Szabo's Technique)

This technique¹¹ utilizes a second guidewire to anchor the stent exactly at the ostium. Primary guidewire goes in the target vessel and the second guidewire (i.e., anchor wire) is placed in aorta (for aorto-ostial lesion) (Fig. 3) or the side branch (for branch ostial lesions) (Fig. 4). The stent is loaded on primary wire and the proximal end (tail) of anchor

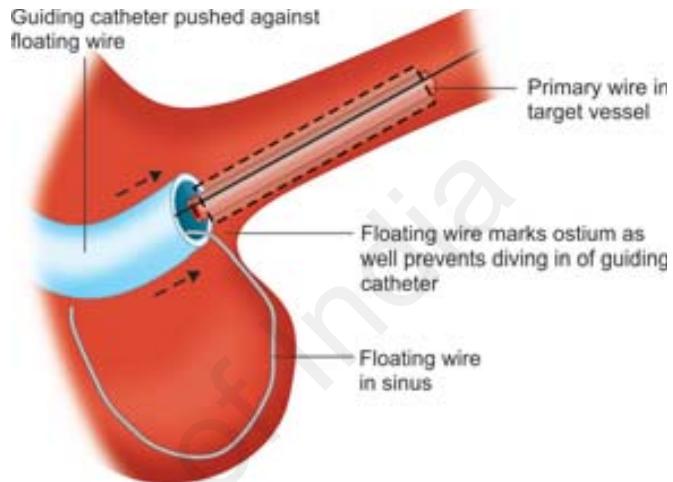

FIG. 2: Floating wire technique. This technique, primarily intended to prevent repeated deep engagement of guiding into ostium, utilizes a secondary wire left floating into aortic sinus between the guiding catheter and coronary ostium. Guiding catheter is advanced over primary wire against the floating wire, which prevents guiding from entering the ostium.

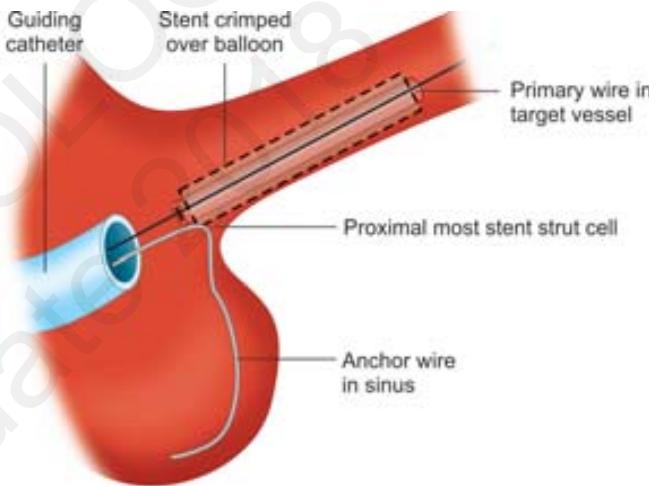

FIG. 3: Szabo's (tail wire) technique for aorto-ostial lesion. The anchor wire goes through the proximal-most struts of stent and lies free into aortic sinus. It anchors the stent at the ostium, thus, avoiding geographic miss.

wire is threaded through the proximal most stent strut cell. Threading can be facilitated by inflating the stent at 2–4 atm while most of stent is still inside the stent cap or sleeve except for proximal 2–3 struts which flare; balloon is deflated, anchor wire tail is threaded through flared proximal most stent strut and then stent is manually recrimped over balloon (modified Szabo's technique). Stent is advanced over both the wire until anchor wire stops its forward motion declaring that proximal edge has reached ostium. Stent is deployed first at low pressures; anchor wire is removed followed by stent balloon inflation at high pressures. Tail wire technique ensures high angiographic success but perfect ostial placement could not be documented in bench testing and IVUS and also is not without complications. Intertwined wires may restrict

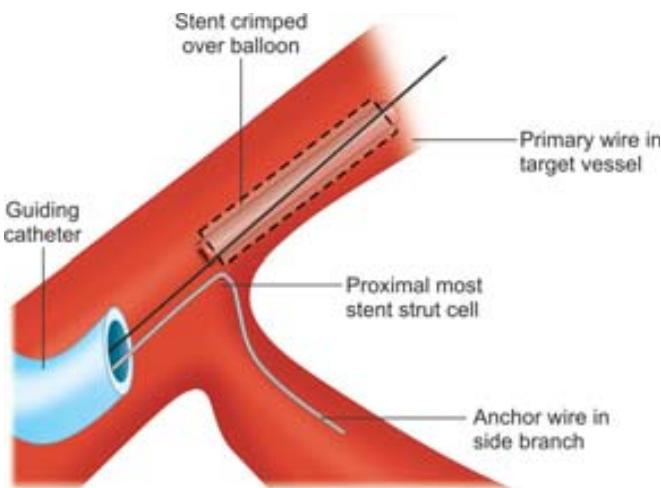

FIG. 4: Szabo's (tail wire) technique for branch-ostial lesion. The anchor wire goes through the proximal-most struts of stent and lies into side branch. It anchors the stent at the ostium, thus avoiding geographic miss.

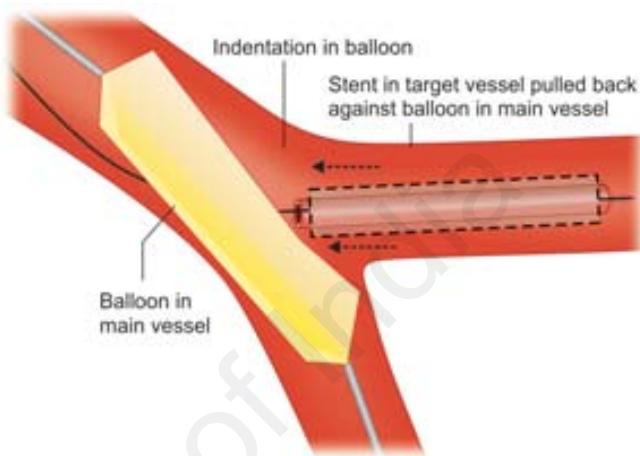

FIG. 6: Stent pull back technique. An inflated balloon is placed in main vessel and the stent in side branch is pulled back till slight indentation appears at the balloon (also known as balloon indentation technique). This prevents overhanging of stent struts in main lumen while ensuring adequate ostial coverage.

FIG. 5: Ostial Pro™ stent system. Ostial Pro™ device has four self-expanding nitinol legs protruding from distal catheter end which prevents deep engagement of ostium and also marks the aorto-ostial plane for correct stent placement.

forward movement of stent, inadequate crimping may result in stent getting stripped off balloon during delivery or stent positioning, forcing the stent can create bend in anchor wire at ostial location causing wire to stuck and avulsion of stent during forceful withdrawal of wire.

Ostial Pro™ Stent System

Self-expanding nitinol feet at the tip of guiding catheter assist in stable positioning (Fig. 5), prevent diving of catheter into ostial lesion and provide a visual aid to align the stent at the aorto-ostial plane.¹²

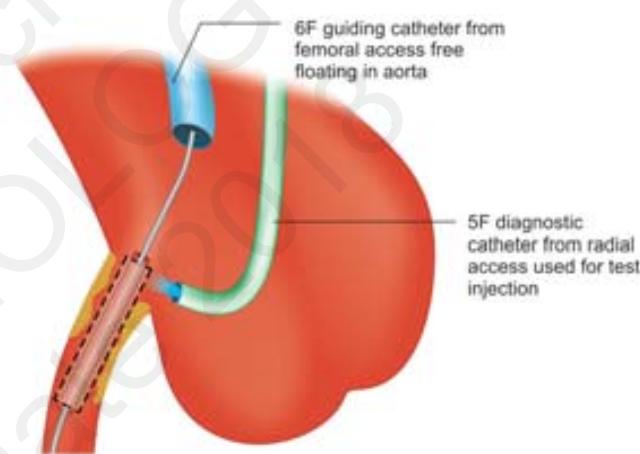

FIG. 7: Two-catheter technique. One guiding catheter and one diagnostic catheter are used simultaneously from different access sites. Guiding catheter is used to deliver stent and is kept disengaged away from ostium while diagnostic catheter placed close to ostium is used to give test injections to visualize stent placement.

Stent Pull Back Technique

In branch ostial lesions, a small balloon is inflated at low pressure in main vessel while stent in branch ostium is pulled back till slight indentation is seen on the balloon in main vessel (Fig. 6). This ensures fewer ostial misses and need for additional stents.¹³

Two-catheter Technique

Sometimes, stent position and ostium cannot be visualized adequately once the guiding is backed out in aorta. Simultaneous use of a second 4 or 5 Fr diagnostic catheter (Fig. 7) placed close to ostium from different access site allows optimal visualization through diagnostic catheter, while maintaining the stable position of guiding catheter away from ostium.¹⁴

CONCLUSION

Ostial lesions are notorious and even simple-looking lesions may end up in suboptimal results or life-threatening complications if not planned properly. Similar to any other lesion, anatomical as well as functional significance of an ostial stenosis should be ascertained before embarking on revascularization. In a patient with multivessel disease, ostial disease must be carefully assessed not as an individual lesion, but in totality along with other prognostic lesions. Factors like diabetic status, left ventricular ejection fraction, syntax score may help decide between coronary artery bypass surgery and PCI.

Thorough evaluation of angiographic findings and detailed planning are the key to achieve the best possible PCI outcome. Anticipation of difficulties and possible complications during a procedure is the sixth sense of an interventionist and help him develop a plan well ahead of time. Choosing a less aggressive guiding catheter, keeping the guide out of ostium or keeping it malaligned to avoid deep engagement and avoiding forceful test injections can help in minimizing ostial trauma and hence ostial and aortic root dissections. Adequate lesion preparation is the most crucial step. IVUS can be a great help by allowing the

interventionist to choose between simple balloon dilatation, cutting balloon or rotablation depending on the plaque morphology. Optimal imaging views and various special techniques like floating wire and anchor wire can help in precise ostial stent placement. Aggressive postdilatation to attain optimal stent expansion is important for best possible long-term outcomes. Box 1 summarizes various steps to be taken care of while dealing with an ostial lesion. Familiarity to challenges and various techniques can help tackle these lesions successfully.

BOX 1 Tips to remember during ostial stenting

- Rule out ostial spasm
- Define the view which best demarcates aorto-ostial plane during diagnostic angiogram
- Use less aggressive guiding catheters
- Keep guidewire park in distal coronary bed, use extra support or buddy wire if needed
- Keep guiding disengaged or noncoaxial to preserve coronary blood flow
- Avoid forceful contrast injections
- Adequate lesion preparation using proper sized balloon; consider cutting balloon or rotablation if intravascular ultrasound suggests so
- Keep proximal stent marker well (2–3 mm) inside the aorta (stent edge is 0.5–1 mm inside markers)
- Utilize multiple views
- Ask the patient to breath slow and shallow
- High pressure stent deployment to ensure stent is well expanded
- High pressure postdilatation

Approach to Management of Chronic Total Occlusion

Pravin K Goel, Roopali Khanna

INTRODUCTION

Chronic total occlusion (CTO) is observed in 16–52% of cases undergoing coronary angiography but constitute only 10–15% of cases undergoing percutaneous coronary intervention (PCI).¹ PCI of CTO lesions is not performed by many interventionists due to fear of procedural failure and complications such as vessel perforation, contrast nephropathy, higher interventional costs, prolonged procedure time, a longer radiation exposure than routine angioplasty, skepticism of benefit and most importantly paucity of widespread expertise and specifically skilled operators. With improving techniques and hardware for PCI and the increasing role of PCI in the management of obstructive coronary artery disease (CAD), CTO, being the most challenging subset, remain the last or unconquered frontier.^{2–4} The purpose of a PCI in CAD is to reduce symptoms and possible future events. These benefits however have not been established at length and study outcomes vary from one study to another. The anticipated benefits of CTO-PCI should exceed the procedural risk. Benefits of CTO-PCI assumed are:

- Improvement in angina
- Improvement in quality of life
- Improved exercise capacity
- Improved left ventricular ejection fraction (LVEF)
- Improvement in cardiac mortality.

Risk associated with CTO-PCI can be categorized into acute and chronic:

- *Acute risk include:*
 - Renal injury
 - Emergency coronary artery bypass graft
 - Periprocedural myocardial infarction (MI)
 - Pericardial tamponade
 - Vascular access complication.
- *Chronic risk include:*
 - *Stent related complication:* Stent thrombosis and stent restenosis
 - Radiation injury.

The CTO interventions as a whole have their benefit, even less well established and available literature shows conflicting results.^{5–7} Moreover, technical challenges involved in CTO procedures, and the unpredictability of the result, along with limited operator expertise has precluded prospective trials. Till date only three prospective trials have been conducted in patients undergoing CTO-PCI but only one is published till date.

The EXPLORE (Evaluating Xience and Left Ventricular Function in Percutaneous Coronary Intervention on Occlusions After ST-Elevation Myocardial Infarction) trial evaluated whether patients with STEMI and concurrent CTO in a non-infarct-related artery benefit from additional PCI of CTO shortly after primary PCI with primary outcome of improvement in LVEF and left ventricular end-diastolic volume (LVEDV) as assessed by cardiac magnetic resonance imaging after 4 months.⁸ A total of 150 patients were enrolled in CTO-PCI group and 154 patients were kept on medical treatment with no CTO-PCI. There was no significant difference in LVEF and LVEDV at end of 4 months but subgroup analysis revealed significant improvement in LVEF in patient with left anterior descending (LAD) artery, CTO emphasizing the importance of extent of myocardial supply of the CTO artery.

The DECISION-CTO (Drug-Eluting Stent Implantation versus Optimal Medical Treatment in Patients with Chronic Total Occlusion) trial (NCT01078051) was presented at the 2017 American College of Cardiology meeting. It randomized 834 CTO patients between optimized medical treatment (OMT) alone and CTO-PCI with OMT. At median follow-up of 3.1 years there was no significant difference with respect to the primary endpoint of the composite of death, MI, stroke, or any revascularization. There were various limitations in the trial, being a underpowered trial, large number of crossover between the two arms, including periprocedural MI as the primary endpoint and early termination of study because of slow enrollment.

The EuroCTO (A Randomized Multicenter Trial to Evaluate the Utilization of Revascularization or Optimal Medical Therapy for the Treatment of Chronic Total Coronary Occlusions) trial (NCT01760083) was presented at the 2017 EuroPCR meeting. It randomized 407 CTO patients into CTO-PCI group and OMT only group. The primary endpoint was improvement in angina as assessed by Seattle Angina Questionnaire. There was significant improvement in angina in patient undergoing CTO-PCI as compared to OMT.

Several observation and retrospective studies have assessed long-term outcome of CTO-PCI compared with medical therapy and have shown lower major adverse cardiac events in CTO-PCI group.⁹⁻¹¹ A study from our institute assessed long-term follow-up in 549 patients undergoing CTO-PCI with median follow-up of 2.9 years.¹² Primary endpoint was defined as event free survival of major adverse cardiac event including death, MI, repeat revascularization [PCI, or coronary artery bypass grafting (CABG)] and recurrent or continued angina. Each individual adverse event was considered as a secondary endpoint. Kaplan-Meier survival analysis showed a better event-free survival in CTO success versus failure ($p = 0.03$). Our study showed successful CTO-PCI was associated with a higher total event free survival but a nonsignificant all-cause mortality difference on long-term follow-up. Complete revascularization was also associated with a better total event-free survival but a significantly lower all-cause mortality in addition at long-term follow-up. There was no significant difference in repeat revascularization rates (repeat PCI and or CABG) in either groups.

When to do Chronic Total Occlusion-Percutaneous Coronary Intervention ?

Evidence of ischemia in the territory supplied by the occluded vessel is a must to treat CTO. This can be confirmed by either clinically evident angina or reversible ischemia documented in a noninvasive study preprocedure in absence of evident angina. Further, territory supplied by the vessel being intervened must have a myocardial supply weightage of at least 10% of the entire myocardium or more, else the risk benefit ratio does not favor intervention.¹³ This will be indirectly equal to a vessel with myocardial value of at least 1.5 as per Green lane scoring system.¹⁴

IMAGING OF CHRONIC TOTAL OCCLUSION LESIONS

Apart from new materials and techniques, the constant development of cardiovascular imaging modalities has helped to improve success and safety of CTO-PCI. Noninvasive imaging technique of coronary computed tomography angiography (coronary CTA) and imaging with intravascular ultrasonography (IVUS) have emerged as a reliable tool to help in CTO intervention. However coronary angiography still forms the basis of a CTO intervention.

Coronary angiography: Several of CTO lesions histopathologically are less than complete with tiny microchannels

connecting proximal to distal stump. These microchannels could be evident on delayed frames on a proper frame by frame analysis of the angiogram in two orthogonal views. The filling pattern of the distal vessel needs to be analyzed frame by frame to differentiate a very slow antegrade filling through microchannels or bridging collaterals or filling retrograde through ipsilateral or contralateral collaterals. Simultaneous injection of feeder vessel and recipient vessel with feeder vessel injection preceding the recipient gives a very good assessment of the length of occlusion almost as good as coronary CTA and should be done in all cases with contralateral collaterals.

Coronary computed tomography angiography: Computed tomography angiography provide good detailed information on lesion length, vessel course, tortuosity, calcification grade, stump morphology, distal vessel opacity, presence of side branches, and presence of bridging collaterals. The only negative side of asking for coronary CTA in all CTO cases is the contrast used (at least additional 50–100 mL) and extra radiation dose in a patient who is due for a long procedure.¹⁵

Intravascular ultrasonography: IVUS provides an axial spatial resolution of 80–150 μm and therefore precise visualization of lumen and vessel wall is possible. IVUS (unlike conventional angiography) can visualize the position of a guidewire within an occluded segment. Thus, intimal and subintimal guidewire tracking can be distinguished, which is crucial for antegrade as well as retrograde wiring techniques. Furthermore, IVUS can be helpful in identifying an ostially located entrance, especially in the unfavorable situation of a stumpless CTO with a side branch at occlusion site. Finally, the usual IVUS information on the target lesion, such as lesion length, lumen area, plaque composition and distribution plays an important role in optimizing stent implantation and reducing in-stent restenosis.^{16,17}

PREDICTORS OF CHRONIC TOTAL OCCLUSION-PERCUTANEOUS CORONARY INTERVENTION SUCCESS

Various scores have been postulated regarding predictors of success of CTO-PCI based on lesion specific and patient profile (Table 1). The J-CTO score is a commonly used scoring model and was derived from a study on 479 CTO cases, to estimate the likelihood of successful guidewire crossing within 30 minutes based on five criteria (intralesion $>45^\circ$ bend, length ≥ 20 mm, calcification, blunt stump, and previously failed attempt).¹⁸ The PROGRESS-CTO (PROspective Global REgistry for the Study of Chronic Total Occlusion Intervention) score includes ambiguous proximal cap, left circumflex target artery, moderate/severe proximal tortuosity and lack of interventional collaterals giving equal score to each characteristics. The ORA score (ostial location, Rentrop filling of distal target vessel <2 and age ≥ 75 years) giving Rentrop filling score 2 and rest of the predictors 1 score.^{19,20} A weighted score (W-CTO) was developed by us for predicting success of antegrade wire crossing in CTO-PCI.²¹ The presence of blunt stump, length of occlusion,

TABLE 1: Various scoring system for predictors of CTO-PCI success

	J-CTO	PROGRESS-CTO	ORA	W-CTO
Stump morphology	Blunt stump (1)	Ambiguous cap (1)	–	Blunt stump (2)
Length of occlusion	≥20 (1)	–	–	≥20 (1.5)
Tortuosity	>45 (1)	Moderate to severe proximal tortuosity (1)	–	>45 (1)
Previous attempt	Yes (1)	–	–	–
Calcification	Mild to moderate (1)	–	–	Yes (1)
Ostial location	–	–	Yes (1)	–
Target vessel	–	Left circumflex artery (1)	Rentrop filling <2 (2)	Rentrop filling <2 (1)
Distal target vessel	–	Poor interventional collaterals (1)	–	–
Age	–	–	>75 years (1)	–
Total score	5	4	4	6.5

CTO, chronic total occlusion; PCI, percutaneous coronary intervention.

presence of calcification, presence of tortuosity and Rentrop filling <2 were given respective score of +2, +1.5, +1, +1, and +1 with total score of 6.5. Score values of 0–2, >2–4, and >4 were classified as low, intermediate and high levels of difficulty for CTO-PCI success and were associated with 98%, 74.2%, and 42.5% ($p < 0.0001$) success rate. The predictability of antegrade wire crossing success was demonstrated to be marginally better with the W-CTO score as compared to the J-CTO score [ROCAUC of 0.82 (J-CTO) versus 0.86 (W-CTO), $p = 0.009$]. These CTO score helps in assessing the success rate and should be applied by operators especially less experienced operators for selecting the case which to perform and which to refer to be performed by more experienced operator.

HYBRID ALGORITHM FOR CHRONIC TOTAL OCCLUSION-PERCUTANEOUS CORONARY INTERVENTION

There are three major techniques for crossing CTO lesion: (1) antegrade wire escalation, (2) antegrade dissection re-entry, and (3) retrograde approach. According to the angiographic characteristics of occlusion the type of approach can be selected (Flowchart 1).

CHRONIC TOTAL OCCLUSION-PERCUTANEOUS CORONARY INTERVENTION TECHNIQUES

Antegrade Wiring

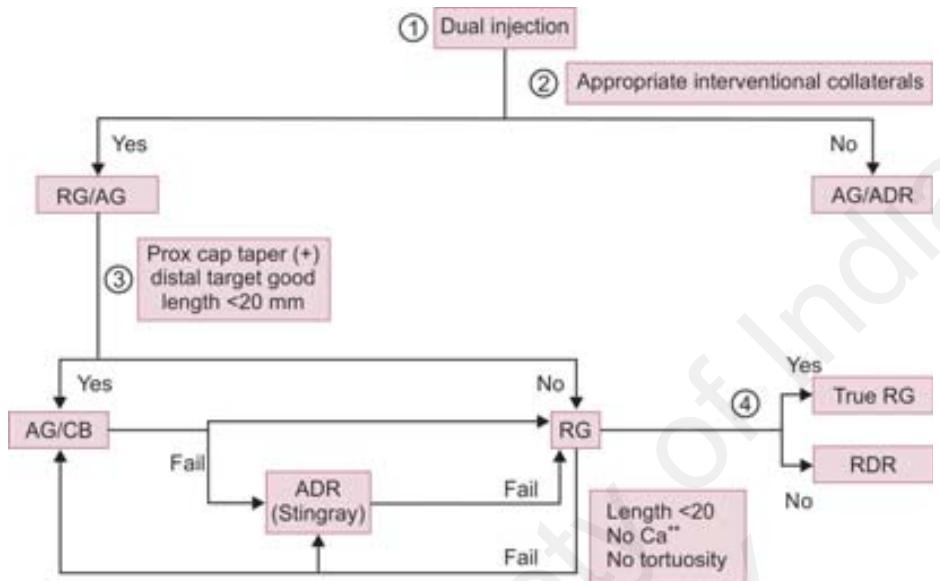

Antegrade approach using a single wire escalation technique and/or parallel wire technique is attempted before changing to a more complex antegrade dissection re-entry approach. For an antegrade procedure intimal plaque tracking is crucial as success rates decrease substantially once the wire enters the subintimal space. Intimal plaque tracking can either be achieved by loose tissue tracking or by intentional intimal plaque tracking. The concept of loose tissue tracking

is based on the histopathological finding that angiographic determined occlusions frequently show residual lumen patency with microchannels and loose connective tissue around them.^{22,23} It is therefore recommend starting the wiring procedure with a soft tapered tip wire like Fielder XT/XTR and changing to an intermediate-stiffness guidewire like Fielder XTA or Gia 1 or Gia 2 depending upon the tactile feedback of the resistance being witnessed in the tissue and the penetrating power of the wire. A tapered tip wire is more likely to enter loose connective tissue and once entered an intermediate wire will automatically track the tissue with low resistance rather than penetrating into the hard atherosclerotic plaque. This concept is supported by the PIKACHU trial (Prospective Multicenter Registry of IKAzuchi-X for Chronic Total Occlusion) where approximately 70% of CTOs could be crossed with an intermediate-stiffness 0.010 inch hydrocoated wire.²⁵ In the parallel wire method, a wire which enters the subintimal space is left there, and a second wire is inserted alongside to find a new channel. When this technique is successful, the following findings are often noted: (1) the second wire crosses over the first inside the CTO; (2) the second wire shows more acute curve than the first wire; (3) the second wire penetrates the lesion from the outer curvature of the coronary artery and then is advanced along the same curvature of the vessel. Indeed, the second wire should be operated intentionally to achieve these findings so that the probability of success increases and the duration of the procedure is shortened. A crusade catheter could be used to bring in the second wire.

The “CrossBoss and Stingray Re-Entry System” (Boston Scientific, Natick, MA, USA) has recently been developed to antegrade dissection re-entry technique.^{26,27}

Retrograde Approach

The retrograde approach requires more operator expertise and has high risk for periprocedural complications like cardiac tamponade due to collateral perforation, donor vessel ischemia, ostial dissection. Choosing the interventional

FLOWCHART 1: Hybrid algorithm: an approach to chronic total occlusion-percutaneous coronary intervention (CTO-PCI).

collateral is the first key step. Unfortunately such channels are usually of small caliber (100–200 µm) and often present a tortuous course making them fairly vulnerable. As injury to an epicardial channel can easily cause cardiac tamponade and therefore selection of a septal channel is preferred septal collaterals.²⁸

“Wire Crossed Balloon Not Crossed”—What Next?

Balloon uncrossable CTOs are rarely found that cannot be crossed with a balloon after successful guidewire crossing. This is often observed in chronic calcific CTOs. These lesions are usually approached with a combination of lesion modification techniques (such as use of microcatheters and multiple balloons) and improving guide support, use of anchoring techniques and use of guide catheter extensions. Other techniques described to cross the balloons in such cases. This includes advancing a microcatheter or Tornus antegradely which creates a small channel over which a small size (1.2 mm × 6 mm) balloon could then advance. If this fails one could use other techniques like the anchor balloon technique or a guideliner as described by others. One could also experience in these chronic lesions at times a situation that balloon has crossed but fails to inflate because of calcium or otherwise. In this situation one may need plaque modification using score balloon, cutting balloon or rotablator.^{29–32}

COMPLICATIONS OF CHRONIC TOTAL OCCLUSION-PERCUTANEOUS CORONARY INTERVENTION

We need to be well aware that CTO-PCI are complex procedures and are not free from complications. Pooled analysis of complications include death 0.2%, emergent CABG surgery

0.1%, stroke less than 0.01%, MI 2.5%, Q-wave MI 0.2%, coronary perforation 2.9%, tamponade 0.3%, and contrast nephropathy 3.8% in a series by Patel et al. compared with successful procedures, unsuccessful procedures had higher rates of death (0.42% vs. 1.54%; p <0.001), perforation (3.65% vs. 10.70%; p <0.001), and tamponade (0% vs. 1.65%; p <0.001).²⁴

When Not to do Chronic Total Occlusion?

Although techniques have improved with great success and impervious safety, we would still advocate to avoid CTO interventions in a few select settings as follows: (1) if two or more major vessels have a CTO; (2) CTOs are present in sequence in same vessel; (3) a small vessel with CTO is not worth the effort; (4) a very long CTO with heavy calcification; (5) very tortuous CTO anatomy with heavy calcification of vessel; (6) a CTO from ostium of artery; and (7) CTOs distal to complex proximal vessel lesions, e.g., CTO of LAD beyond a severe/moderate LM bifurcation stenosis or CTO of CX/OM beyond an ostial CX calcific stenosis. Retrograde approach to do CTO-PCI should not be used if donor artery is heavily calcified or with mild or moderate long segment disease which otherwise would not need anything to be done or would risk donor artery closure.

CONCLUSION

With improvement in techniques and hardware the success of CTO-PCI has significantly increased. Appropriate selection of case and CTO technique can make it a safe procedure. PCI for CTO is an approachable goal with good skills and an experienced operator, a good understanding of the disease, availability of required hardware and wisdom of when to do and when not to do or when to stop.

Hybrid Coronary Revascularization

C Raghu

INTRODUCTION

Over the past six decades the gold standard for myocardial revascularization has been coronary artery bypass grafting (CABG). Balloon angioplasty was first performed in 1977 as an alternative to bypass,¹ and has evolved to implantation of stents into the coronary arteries, known as percutaneous coronary intervention (PCI). Revascularization by CABG and PCI is different approaches each with its own strengths and weaknesses. Of late, attempts are being made to combine these two approaches together to maximize patient outcomes and recovery.

BENEFITS OF CORONARY ARTERY BYPASS GRAFTING OVER PERCUTANEOUS CORONARY INTERVENTION

As per latest guidelines, CABG is proven to be superior to medical therapy for the treatment of advanced coronary artery disease (CAD).² Major reason for the success of CABG is revascularization of the left anterior descending artery (LAD), which supplies a majority of the myocardium performed by anastomosing the left internal mammary artery (LIMA) to the LAD. Freedom from atherosclerosis contributes the long-term patency rates of LIMA to LAD up to 95% at 10 years.³ These results could be replicated both with open and minimally invasive approaches to CABG.⁴ Repeat revascularization were more common after PCI of the LAD compared to CABG.

In the past two decades many studies comparing CABG to PCI showed that major adverse cardiac or cerebrovascular events (MACCE) were more common in the PCI group.^{5,6} Despite large prospective trials and many observational studies supporting the benefits of CABG over PCI, in practice PCI is performed much more frequently.

WHY PERCUTANEOUS CORONARY INTERVENTION IS PREFERRED IN PRACTICE?

Percutaneous coronary intervention is preferred over CABG because of the minimally invasive nature of the approach. Patients are typically return back home within 48 hours after PCI, especially after elective cases, and periprocedure complications are often lower. Neurological complications such as stroke and neurocognitive dysfunction are lower with PCI compared to CABG.^{5,6} CABG needs sternotomy so there is risk of deep sternal wound infection. In addition, CABG has higher rates of blood transfusion, atrial fibrillation, and overall morbidity and short-term mortality.

Mid-term and long-term rates of MACCE following PCI are higher than CABG, which is attributable to higher rates of repeat interventions. Even though repeat interventions are an important outcome measure, they are not viewed as seriously as CABG related morbidity. 5-year mortality rates are not different between PCI and CABG in both the SYNTAX (Synergy between PCI with Taxus and Cardiac Surgery)⁷ and BEST (randomized Comparison of Coronary Artery Bypass Surgery and Everolimus-Eluting Stent Implantation in the Treatment of Patients with Multivessel Coronary Artery Disease trial).⁶ Current generation drug-eluting stents (DESs) have improved rates of stent thrombosis and mortality over bare-metal stents (BMS) and early DES.⁸ Owing to these advantages, lesions that were previously treated only with CABG are now being approached by PCI. For example, patients with unprotected left main disease have historically been referred for CABG, but recent trials have shown similar MACCE rates with PCI.⁹

Beyond stents numerous other advances such as radial access decreasing major bleeding,¹⁰ optical coherence tomography, and intravascular ultrasound have improved

outcomes in chronic total occlusions PCI¹¹ and fractional flow reserve (FFR) betters the necessity for PCI.¹²

IN CORONARY ARTERY BYPASS GRAFTING, WHICH IS THE PREFERRED SURGICAL CONDUIT?

Saphenous vein grafts (SVGs) are routinely used as additional conduits for vessels other than LAD. Compared to LIMA, SVGs are associated with inferior longevity.¹³ Alternately, use of multiple arterial grafts is shown to be superior to SVGs. Common arterial conduits include the right internal mammary or radial arteries. Despite lack of strong evidence, current Society of Thoracic Surgeons guidelines recommend considering the use of multiple arterial grafts when possible.¹⁴ But in practice, only about 7% of CABG operations are performed with more than one arterial graft.¹⁴

WHICH IS BETTER ON-PUMP VERSUS OFF-PUMP SURGERY?

Off-pump coronary artery bypass (OPCAB) was originally developed in the 1970s to decrease the risks of CABG associated with cardiopulmonary bypass (CPB), including stroke, inflammation, blood usage, kidney injury, etc. Currently the initial enthusiasm seen with OPCAB during 1990–2000s has slightly decreased. Evidence in the form of ROOBY (Randomized On/Off Bypass) and GOPCABE (German Off-Pump CABG Trial in Elderly Patients) trials contributed to this. ROOBY trial showed higher MACCE at 1 year, lower graft patency, and lower rates of complete revascularization with OPCAB.¹⁵ The GOPCABE trial studied a higher-risk group than ROOBY and did not find any superiority of OPCAB.

MINIMALLY INVASIVE DIRECT CORONARY ARTERY BYPASS SURGERY

Minimally invasive direct coronary artery bypass (MIDCAB) is a technique designed to reduce the invasiveness of CABG by avoiding a median sternotomy. MIDCAB, introduced in 1995, is commonly performed via an inframammary left anterior thoracotomy in the fourth or fifth interspace. Comparing MIDCAB and OPCAB, there was no difference in graft patency¹⁶ but with additional advantages of quicker recovery, decreased ventilator times, and hospital length of stay. Limitation with the MIDCAB approach is the significant learning curve and related technical difficulty of the procedure.

ROBOTIC-ASSISTED CORONARY ARTERY BYPASS GRAFTING

A novel approach to surgery using robots was approved for use in 2000 (Intuitive Surgical, Sunnyvale, CA, USA). Surgeons sit at a console rather than standing at the bedside, controlling robotic arms that are performing surgery. Robotic

surgery is a shot in the arm for minimally invasive surgery. Instead of long instruments that can only be manipulated outside the body in endoscopic surgery, robotic instruments maintain full range of motion inside the body cavity. This allows unprecedented operative precision. The use of a three-dimensional high-definition camera greatly improves visualization of the operative field creating a clarity that was never seen in endoscopic surgery.

With the robotic arm, superior degrees of freedom to operate and improved visualization, the LIMA can be dissected from the chest wall using the robotic console. Using a robotic approach sternotomy can easily be avoided along with its attendant sternal wound infection, prolonged recovery, and poor cosmesis.

ENDOSCOPIC BYPASS GRAFTING

Total endoscopic coronary artery bypass grafting (TECAB) is the extension of utilizing robotics into coronary anastomosis. Some centers have used this exclusively with the LIMA-to-LAD, while others have demonstrated the feasibility of complete revascularization with TECAB. While TECAB is commonly performed off-pump, CPB may be used in cases where the patient's hemodynamics does not tolerate positioning.

The major advantage of robotic-assisted CABG and TECAB are shorter hospital stays and quicker return to work compared to single-vessel OPCAB. Long-term MACCE rates have been reported with this approach. During the learning curve with TECAB conversion to sternotomy and longer operating hours are common, especially if multiple grafting is needed. The rate of these challenges seems to decline with experience.

HYBRID CORONARY REVASCULARIZATION

From the discussion above, one can easily understand that multiple strategies exist for performing myocardial revascularization. The spectrum of approaches ranging from PCI to ONCAB represents escalating degrees of invasiveness. Patients perceive that PCI is quick and easy while CABG is a painful operation after which patients spend a considerable time in intensive care and require prolonged recovery. At the same time, they may be unwilling to trade an early short-term risk or death, stroke, or infection for a potentially long-term, prolonged, and better quality of life.

To assuage patients' fears about open surgery, various minimally invasive techniques have been developed including OPCAB, MIDCAB, and robotic approaches. The major limitation with these novel approaches is many centers have not adopted them. This is due in part due to the potentially steep learning curves and during this learning curve even in the best hands; outcomes and graft occlusion rates may not be as good as traditional open surgery. LIMA-to-LAD anastomosis is most easily performed with minimally invasive techniques since the LAD courses on the anterior

BOX 1 Goals of hybrid revascularization

- Achieve similar or better postoperative morbidity and mortality than open CABG
- Maintain equivalent patency of LIMA-to-LAD to open techniques
- Improve recovery from surgery (length of stay, return to work and activity)
- Improve rates of repeat interventions and long-term outcomes over PCI
- Achieve excellent patient satisfaction
- Ensure cost effectiveness in the short and long term

surface of the heart and can be readily accessed through minimally invasive incisions.

Hybrid coronary revascularization (HCR) has been developed to address these various issues. HCR in principle is to perform the LIMA-to-LAD anastomosis using a minimally invasive surgical technique and revascularize the rest of the coronary lesions with PCI.¹⁷ This represents a “best of both worlds” approach.

Goals of HCR are summarized in box 1.

Hybrid coronary revascularization first reported in 1996,¹⁸ till date has more than 3,000 cases reported in the literature.¹⁹ But HCR is currently applicable to a minority of patients with CAD. In a multicenter observational study, 12% of patients presenting with significant CAD were found eligible for HCR by both a surgeon and cardiologist.²⁰ MIDCAB, robotic-assisted CABG, and TECAB are all used frequently as the surgical approach. PCI and CABG can be performed in the same operative setting, but more commonly the procedures are performed separately (often several days apart). The optimal timing for HCR has not yet been studied. Theoretical strengths and weaknesses of each approach are summarized in table 1. The preferred timing of HCR is best tailored to the individual patient and center.

HYBRID OUTCOMES

With improved technical expertise and technological advances results with PCI continue to get better, in the form of reduced rates of reintervention. With LIMA-to-LAD using minimally invasive surgical approaches recent series demonstrated excellent rates of LIMA patency (96–100%). There were few conversions to sternotomy, length of stay was low, and mid- and long-term rates of MACCE were not concerning. These data support the safety and efficacy of minimally invasive coronary revascularization (one of the main goals of HCR).

A number of large series of HCR have recently been performed, summarized in table 2. Postoperative survival (99–100%) and LIMA patency rates (95–100%) were excellent. Conversions to sternotomy were uncommon, consistent across different minimally invasive strategies. Reinterventions when required, were most commonly for

TABLE 2: Recent series of HCR

Year	Surgical technique	n	Survival (%)	LIMA patency (%)	Survival	LOS days	CTS (%)
2011 ²¹	Mid CAB	104	100	100	1 (18 months)	8.2	1
2013 ²²	Mid CAB	166	98.8	100	17 (5 years)	6.5	2.4
2014 ²³	Robotic	96	100	94	21 (5 years)	4	2.1
2014 ²⁴	TECAB	180	100	NR	20 (5 years)	6	2.2
2014 ²⁵	Mid CAB	98	100	99	10.2 (1 year)	8.8	6
2014 ²⁶	Robotic	300	98.7	97.6	NR	5	2
2015 ²⁷	Mid CAB	100	100	95	20 (1 year)	8	0

CAB, coronary artery bypass; CTS, conversion to sternotomy; HCR, hybrid coronary revascularization; LIMA, left internal mammary artery; LOS, length of stay; MACCE, major adverse cardiac or cerebrovascular events; n, no. of patients; TECAB, total endoscopic coronary artery bypass grafting.

previous PCI targets or coronaries not previously intervened on; there did not appear to be any significant issues with the LIMA-to-LAD anastomosis at the intermediate term (up to 5 years).

CONCLUSION

Compared to traditional open CABG, minimally invasive techniques to CABG provide an excellent alternative in carefully selected patients. Over the past two decades, the MIDCAB technique has been well established, with many groups showing excellent results. Another exciting novel vista robotic surgery showed excellent results. A substantial learning curve to all these minimally invasive techniques limits their acceptance across many centers. Results from both MIDCAB and robotic approaches, especially patency of the LIMA-to-LAD anastomosis, are excellent and appear to be equivalent to one performed via a sternotomy.

Hybrid coronary revascularization takes advantage of the excellent durability of the LIMA-to-LAD anastomosis and combines with latest PCI technologies to provide an excellent alternative to open CABG. The key for the success in developing HCR at a center is a dedicated surgeon and interventional cardiologist. HCR by nature is multidisciplinary and a heart team approach for patients with coronary disease is essential; this will ensure ideal patient selection and optimize results. HCR has developed to combine the superior results obtained with both approaches. Though in near future practice of HCR may not radically change the way how CABG is performed. But as surgeons acquire the necessary skill set with minimally invasive CABG techniques, HCR is a therapy for niche centers.

Should all Percutaneous Coronary Interventions be Radial Only?

Tejas Patel, Surender Deora, Sanjay Shah

BACKGROUND

Before reaching the final phase of optimization, any new technique or technology goes through various phases of observations. The overall experience, supported by data demonstrates the exceptional quality of a particular technology or technique, which eventually leads to natural devolution and extinction of an outmoded method. Cardiac catheterization and coronary angiography are glaring examples. In a span of less than a decade the Mason Sones' brachial artery cut-down is long gone, having given way to Judkin's transfemoral approach (TFA). Kiemeneij demonstrated the safety of percutaneous coronary interventions (PCI) through the transradial approach (TRA), without major bleeding risks engendered by TFA in heavily anticoagulated patients. The evolving data supporting TRA over TFA has generated strong opinions amongst interventional cardiologists aligned with one technique over the other.¹ Which technique is quicker, safer, cost-effective, more comfortable, and easily reproducible? It took about two decades for the interventional cardiologists to be convinced regarding the overall superiority of TRA over TFA.⁴⁻¹⁵

Transradial approach was largely guided by case reports, case series and small randomized studies, during the first decade of its inception.⁴⁻⁶ Subsequently, many studies examined the different technical aspects, outcomes, advantages and disadvantages of TRA.⁴⁻¹⁵ Over 1,500 positive papers have been published on transradial interventions (TRI), forming a robust evidence base to drive its practice. In spite of being a globally accepted technique, the recognition of TRA in some parts seems to be slower as compared to many other parts of the world.^{2,3} Young cardiologists are particularly more enthusiastic to adopt TRA. However, many senior interventional cardiologists who have practiced TFA for several decades are not very keen for change. The major cause of their reluctance is an occasional negative experience with a complex PCI in a patient on whom they are forced to use TRA. It is important to understand that there is a definite "new learning curve" for TRA, even for the

most experienced interventional cardiologist.⁴⁻⁶ During this phase, the operator has to deal with some cases of failure and change-overs, lengthier procedural time and higher radiation exposure, which induces negative feelings for TRA. However, once the learning curve is over the operator will have the confidence to overcome all of the aforementioned barriers. Exponential growth in the number of interventional cardiologists has led to a reduction of individual procedural volume creating a challenge for a new cardiologist to overcome the learning curve. A practical solution for this problem is to work in groups of two, three or four preferably having one reasonably experienced radial operator available. Regardless of the superiority of the TRA, the transformation of a femoral operator into an accomplished radial operator will not be possible without an organized and concerted effort. The perpetuation of a femoral operator's prior negative experience becomes his "Achilles heel" and prevents him from being able to accept a slightly more complex technique despite its superior safety record. Nonetheless, the operator can overcome most of the technical problems related to TRI with increasing experience and persistence, much like that required to conquer the occasional problems encountered in TFA. In order to achieve overall acceptability of any procedure, it is important to engender confidence of a high success rate even for low volume operators and beginners. In order to demonstrate the clinical advantage of TRA over TFA, dedicated radial operators took almost two decades to complete clinical trials due to the lack of industry resources and general ignorance of many interventional cardiologists.

Primary Percutaneous Coronary Interventions and Transradial Approach

Patients presenting with ST-elevation myocardial infarction (STEMI) not only benefit from the utilization of aggressive anticoagulant and antiplatelet therapy, but also demonstrate higher rates of bleeding complications compared to low-risk patients. TRA is therefore an effective approach for primary PCI.⁷⁻¹⁵ The large multicenter studies have demonstrated

reduction in bleeding and improvement in patient outcomes using TRA.⁷⁻¹⁰ Although most studies report no delay in door-to-balloon times with TRA versus TFA, some do report delay up to 11 minutes. In the absence of data from large randomized studies, the clinical impact of any small delay in reperfusion should not be measured against the benefit of decrease in bleeding. It is recommended that primary PCI via TRA be attempted only once the operator is fully facile with complex PCI using this technique, because delays appear to be more common with less experienced radial operators. Simultaneous preparation of groin is generally recommended for primary PCI procedures planned through TRA, so that delay can be minimized if cross-over becomes necessary and the groin is ready to receive large caliber hemodynamic support system (i.e., intra-aortic balloon pump or Impella device), should they become necessary.^{4,5} Although, it is not a routine practice, we recommend that beginners inject contrast through the puncture cannula to define the vascular anatomy before introducing the radial sheath. If anatomy is unfavorable, immediate switch-over to TFA will save important initial time. As experience increases, the number of cross-over reduces remarkably. It is important to avoid working through extreme subclavian tortuositys and arteria lusoria during the initial phase of the TRI program.⁴⁻⁶

Chronic Total Occlusions and Transradial Approach

Chronic total occlusions (CTOs) intervention is a difficult and challenging procedure. The success rate has increased from 60% to almost 90% amongst accomplished operators. While TFA is traditionally preferred, in last decade a good number of studies have shown feasibility, efficacy and equivalent success rates using TRA.^{4-6,17} Although, an experienced radial operator should be able to treat almost any CTO, a beginner should avoid long segment CTOs with flat stumps and presence of intra-arterial collaterals.

Left Main Coronary Artery Lesions and Transradial Approach

In last several years several trials have documented the feasibility, safety and results of left main coronary artery (LMCA) stenting.^{6-8,33,34} Although most studies have been performed through TFA, a few have demonstrated success of TRA for LMCA stenting.^{4-6,16} Right atrium (RA) having diameter more than 2 mm can accommodate a 7 F introducer sheath. If a 7 F guide catheter is necessary and RA diameter is small, sheathless guide system, modified sheathless guide catheter (Combo) technique, slender technique or balloon-assisted tracking (BAT) technique can help successful passage of a 7 F guide catheter.⁴⁻⁶

Transradial Approach—Impact on Bleeding Incidence and Outcomes

Periprocedural bleeding remains an important complication of PCI.⁴⁻¹⁵ Many studies have demonstrated that the most common site of bleeding in patients of PCI is related to the vascular access site and that bleeding is associated with

worse short- and long-term outcomes.³⁻¹⁵ TRA has not only shown reduction in bleeding and improvement in clinical outcomes, but also mortality benefit.⁴⁻¹⁵ Rao et al., retrospectively analyzed data from 593,094 procedures in the National Cardiovascular Data Registry (606 sites; 2004 to 2007).¹² They evaluated trends in use and outcomes of TRA for PCI. TRA was associated with a procedural success rate similar to TFA, and with significantly lower rates of bleeding and vascular complications, even amongst high-risk groups including elderly patients, women, and patients with acute coronary syndrome (ACS). In the (Mortality benefit of Reduced Transfusion after PCI via the Arm or Leg) MORTAL study reported on reductions in mortality, likely mediated through reduced transfusions after PCIs performed through TRA when compared with TFA.¹¹ This study evaluated 38,872 PCI procedures in 32,822 patients in British Columbia and Canada. TFA was used in 79.5% of PCIs and TRA in 20.5%. In the TFA group, 2.8% of procedures were associated with the need for periprocedural transfusions, while in the TRA group and only 1.4% of the procedures required a transfusion. Thus, the transfusion rate was associated with a significant reduction in mortality at 1 month and 1 year. The death rates at 1 month of the transfused group versus the non-transfused group were 12.6% and 1.3%, respectively. At the end of 1 year, the death rates were 22.9% and 3.2%. In Radial verus Femoral access for coronary intervention (RIVAL) study,¹⁷ out of 7,021 patients with ACS from 158 hospitals in 32 countries, 3,507 patients were randomly assigned in TRA group and 3,514 to TFA group.⁷ Although, the study concluded that both TRA and TFA are safe and effective for PCI, the local vascular complication rate was significantly lower in TRA group ($n = 42$ for TRA group versus $n = 106$ for TFA group, $p < 0.001$). Investigators also observed statistically significant (40%) relative reduction in the risk of death, myocardial infarction (MI), stroke or non-coronary artery bypass graft (CABG)-related major bleeding and a significant (61%) relative reduction in the risk of death among STEMI patients treated via radial route. They also showed a significant reduction in the risk of the primary outcome (51%) amongst PCI centers that performed the highest volume of radial procedures. RIFLE-STEACS (Radial versus Femoral Randomized Investigation in ST-segment Elevation Acute Coronary Syndrome) was a prospective randomized parallel group multicenter study for evaluation of TRA versus TFA for primary PCI.⁸ A total of 1,001 patients were randomized between these two groups. The investigators found that at 1 month, the rate of net adverse clinical events (NACE) was significantly lower in the radial group versus the femoral group (13.6% vs. 21%). This difference was determined by a reduction of both the major adverse cardiac and cerebrovascular events (7.2% vs. 11.4%) and of bleeding (7.8% vs. 12.2%). In particular, the rate of cardiac death at 1 month was 9.2% in the femoral group and 5.2% in the radial group.

Radiation Exposure and Transradial Approach

Increased operator radiation exposure with TRA has been a concern. This results primarily from a more proximity to the

radiation source.^{4,5} Medial positioning of the arm following access and attention to radiation shielding helps to mitigate this concern. Radiation exposure decreases as the operator experience increases. Absolute increase in fluoroscopy time and dose area product (DAP) with TRA compared to TFA is small, likely representing minimal risk to the patient (0.002% increase in lifetime cancer risk), and must be balanced against the significant benefits of decreased access site complications and bleeding.^{4,5} The REVERE (Randomized Evaluation of Vascular Entry Site and Radiation Exposure) study randomized patients to TFA, right TRA and left TRA in 1:1:1 fashion, and has shown patient's exposure being similar for all groups.¹⁸ Similarly, the FERARI study showed that the mean fluoroscopy time, median DAP, procedural duration and the amount of contrast agent used were not significantly different in TRA versus TFA groups.¹⁹

Transradial Approach: Quality of Life and Economic Benefits

Early ambulation provides potential cost reduction through various avenues, including expedited room turnover or increased throughput (both through cath lab and recovery unit); reduced intensity of care required by nursing and support staff; shorter length of stay; enhanced ability to perform same day PCI; and a more rapid return to productivity for working patients.^{4-6,20-22} Large groin hematoma and retroperitoneal hematoma can lead to need for several additional investigations, (i.e., femoral vascular ultrasound, computed tomography (CT) of abdomen or pelvis and lab investigations), blood transfusions and longer hospital stay.⁴⁻⁶ This additional cost of treating the complications and prolonged hospital stay can be reduced using TRA. Cooper et al., compared quality of life parameters of patients undergoing TFA and TRA.²⁰ Of patients, who have had both TFA and TRA, 80% had strong preference for TRA, 18% were undecided and only 2% had strong preference for TFA. Amoroso et al., quantified the workload for both cath lab and recovery area nurses following 260 consecutive TRI (n = 208) and transfemoral intervention (TFI) (n = 52) procedures. The workload was significantly reduced for TRI procedures (TRI = 86 min vs. TFI = 174 min, p <0.001) and for TRI recovery time (TRI = 386 min vs. TFI = 720 min).²¹ The workload and time savings were related to less time spent for sheath removal, early patient mobility, shorter recovery time and shorter time to ambulation. It is also rational to expect that those patients experiencing access site complications, significantly more frequent with TFA, would be delayed in returning to work by an extended recovery. Although early ambulation is possible with use of femoral vascular closure devices, there is no reduction in bleeding and vascular complication rates and approximately 5 times the closure cost of a radial hemostasis device.⁴⁻⁶ So, improved quality of life for the patients, relatively shorter and relaxed periprocedural care for the nursing and supportive staff and significant cost savings for the hospital management are good reasons to use TRA.

CONCLUSION

In a nutshell, everyday practice is now driven by "evidence-based medicine" instead of "personal experience" or "anecdotal" medicine. International guidelines are regularly published and periodically updated to provide busy professionals guidance on how their practice should evolve over the time. As the superiority of TRA over TFA is well documented, it is high time to change the mindset.

Contemporary Coronary Stents: Implications for My Practice

Neha Maddali, Kevin Marzo, Ramesh Daggubati

INTRODUCTION

Since Andreas Gruentzig's invention of the first balloon angioplasty in 1977,¹ percutaneous coronary intervention (PCI) has become one of the most commonly performed therapeutic procedures in the United States and around the world.² Preliminary attempts to utilize balloon angioplasty were restricted by the occurrence of restenosis in approximately 30–50% of patients² and enormously high rates of sudden vessel closure, dissection, and arterial recoil. These limitations prompted the innovation of the bare-metal stent (BMS) in the mid 1980s as a framework for vessels with the objective of maintaining luminal integrity.² In 1986, Ulrich Sigwart, and Jacques Puel initiated the second revolution in interventional cardiology with the first implantation of a self-expanding Wallstent in human coronary arteries (Fig. 1).³ Julio Palmaz and Richard Schatz manufactured the widely used Food and Drug Administration (FDA) approved stent in the USA in 1994 (Fig. 2). The Palmaz-Schatz (Johnson and Johnson) is a balloon expandable slotted tube stent design that was well studied and most used in 1990s.⁴ Around the same time, Cesare Gianturco and Gary Roubin developed a balloon expandable coil stent with wrapped stainless steel

which was FDA approved in 1993 for acute vessel closure as a bail out therapy (Fig. 3).²

However, since its creation and first implantation, although BMS has been shown to reduce clinical and angiographic restenosis by 20–30%,⁵ vessel response to stent-mediated injury and endothelial cell denudation induces neointimal hyperplasia.^{6,7} This proliferation and migration of vascular muscle cells ultimately results in vessel shrinkage,

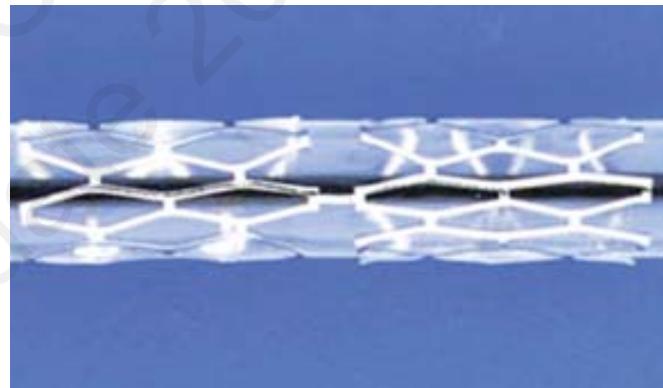

FIG. 2: The Palmaz-Schatz stent.

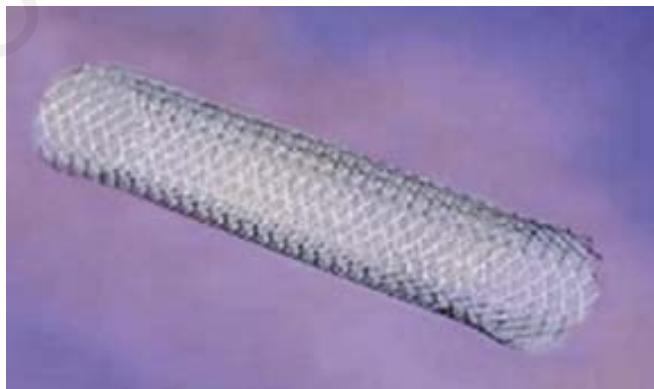

FIG. 1: The Wallstent, this was the first self-expanding stent ever used in humans.

FIG. 3: The Gianturco-Roubin stent.

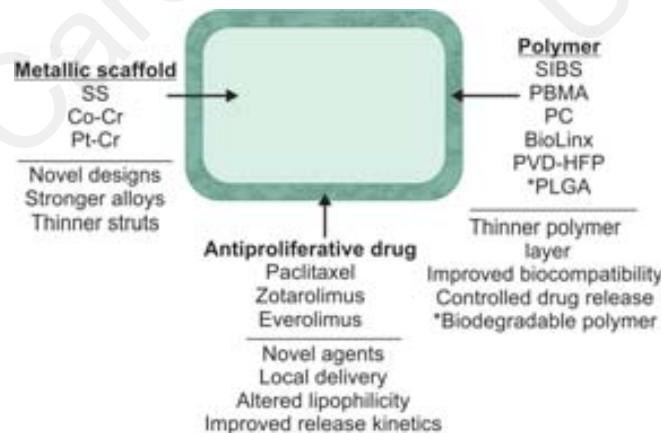

decreased arterial lumen space, and a necessity for revascularization.²

Hence, the first generation drug-eluting stent (DES) was designed to minimize the prospect of in-stent restenosis (ISR). The DES consists of a BMS structure coated in a polymer and controlled release antiproliferative drugs. The drugs, i.e., paclitaxel and zotarolimus, disrupt the central molecular processes linked to ISR.

In comparison to BMSs, first-generation and improved second-generation DESs demonstrate the declining need for revascularization. This usage parallels itself in clinical medicine, in 2006, approximately 76% of all stents inserted in patients were DESs,⁸ and in the United States, DESs are now implanted in over 500,000 patients annually.⁹ Yet although practitioners are cognizant of its potential benefits in treating coronary disease, the New England Journal of Medicine issued evidence of an increased risk in stent thrombosis (ST), in addition to comparable risks of myocardial infarction (MI) and death to BMSs, after insertion of DESs releasing sirolimus and paclitaxel. This report, along with other papers displayed at the European Society of Cardiology Congress in 2006, questioned the stent's clinical efficacy and long-term safety.¹⁰ Since the report's publication, substantial improvements have been made to DES technology to increase public safety; these new developments, particularly ultra-thin DESs, promote its revitalization in the clinical field. The ultra-thin DESs have thinner struts and new biocompatible polymers with the objective of diminishing vascular damage. This chapter focuses on the improved design, safety, and efficiency of the next generation ultra-thin DES and bioresorbable stent systems against first generation DESs and its implications for prospective clinical practice.

DESIGN

The stent platform is comprised of three significant components: (1) metallic stent, (2) antiproliferative drug, and (3) polymer coating for steady drug release (Fig. 4).⁵ There are three basic stent designs which are coil, tubular mesh, and slotted tube stents.

PBMA, poly(*n*-butyl methacrylate); PC, phosphorylcholine; PLGA, poly(lactic-co-glycolic acid); PVD-HFP, poly(vinylidene fluoride-co-hexafluoropropylene); SIBS, poly(styrene-*b*-isobutylene-*b*-styrene; Co-Cr, cobalt-chromium; Pt-Cr, platinum-chromium.

FIG. 4: Cross-section of drug-eluting stent platform.

Metallic Stent Scaffold

Drug-eluting stent metallic platforms must possess a low-crimped profile and elevated flexibility to withstand transportation from the femoral or radial arteries to throughout the vigorous cardiovascular system. Furthermore, the platform should retain high radial strength to maintain a constant vessel diameter and homogeneously distribute the drug throughout the stent to the surrounding vessel. To ensure these prerequisites, scholars utilized biologically inert metals with high radial strength. First-generation DESs were primarily composed of stainless steel and had a large stent strut thickness of 135 µm.¹¹ However, due to incipient parallels between strut thickness and ISR rates, metallic alloys such as cobalt-chromium and platinum-chromium have antiquated steel stents. These alloys contribute to the slenderness of second generation DESs, while maintaining corrosion resistance and simultaneously increasing yield strength, radiopacity, and flexibility. In addition to material substance, geometric configuration is vital to determining stent thickness. Scaffolds with fewer hoop connectors sanction vessel conformability and increased elasticity, reducing the risk of restenosis, arterial injury, and thrombogenicity after implantation.² Table 1 portrays FDA approved DES and their relative metals and thicknesses.^{2,5}

Antiproliferative Drug

A drug-eluting stent implantation can often induce mechanical injury to the proximate vessel. This injury activates an automatic healing reaction: platelet stimulation, thrombus formation, and monocyte and neutrophil collection all occur at the implantation site.⁷ As smooth muscle cells activate, proliferate, and migrate to the stent, the responses eventually lead to neointimal hyperplasia and ISR. Thus, to combat neointimal growth but maintain vascular healing, antiproliferative or antirestenosis drugs are embedded within the stent polymer to reduce restenosis and ISR rates. The main antiproliferative drugs in clinical use include paclitaxel, sirolimus, zotarolimus, everolimus, and ridaforolimus.⁵ Paclitaxel and sirolimus were particularly utilized in first-generation DESs. Paclitaxel stabilizes microtubules and averts smooth muscle cell proliferation by halting the cell cycle in the G0-G1 and G2-M phase. Sirolimus binds to the cytosolic FK binding protein 12 (FKBP12) to interrupt and suspend the cell cycle in the G1-S phase.⁷ This disrupts the cytostatic proliferation of vascular smooth muscle cells.¹² Both zotarolimus, the first treatment created for ISR, and everolimus, which are used in second generation DESs, are analogs of sirolimus.

Polymer Coating

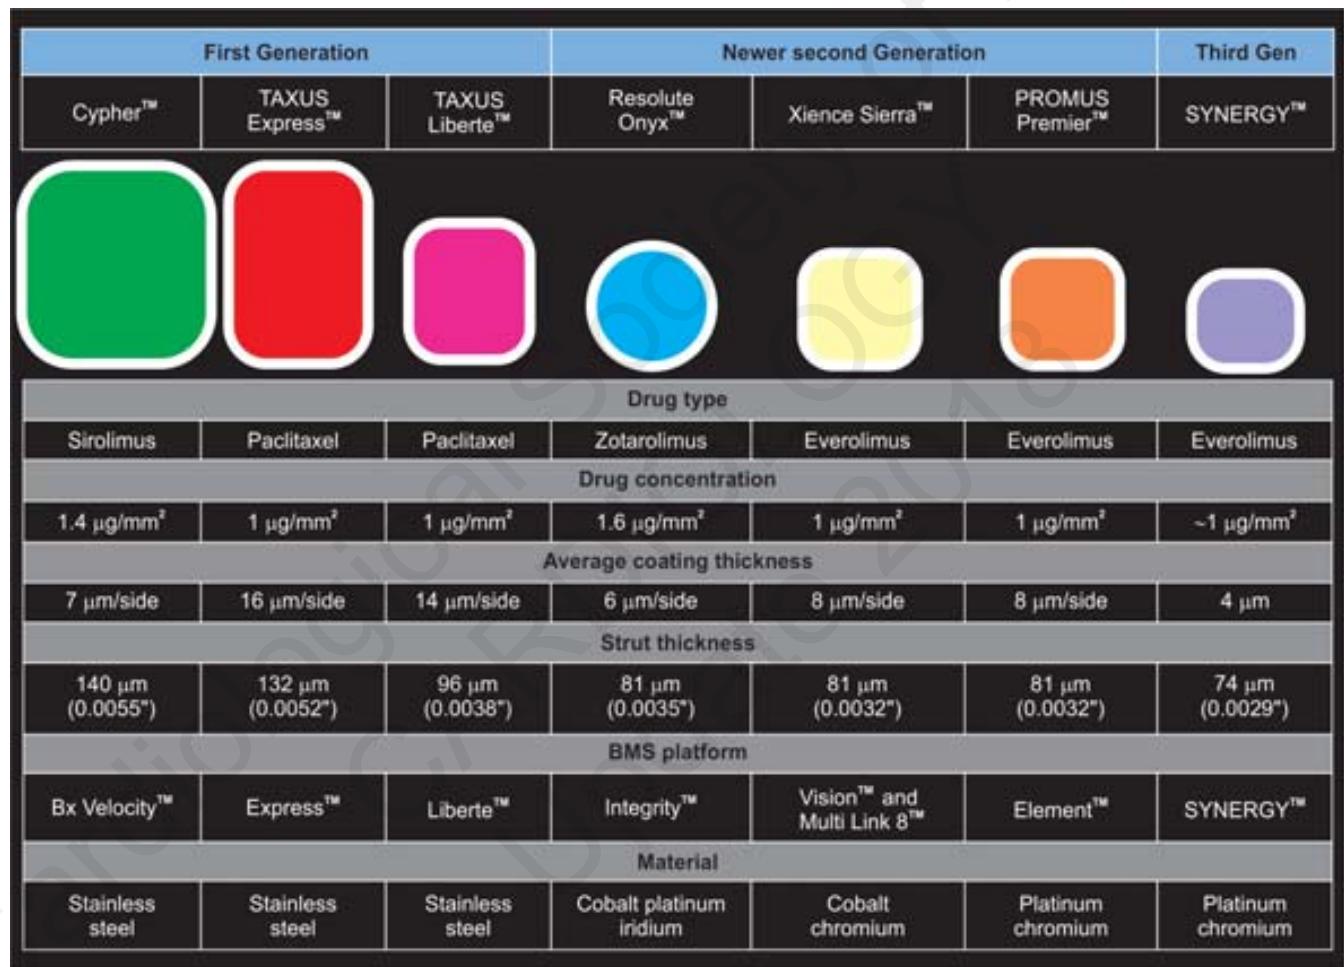

Polymer coatings that encase the abluminal surface of the metallic stent function as drug carriers by enabling controlled and confined drug release. When the coatings amalgamate with antiproliferative or antirestenotic drugs, a drug-polymer matrix forms and diffuses. The diffusion rate is dependent on the material, structure, and quantity of polymers utilized in the drug-polymer matrix.

BMS, bare-metal stent.

FIG. 5: Strut profiles for contemporary stent platforms.

Currently, in first- and second-generation DESs, permanent synthetic polymer coats, i.e., poly(ethylene-co-vinyl acetate) (PEVA), poly(n-butyl methacrylate) (PBMA), and tri-block copolymer, poly(styrene-b-isobutylene-b-styrene) (SIBS), have proven most efficacious in local drug delivery from the stent to the surrounding vessel.⁷ However, clinical evidence correlates permanent DES polymer coats to probable hypersensitivity, late ST, and insufficient reendothelialization. These critical issues led to the development of highly biocompatible permanent polymers such as phosphorylcholine (PC) and copolymer, poly(vinylidene fluoride-co-hexa-

fluoropropylene) (PVDF-HFP) in ultra-thin DESs. The polymers imitate the phospholipids on erythrocyte surfaces; this action induces marginal thrombogenicity and lowers vessel injury.⁷ Furthermore, the advanced polymers decrease complete strut thickness by reducing polymer thickness by 40–70%.⁵ The new EluNIR Medinol stents have an elastic polymer coating.

Recent research has fixated on contemporary biodegradable polymers and their potential in reducing restenosis rates (Fig. 5). These polymers permit an even smaller effective strut thickness as the polymers resorb after a

period of drug elution. The 74 µm SYNERGY bioabsorbable polymer (BP)-DES contains a platinum-chromium metallic stent and biodegradable poly(lactic-co-glycolic acid) (PGLA) polymer; demonstrated in the randomized EVOLVE (Evaluation of Cinacalcet Hydrochloride Therapy to Lower Cardiovascular Events) trials, the platform has exhibited clinical efficacy and safety.⁷ At a 2-year review, patients with SYNERGY have not witnessed any augmentation in the 1.1% target lesion revascularization (TLR) and 0% ST rates from their 1st year examination.¹³ Platforms such as SYNERGY have pioneered the development of ultra-thin struts and have sparked early clinical research to develop even thinner and more effective struts by replacing the polymer coating with “microfabricated and nanofabricated reservoirs” on the metallic scaffold.¹⁴

IMPLICATIONS ON CLINICAL PRACTICE

As technology has evolved, it has become more and more difficult to show superiority between stents of the same generation. In the next few segments, we will highlight on few features that may help one choose a particular type of stent.

Significance of Strut Thickness in Drug-eluting Stents

Stent strut thickness is crucial to determining a platform’s safety and clinical efficacy. Thinner stents have a plethora of advantages over antiquated BMSs and first- and second-generation DESs, including a reduced risk of side branch occlusion, simplicity in tracking the stent inside the vessel, and improved flexibility.¹⁵ Strut fractures were more common with the first-generation DES.

In a trial investigating the correlation between ST and *ex vivo* flow loop stent design, results indicated thick-strut stents of 162 µm were 1.5-fold more thrombogenic than thinner stents of 81 µm with an identical composition, structure, polymer coating, and antiproliferative drug (Fig. 6).⁷ Additionally, after a 3 days of implantation in porcine coronary arteries, thick struts indicated an 60% increase in thrombosis and an overall accumulation in fibrin deposition than thin struts.¹⁶

A thinner strut thickness moreover accelerates stent endothelialization than its thicker counterparts. Due to a smaller area, the thinner stent does not require as much neointimal tissue coverage. In a preclinical study examining strut thickness effect on strut tissue coverage in rabbit models,

after a 14-day period, strut tissue coverage was highest (95%) in thinner struts (81 µm) in comparison to the 97 µm (88%) and 132 µm (77%) thicker struts. The study concluded strut thickness modulated blood flow. Thus, as a result, stagnation and recirculation are more probable to transpire in thicker struts.¹⁷

Furthermore, clinical evidence suggests strut thickness determines the efficacy review of certain coronary devices. For instance, in the ISAR-STEREO (Intracoronary Stenting and Angiographic Results: Strut Thickness Effect on Restenosis Outcome) trial, a thin-strut of 50 µm displayed over a 10% reduction of binary restenosis (BR) at a 6-month angiogram follow-up from a 140 µm thick strut BMS. Therefore, the reduction of BR lead to a decrease (13.8–8.6%; $p = 0.03$) in repeat intervention and revascularization at the target vessel.¹⁸ Results indicate that thicker struts trigger greater on-site coronary inflammation, vessel damage, and disturb the internal elastic lamina than thinner-strut platforms. The resulting inflammation induces in-stent neointimal hyperplasia, ultimately promoting restenosis.¹⁵

Clinical Efficacy of Biodegradable and Bioresorbable Drug-eluting Stents

Although once thought to be effective and promising, recent research has questioned biodegradable and bioresorbable DES clinical efficacy. Many of the stents, specifically the Abbott Vascular Absorb Bioresorbable Vascular Scaffold (BVS) system, have been recalled in response to meta-analyses from recent studies.¹⁹ The ABSORB III trial 2 years results were presented at the American College of Cardiology assembly in 2017 and dampened hope for bioresorbable stents use in the future. In the ABSORB trials, the rate of ischemia-driven TLR (ID-TLR) and target vessel MI was higher with BVSs in comparison to DESs.²⁰ In addition, Absorb BVS had slightly higher rates of target lesion failure (TLF), scarce cases of late ST, and a generally greater percentage of poor outcomes compared to Xience, a DES. However, although the technology has had several impediments, companies are still optimistically insisting to improve the BVS platforms to eventually improve patient outcomes.

Clinical Efficacy of Ultra-thin Drug-eluting Stents

Since the release of ultra-thin strut DESs, only few clinical trials have been performed for three ultra-thin strut stents. The stents include the BioMime sirolimus-eluting stent (SES) (65 µm strut thickness), the MiStent SES (64 µm strut thickness), and the Orsiro SES (60 µm strut thickness). One such study, the BIOTRONIK (A Prospective Randomized Multicenter Study to Assess the Safety and Effectiveness of the Orsiro Sirolimus Eluting Coronary Stent System in the Treatment of Subjects with up to Three *De Novo* or Restenotic Coronary Artery Lesions), or the BIOFLOW V trial, has showcased the ultra-thin DES's superiority to fluoropolymer-based everolimus-eluting stent (EES) and potential safety. In the trial, both the Orsiro SES and the Xience EES were evaluated. Results indicated that the Orsiro SES was more

effective in reducing TLF and were inferior to fluoropolymer EESs.²¹

Additionally, the Merit V trial indicated a lower risk of MI in the BioMime SES in comparison to the Xience EES (0.6% vs. 4.8%; $p = 0.03$). While the results do not precisely determine an explanation for the lower MI rate in ultra-thin DESs, the rates are feasibly accredited to the reduced rate of ST due to a reduction in stent strut thickness.

DRUG-ELUTING STENT SAFETY AND EFFICACY IN SPECIFIC PATIENT POPULATIONS

Acute Myocardial Infarction

Drug-eluting stent implantation is a very common therapeutic procedure in acute coronary syndromes.⁵ Acute coronary syndrome can initiate future stent malapposition and potential delayed arterial vessel healing. Thus, many patients with these syndromes are denied potentially helpful clinical treatment. However, new DES platforms, such as ultra-thin struts, have been found to be safe and effective in patients suffering from this disease. The EXAMINATION trial revealed patients with ST-elevation MI (STEMI) had lower rates of TLR in EES to BMS.⁵

Chronic Kidney Disease

Chronic kidney disease (CKD) is a common comorbidity with many cardiovascular diseases, and in conjunction, CKD can increase mortality and morbidity rates. Additionally, after BMS or first-generation DES implantation, CKD is concomitant with restenosis and ST. Unlike previous DES, second- and current-generation DES have showed a high-efficacious rate among clinical trials in patients with CKD.^{5,22}

Diabetes Mellitus

Patients with diabetes mellitus (DM) are at an extremely high risk for restenosis, MI, repeat revascularization, and mortality after stent implantation.²³ Previous research has approximated DES and BMS platforms to be equally as successful if dual antiplatelet therapy (DAPT) is used for a minimum of 6 months. However, in certain aspects, DESs have proven to be superior in lowering restenosis rates in diabetics. A 42-trial mixed treatment comparison meta-analysis concluded that DES were noninferior to BMS and additionally decreased TVR rates in DES platforms.²⁴ Although DESs are more commonly utilized, the preeminent DES platform for diabetic treatment remains uncertain. In an effort to specialize a DES for diabetic patients, the Medtronic stent resolute zotarolimus-eluting stent was manufactured, becoming the first FDA approved stent for patients with DM.^{25,26}

High-bleeding Risk Patients

The SYNERGY bioabsorbable polymer everolimus DES is commonly used in patients with high-bleeding risk presumably due to the need of shorter DAPT duration in such patients. However, similar results were seen with durable

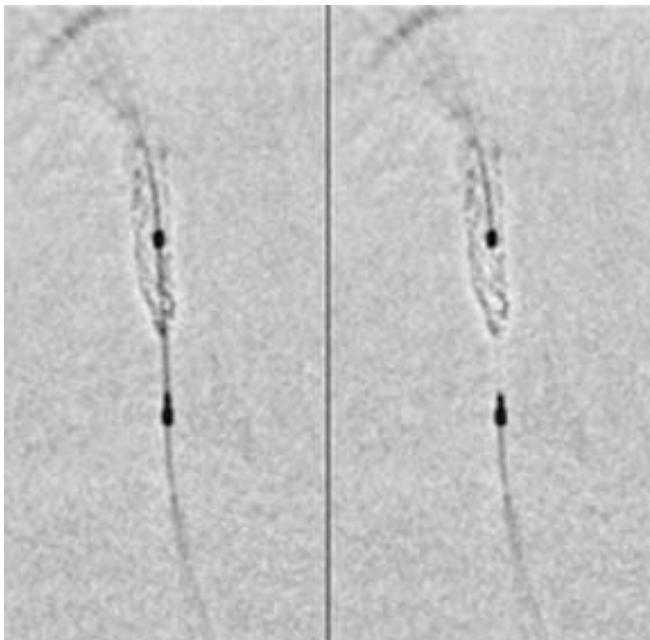

FIG. 7: Incidence of longitudinal deformation in vessel after stent implantation.

polymer thin or ultrathin stents in smaller clinical trials. US FDA has not made any recommendations to shorten the DAPT with any currently approved stents though guidelines recommend to shorten DAPT in low ischemic risk and high-bleeding risk patients.

Bioresorbable Vascular Scaffolds

Though currently BVS are not used except in clinical trials, one has to marvel at the idea of nonmetallic scaffold. Strut thickness of the first-generation BVS was larger than the first-generation DES. Second-generation BVS with 100–125 μm strut thickness are being evaluated in large clinical trials by Meril Lifesciences and REVA Medical.^{27,28}

Safety Outcomes and Complications of Newer DES: Longitudinal Deformation

Although there are many strengths to DES, it is equally as important to discuss the stents' weaknesses in clinical practice and trial. Some modifications introduced in novel stent platforms may result in a reduction in their longitudinal strength as a derivative of attempting to increase flexibility (Fig. 7).²⁹ Longitudinal stent deformation is outlined as the reduction of a platform in the longitudinal axis after a successful stent implantation.⁵ This deformation can lead to the protrusion of struts into the vessel lumen. This malposition may eventually result in disruption of blood flow and increased ST.³⁰ Longitudinal stent deformation occurs in 0.1–1.0% of total DES platform insertions. The rates of stent deformation are lower in older generation stiffer DES struts.⁵ Recent research is concentrated on stents focused on specific lesions to avoid longitudinal compression.

CONCLUSION

Drug-eluting stents were developed to reduce the risk of ISR seen with BMS. Concerns for high-risk of late and very late adverse events seen with first-generation DESs have significantly decreased with the use of contemporary platforms, owing to advances in technology including scaffold design, novel metallic alloys leading to thinner struts, polymer biocompatibility, and antiproliferative drug development and delivery. Several randomized controlled trials and meta-analyses, have consistently shown the efficacy and safety of contemporary DES platforms in both short-term and long-term follow-up. Given their proven efficacy and safety profile, the use of contemporary DESs has become standard in most clinical scenarios, including high-risk settings such as CKD, acute MI, and diabetic population.

Fractional Flow Reserve and Instantaneous Wave-free Ratio—Which Should Be the Gold Standard?

Nagendra Boopathy Senguttuvan, Nitish Naik, Kewal C Goswami

INTRODUCTION

Clinical improvement after percutaneous coronary intervention (PCI) is based on intervening on lesions that are hemodynamically significant. Assessing hemodynamic significance of coronary lesions, it is not a new entity for interventional community. Andreas Gruntzig did his first angioplasty after assessing the pressure gradient across the lesion in proximal left anterior descending artery (LAD).¹ Until a decade ago, angiography was considered the gold standard before any form of coronary intervention. However with its inherent limitations,² it often misses eccentric lesions especially in the ostium or in a highly tortuous anatomy or in a calcified spot. Physiological assessment of coronary stenosis has revealed that nearly one-third of intermediate severity lesions (diameter stenosis from 50% to 70%) are in fact functionally significant. About 20% of the lesions that have a diameter stenosis of 70–90% are not functionally significant. Imaging tools such as intravascular ultrasound (IVUS) and optical coherence topography (OCT) are being used since many years to assess the significance of lesions and to assess the result of PCI. However, both these techniques still serve only anatomical and morphological analysis of coronary lesions rather than their functional significance.

Different physiological modalities have been used to assess the significance of coronary lesions before interventions including coronary flow reserve (CFR), fractional flow reserve (FFR), and relative flow reserve (RFR). CFR is the ratio of maximal hyperemic blood flow to the baseline coronary blood flow. It is dynamic and hence is often affected by variables such as heart rate, blood pressure, and microvascular resistance. With increasing coronary stenosis, CFR is reduced though the baseline flow remains largely unchanged to a coronary stenosis severity of up to 90% or more. FFR is the ratio of maximal hyperemic blood flow in a coronary with a stenosis to the maximal hyperemic blood flow in the same vessel without a stenosis. Thus in an artery without any stenosis, FFR should be 1.0. The use of FFR to

guide clinical management is now well established and its use have been proved in many trials.^{3–6} Recently, even resting indices of coronary blood flow have been studied in patients with coronary artery disease (CAD) to assess the significance of lesions that include Pd/Pa (ratio of distal pressure to proximal pressure) and instantaneous wave-free ratio (iFR).⁷ A lot of evidence has now accumulated comparing the efficacy of resting indices, especially iFR to FFR. In this review, we intend to discuss currently available evidence on FFR and iFR to help clinicians in identifying the modality that will be relevant in decision-making in clinical practice.

FRACTIONAL FLOW RESERVE

Fractional flow reserve was first described *in vivo* by Pijls et al.³ in 1993. It is defined as the ratio of maximal flow in the coronary artery with stenosis to the maximal flow that happens in the same vessel in a hypothetical situation without stenosis. By following work of Gould⁸ who proposed that coronary arterial circulation with lesion behaved as electrical circuit with a serial connections, Pijls proposed that flow was directly proportional to pressure given the resistance was kept stable and minimum using Ohm's law.³ When resistance is constant, pressure is directly proportional to the flow.³ FFR measures the flow across a lesion by quantifying the pressure across the lesion, when resistance is constant and at its lowest level. Coronary arterioles play the primary role in increasing the coronary circulation resistance. By achieving vasodilation of arterioles (maximal hyperemia), pressure measured across a lesion helps to assess the flow across lesions. Hence, it represents the amount of blood flow limitation attributable due to the presence of an epicardial stenosis. Hence, FFR can be defined as the ratio of distal pressure to the proximal pressure across a stenosis at maximal hyperemia (see Fig. 1).

$$\text{FFR} = \frac{\text{Pd}-\text{Pv}}{\text{Pa}-\text{Pv}}$$

where Pd is the distal pressure; Pa the proximal pressure (aortic pressure); Pv the coronary venous pressure

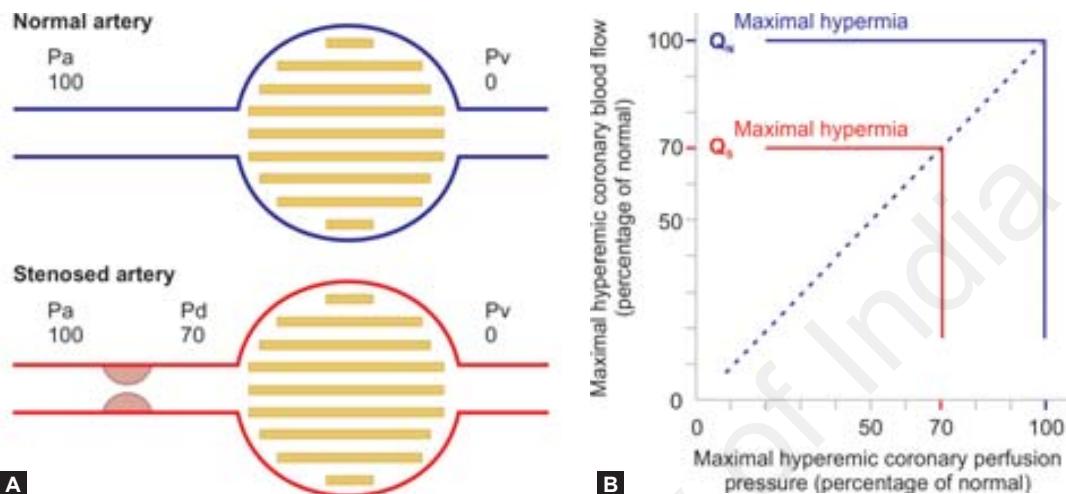

FIG. 1: A, Schematic representation of FFR physiology (Pa, aortic pressure; Pd, pressure distal to stenosis; Pv, central venous pressure); B, Linear relationship of coronary blood flow at maximal hyperemia to coronary pressure. Q_N and Q_S are coronary blood flow during maximal hyperemia is normal and stenosed arteries respectively.

TABLE 1: Pharmacological agents used to achieve maximal hyperemia during FFR

Agent	Route	Dose	Peak effect	Duration
Adenosine	Intravenous	Infusion: 140 µg/kg/min	30–45 s	2 min infusion
	Intracoronary	LCA: 200 µg RCA: 100 µg	<10 s	<20 s
Papaverine	Intracoronary	LCA: 16–20 µg	10–30 s	45–60 s
		RCA: 12–16 µg		
Regadenoson	Intravenous	400 µg bolus	30 s	2.5 min

LCA, left coronary artery; RCA, right coronary artery.

As coronary venous pressure is low, it can be removed from the equation making:

$$\text{FFR} = \text{Pd}/\text{Pa}$$

Maximal hyperemia is achieved by intracoronary nitroglycerine (NTG) along with intracoronary or intravenous (IV) adenosine.⁹ Other agents such as papaverine, regadenoson, and sodium nitroprusside have also been used to produce maximal vasodilatation (Table 1). Initial studies recommended a value of ≤ 0.75 as definitely significant and values between 0.76 and 0.8 to be considered in the gray zone; however, current guidelines suggest that values ≤ 0.80 be considered as abnormal and values > 0.80 be considered as insignificant.

ADVANTAGES OF FRACTIONAL FLOW RESERVE

Fractional flow reserve is easy to perform in the catheterization laboratory and easy to interpret with less intra- and interobserver variations. There are a number of companies that are now providing FFR commercially (Table 2). FFR accounts not only for the vessel stenosis but also for collateral flow and the size of the distal myocardial bed. It is independent of

heart rate, blood pressure, and left ventricular (LV) function. However, care needs to be taken in performing FFR during maximal hyperemia and making sure that all precautions are taken to ensure accurate pressure measurements (Box 1). FFR values may be false negative if there is inadequate hyperemia due to inappropriate dose, damping from the guide catheter (preventing increase in blood flow), or in an acute coronary syndrome (ACS) due to microvascular dysfunction. These values may be false positive due to incorrect calibration or signal drift in the guide catheter or guidewire. Recently, it was postulated that FFR may vary in patients with arterial

TABLE 2: Available FFR technologies

Manufacturer	Name of product	Method	Advantages
Abbott St. Jude	Certus	Piezoelectric pressure wire	Wireless connection of wire with machine
	Aeris		Thermodilution blood flow measurement
Philips Volcano	Verrata	Piezoelectric pressure wire	FFR; iFR
			Doppler-tipped pressure and flowwire
Boston Scientific	COMET	Optical sensor wire	Less likely to be affected by signal drift, better wire performance
Opsens Medical	OptoWire	Optical sensor wire	Less likely to be affected by signal drift, better wire performance
Acist Medical	Navvus	Optical sensor monorail microcatheter	Improved steerability; any guidewire may be used

FFR, fractional flow reserve; iFR, instantaneous wave-free ratio.

BOX 1 Steps of FFR

- Anticoagulation to achieve therapeutic levels as in PCI
- Place the wire flat and flush FFR wire in its delivery spiral package with 10–20 mL of saline
- Connect the FFR wire with the machine; in wireless systems, the wire will communicate with the machine
- Remove FFR wire and introduce into the guide catheter gently after making the standard tip-shaping technique on the wire as required for the lesion
- Advance the wire such that the junction of the radio-opaque and radiolucent region of the wire (where the pressure transducer is located) is just beyond the tip of the guiding catheter. Nitroglycerine can be administered to prevent coronary vasospasm
- Ensure that the guide catheter is properly hooked without damping or ventricularization. If there is an ostial lesion, then guide catheter should be unhooked and the radioopaque–radiolucent junction of wire should be in the aortic root
- Remove the introducer needle, flush the guide, and then equalize the readings of the pressure from the guide catheter and the pressure wire. Ensure there is no contrast in the guide to prevent spurious readings. The Y connector should be closed tightly to prevent leakage and fall in pressure. The Pd and Pa reading ratio should be 1.0. If the difference between the two pressures exceeds 15 mm Hg then FFR readings are not valid
- Ensure that the pressure transducers are at mid-chest level. If the transducers are positioned above the mid-chest level, then the pressure will be underestimated (pressure is too low). If the pressure transducer is located too high, then the pressure will be overestimated (pressure too high)
- Once equalized, the pressure wire should be advanced to beyond the lesion under evaluation such that the pressure transducer is beyond the lesion. The introducer may be reinserted if needed to facilitate smooth handling of the wire. However, after parking the wire beyond the lesion being tested, the introducer should be removed before making any measurements
- The wire should be positioned such that the pressure transducer is at least three vessel diameter lengths beyond the lesion to prevent overestimation just beyond the lesion due to turbulence
- Check FFR value once the wire is beyond the lesion being evaluated. Wait for pressures to stabilize. If baseline resting Pd/Pa is <0.80, then the lesion is significant at rest and pharmacological hyperemia is not required
- If resting Pd/Pa is >0.80, then administer coronary vasodilator as per protocol. Ensure appropriate dose is administered
- Measure FFR reading at maximal hyperemia; document and store reading
- Once FFR reading is taken gently, withdraw wire and recheck that both pressures are equal to ensure that there is no drift
- If there are multiple lesions/tandem lesions, then assess FFR of the entire vessel. FFR wire may be withdrawn during maximal hyperemia to assess individual lesions if clinically necessary
- Take a final angiogram after removal of the wire to check for any wire-related complications
- If FFR is significant then PCI can be performed on the FFR wire by disconnecting the wire from the analyzer. Post-PCI measurements can be taken by reconnecting the pressure wire and with maximal hyperemia

FFR, fractional flow reserve; PCI, percutaneous coronary intervention.

hypotension¹⁰ findings which need to be confirmed in larger studies. At present, it is considered to be the gold standard for assessing a lesion's functional significance.¹¹

CLINICAL UTILITY OF FRACTIONAL FLOW RESERVE

Clinical use of FFR is now well established in assessing intermediate-grade lesions during coronary intervention. The deferral of percutaneous intervention (DEFER) study⁴ where CAD patients with FFR>0.75 and FFR<0.75 underwent revascularization or medical therapy. Patients with FFR <0.75 who did not get revascularized had more major adverse coronary events (MACE). On the contrary, patients with FFR >0.75 who did not undergo revascularization did equally good as compared to those with FFR <0.75 who underwent revascularization. In the landmark FAME-1 (FFR vs. angiography for multivessel evaluation 1) study,^{5,12} it was observed that FFR-guided PCI is better than angiography-guided PCI. In FAME substudy,¹³ it was found that 20% of lesion which had been classified as significant by angiogram (70–90%) was found to be physiologically insignificant. A total of 497 patients were studied who were stratified into

tertiles based on their syntax score.¹⁴ After determining the functional syntax score (FSS) for each patient (calculating syntax score only for lesions that are functionally significant), they observed that 32% changed to a low-risk category from intermediate- or high-risk group that would have resulted in change in their treatment modality. It was noticed that FSS and procedure time were the only factors that were associated independently with 1 year MACE. It was also found that FSS had a better predictive accuracy for MACE as compared with conventional syntax score. It was also observed that the presence of angiographically significant, but functionally insignificant, lesion that led to residual syntax score did not affect the prognosis of the patients.¹⁵ This study emphasizes that almost one in three patients landed up in appropriate change in treatment modality after FSS assessment. FFR was found to be equally good in female patients,¹⁶ in patients with unstable angina, and non-ST elevation myocardial infarction (NSTEMI).¹⁷ FFR was also shown to be useful in patients with severe LV dysfunction, unless their lesion is very tight which may lead to clinically irrelevant overestimation of FFR.¹⁸ It was also found that the chance to have a MACE due to FFR insignificant lesion is 0.02% over a year, which is very minimal. FFR-guided PCI was found to be superior to medical

therapy alone in patients with CAD.¹⁹ A 5-year follow-up of FAME-2 study showed an initial FFR-guided PCI in patients with stable CAD with a significantly fewer rate of composite end point that included death, myocardial infarction (MI), and urgent revascularization.²⁰ It also showed that those who had FFR >0.8 had a favorable outcome with medical therapy alone.²⁰

Grafting vessels with a stenosis >50% is standard practice in patients scheduled for surgery, though it is known that rates of graft failure are higher in patients with insignificant stenosis. In a small study, patients who had 50–70% stenosis and were scheduled for bypass surgery underwent FFR at the time of angiography. These patients were reevaluated a year later to assess graft patency. There was a higher rate of graft failure when these were done in FFR negative lesions though angiographic stenosis was 50–70%.

Fractional flow reserve also helps in assessing long lesions to assess their hemodynamic significance. FFR wire pullback during sustained maximal hyperemia can help decide significance of long lesions guiding therapy. In assessing serial lesions/long lesions the total FFR across all lesions should be measured with IV adenosine as per standard protocol. If the summed FFR of the entire segment is <0.80, then a pressure pullback during IV adenosine hyperemia should be performed to assess individual lesions. Decision for PCI of the most severely narrowed lesion is then determined by the lesion that produces the biggest pressure gradient. After stenting the lesion with the largest ΔP , the remaining lesion/s FFR should be reassessed.

Fractional flow reserve is also a useful strategy for bifurcation lesions. It has been shown that though jailed side branches often have angiographically significant disease, most of these vessels have FFR values >0.75.

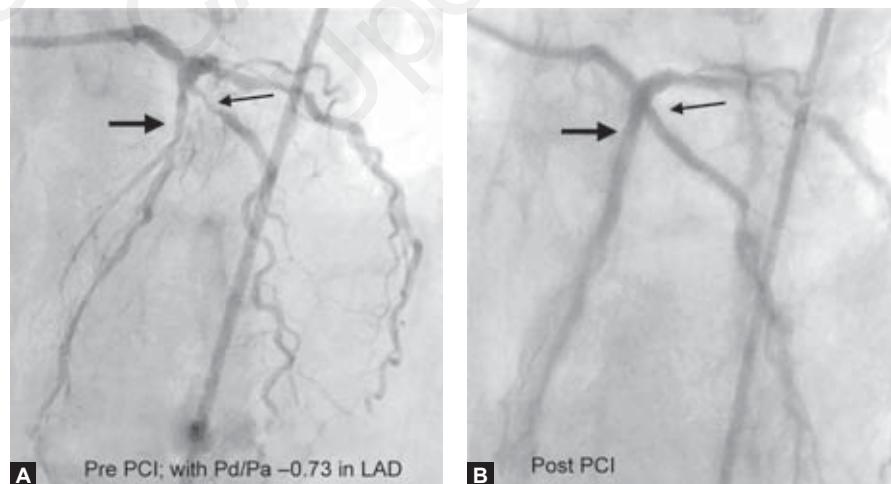

Assessing equivocal ostial or body lesions in the left main is as per standard protocols except that care needs to be taken that the guide catheter does not wedge as well

as that the equalization of pressures is done in the aortic root. For intermediate severity distal lesions of the left main involving the bifurcation, FFR has to be assessed in both the LAD and left circumflex arteries. It is generally useful to first assess FFR in the less diseased of the two vessels, preferably the LAD using a manual slow pullback—if the FFR is <0.80 then it needs revascularization. If it is >0.85 then it does not merit any intervention. If the value is between 0.8 and 0.85 and there is significant distal disease in the other vessel, the decision should be based on additional imaging (IVUS). The presence of significant coexistent disease in the LAD and/or circumflex artery will increase FFR across the left main if these lesions supply a large area of jeopardized myocardium; if these lesions are in distal branches their effect on FFR of the left main will be minimal.

Assessment of vein grafts using FFR varies according to the presence or absence of antegrade flow in the graft. In grafts that have no antegrade flow, FFR accurately depicts blood flow in the distal myocardial bed. However, in grafts that have residual flow as well as collateral flow, FFR may be normal.

CASE STUDY

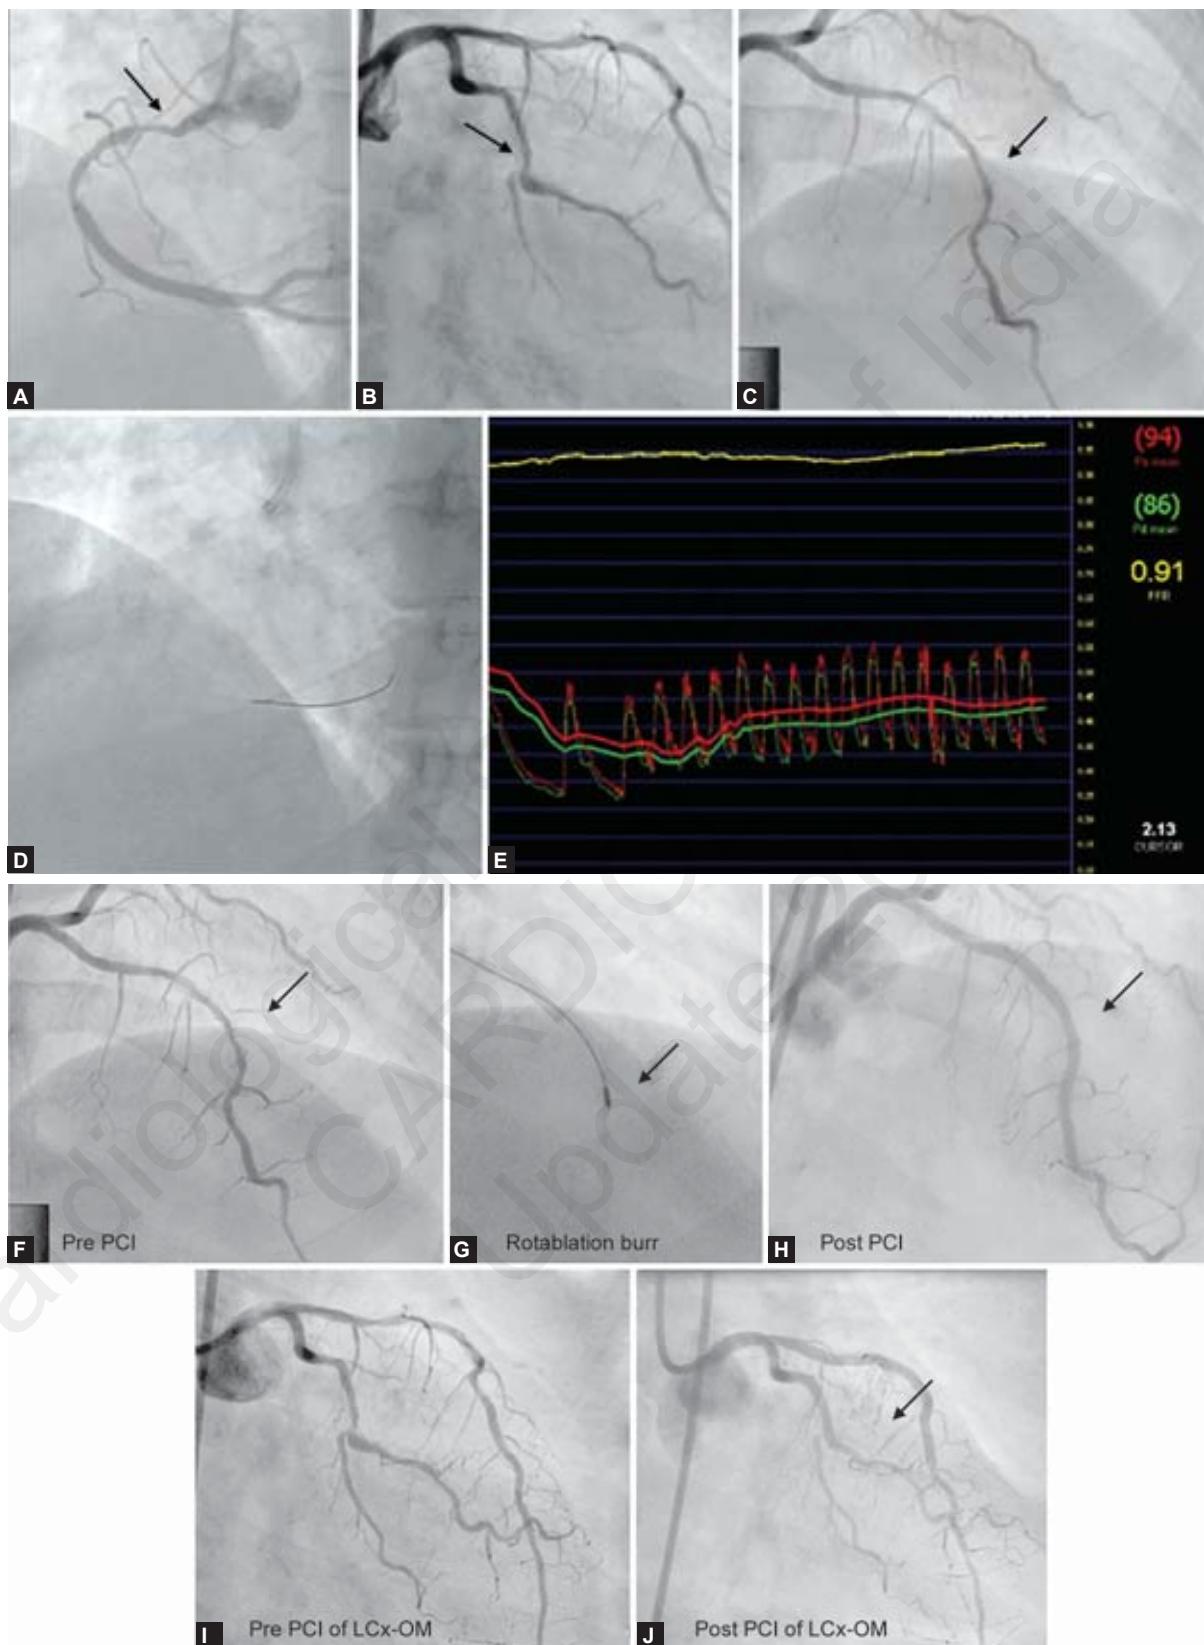

A 75-year-old elderly man presented with NSTEMI. Coronary angiogram done elsewhere was reported to have a critical diagonal disease with borderline LAD disease (Fig. 2A) and was advised to have a PCI to diagonal and was put on maximal medical treatment. However, he was having recurrent unstable angina. Hence, he was taken up for FFR-guided PCI-to-LAD. Even without adenosine, Pd/Pa was significant (0.73). He underwent PCI-to-LAD and diagonal using V-stenting strategy (Fig. 2B) and is doing fine. But for FFR, the decision would have been to perform PCI of the diagonal branch alone which would have risked leaving him with an unstable significant plaque in LAD.

AP, anteroposterior; FFR, fractional flow reserve; LAD, left anterior descending artery; PCI, percutaneous coronary intervention.

FIG. 2: A, AP Cranial projection showing an angiographically mild proximal LAD lesion (bold black arrow) and a tight diagonal lesion (small black arrow). FFR was 0.73 across the proximal LAD lesion (significant); B, PCI was done using a V stent strategy.

Additional case examples where FFR significantly changed management strategy in patients are provided in figures 3 and 4.

INSTANTANEOUS WAVE-FREE PRESSURE RATIO

In spite of the established value of FFR-guided revascularization, it is not commonly used in routine clinical practice due to various reasons including operator's preference, increased time with FFR, side effects of adenosine, and added cost of these procedures. Recently, resting indices of coronary blood flow have been proposed to assess the significance of lesions. Among them, Pd/Pa and iFR are the most well studied. Using coronary wave intensity analysis there is a period in diastole during which there are no waves from the aortic pressure head or from the reflected pressure waves from the coronary microcirculation. This wave-free period can be used for assessing FFR as there is minimal coronary resistance though coronary blood flow is at its peak. Pd/Pa during this phase is called iFR. This method is emerging as a potent competitor of FFR as the gold standard modality to assess the significance of lesions (Fig. 5). Mamas et al.²¹ observed significant linear correlation between Pd/Pa and FFR. Sen et al. found that intracoronary resistance is constant and minimum during a particular wave-free period during diastole. They compared the intracoronary resistance at rest measured during the wave-free period with that of postvasodilatation (during FFR). It was concluded that iFR (ratio of distal to proximal pressure measured during this wave-free period) correlated very closely with FFR.⁷ Jeremias et al.²² studied the relation between Pd/Pa, iFR, and FFR. They found that the appropriate cut-off point of iFR and Pd/Pa for FFR ≤ 0.80 were 0.90 and 0.92 respectively with no significant difference between these resting measures. They found that iFR and Pd/Pa can predict positive or negative FFR with an accuracy of 90% in two-thirds and half of the patients respectively. There are several assumptions in the measurement of iFR. Foremost important assumption in iFR measurement is wave-free interval where the coronary

iFR, instantaneous wave-free ratio.

FIG. 5: iFR pullback using the Phillips Volcano system.

resistance is not only minimal but is also near equivalent to the coronary resistance measured with maximal hyperemia. It is also presumed that the pressure coronary flow relationship is proportional during this period. Though assumptions have not been perfect, that is the microvascular resistance measured in wave-free period is higher than that of maximal hyperemia-related microresistance, landmark studies have been published recently that compared the efficacy of FFR with iFR-guided revascularization.

COMPARISON OF INVASIVE PHYSIOLOGICAL INDICES TO NONINVASIVE PHYSIOLOGY MEASURED BY POSITRON EMISSION TOMOGRAPHY

There is always a debate whether CFR is better or FFR is better. Hwang et al. studied the relation between invasive physiological indices such as FFR, iFR, and Pd/Pa to

noninvasively measured parameters such as CFR and RFR by ammonia-based positron emission tomography (PET). They found significant correlation between invasive physiological indices and PET-derived CFR and RFR.

HYBRID APPROACH

A hybrid approach of combining iFR with FFR was proposed to increase the identification of physiologically significant lesions. Rivero et al.²³ suggested a hybrid approach of doing iFR for all and doing intracoronary adenosine fractional flow reserve (IC-FFR) for individuals with iFR between 0.85 and 0.92 increased the sensitivity, positive predictive value, and specificity of this strategy.

STANDALONE INSTANTANEOUS WAVE-FREE RATIO APPROACH

Two large randomized studies compared the efficacy of iFR-based revascularization versus FFR-guided revascularization. They have taken 0.89 as the cut-off point for iFR and 0.8 as cut-off point for FFR.

DEFINE-FLAIR²⁴ was a randomized, noninferiority trial that enrolled 2,492 patients with CAD. They were randomized in 1:1 fashion to undergo either iFR- or FFR-guided coronary revascularization. The primary end point was the 1 year risk of MACE, which were a composite of death, nonfatal MI, or unplanned revascularization. No difference in primary end point was observed between the groups at 1 year [6.8% in the iFR group vs. 7.0% in the FFR group ($p < 0.001$ for noninferiority)]. There was also no difference in the secondary end points that included individual components of primary end points separately. The number of patients who had adverse procedural symptoms and clinical signs was significantly lower in the iFR group (3.1% vs. 30.8%, $p \leq 0.001$). It was also noticed that the median procedural time was significantly shorter in iFR arm (40.5 min vs. 45.0 min, $p = 0.001$). One important point, that needs to be emphasized, is the increased use of revascularization in FFR arm. In other words, functionally significant lesions were lower with iFR as compared to FFR [iFR (28.6% vs. 34.6%, $p = 0.004$)], and hence led to fewer revascularization procedures (47.5% vs. 53.4%, $p = 0.003$) with similar 1 year clinical outcome.

Instantaneous wave-free ratio-SWEDE-HEART study²⁵ was a multicentric, open-labeled, noninferiority, randomized controlled trial. This trial enrolled 2,037 patients with stable angina or ACS with indication of physiological assessment and randomized them to iFR- versus FFR-guided revascularization. Primary end point was the composite of death from any cause/nonfatal MI or unplanned revascularization within 12 months of the procedure. The primary end point was observed in 6.7% in iFR group versus 6.1% in FFR-guided group ($p = 0.007$ for noninferiority). A significant higher proportion of patients in FFR group developed chest discomfort as compared to iFR group (related to adenosine). This study concluded that coronary revascularization guided by iFR was noninferior to revascularization guided by FFR

at 12 months with lower adverse procedural reactions and shorter procedural time. A meta-analysis studying death and MI combining both DEFINE-FLAIR and iFR-SWEDE-HEART trials has been conducted.²⁶ Though numerically higher death rates were observed in iFR arm, these were not statistically significant.

There are some limitations of both these trials. It is well known that iFR and FFR were concordant in 80% of cases.²⁷ Hence, both these trials could affect the outcomes of 20% individuals only. This will decrease the power of the study drastically. Though the vessel involved were reported, location of disease in particular vessel were not reported in both these trials. Previously Kobayashi et al.²⁸ reported that resting indices including contrast FFR, iFR, and Pd/Pa are less accurate in identifying the significance of lesions in LM/pLAD as compared with non-LM/pLAD. This is likely due to the huge amount of myocardial mass supplied by LM/pLAD.

MERITS AND DEMERITS

One major advantage of iFR is virtual PCI, that is effect of virtual PCI (Fig. 3) on tandem lesions. It was shown to be accurate and was helpful in changing the treatment strategy in one-third of patients.²⁹ Another point that was shown in the patient level analysis of the above two studies showed that patients with ACS had more MACE as compared to stable CAD in FFR arm unlike iFR arm where there was no significant difference. In difficult to wire lesions, microcatheter-based FFR could be used.³⁰

CONCLUSION

Using physiology-based revascularization strategy either by FFR or iFR seems to be the best method to assess intermediate-grade lesions. Though FFR-based revascularization strategy is considered the gold standard modality until recently, a simpler, less time-consuming and more patient-friendly product; iFR, which has been found to be noninferior to FFR is now available. We believe using iFR technology may allow us to use the benefit of the physiology in many of our patients routinely. It does not imply that centers/operators using FFR routinely for intermediate lesions should change to iFR. It is rather time that interventional cardiologists start incorporating functional PCI using iFR or FFR to improve patient outcomes when clinically indicated. The emergence of even newer technologies such as quantitative flow ratio (QFR) which is computed as a 3D reconstruction of the diseased coronary artery from angiographic views may simplify functional assessment even further.

Optical Coherence Tomography in Coronary Artery Disease: A Review

Ashwat S Dhillon, Leah Raj, Anil Kumar Mehra

INTRODUCTION

Coronary angiography is the most easily accessible and universally used current method to assess coronary anatomy and as a guide to therapy including percutaneous coronary intervention (PCI), but it only provides a lumogram. In order to study arterial lumen as well as arterial wall structure, intravascular ultrasound (IVUS) and intracoronary optical coherence tomography (OCT) are currently available modalities of invasive imaging. IVUS has been in use for over 30 years with limited routine clinical penetration despite proven improvement in major adverse cardiac event (MACE) with IVUS-guided PCI use compared to angiography-guided PCI.¹ OCT is a recently developed new tool available for clinical use in its current form since 2007. Although, there are no large scale clinical data with OCT in comparison to angiography-guided PCI, it has distinct technological advantages as an imaging modality compared to IVUS. It is important as an interventional cardiologist to understand the advantages and disadvantages of both imaging modalities for clinical use. Adequate training in the acquisition of images and especially image interpretation may be an important factor in addition to cost and time, in the variable utilization of these important technologies for guidance during PCI and follow-up.

PRINCIPLES OF OPTICAL COHERENCE TOMOGRAPHY

Optical coherence tomography is a light interference-based imaging technique that uses near-infrared (NIR) light with a central wavelength range of 1250–1350 nm to generate cross-sectional (tomographic) view of the vasculature.² The key features of the three-dimensional (3D) cross-sectional images are: a very high spatial resolution (10 µm or less vs. 100 µm by IVUS) and high tissue contrast.³ OCT is based on the principle of light interference, i.e., backscattered (reflected) from the analyzed tissue. Current commercially available system

of intracoronary OCT (Ilumien Optis PCI Optimization System, Light Lab Imaging Inc., St Jude Medical, MA) employ a technique known as frequency domain (FD) OCT that enables imaging at 180 frames/sec with imaging length of 75 mm in survey mode and 54 mm in high-resolution images.

Introduction of FD-OCT with rapid automatic analysis and display of the 3D data of the coronary artery imaging has made possible for it to be used as a routine intravascular imaging tool for guidance during PCI. In FD-OCT, NIR light generated from fast tunable laser with variable narrow frequency sweep travels through an optical fiber and is projected after splitting on to a fixed reference mirror as well as outwards and perpendicular to the catheter on to the vasculature at variable depth. The backscattered (reflected) interference signals of different wavelengths and amplitude from both the mirror and the tissue are detected and amplified. The Fourier transformation converts it into an amplitude versus depth for display as an axial image (A-line image). As the catheter rotates, there are 500 A-line scan images generated per frame to combine and display as a B-mode cross-sectional tomographic view of the structure. The motor drive unit of the current system rotates the probe and automatically pulls back spirally at a speed of 30 mm/sec generating 180 frames/sec and this is displayed as the longitudinal view (L-view). The rapid scan and pullback allows the imaging to be done without the need for the occlusion of the blood vessel being imaged with no effect of the rapid motion of the heart during the cardiac cycle on the images.¹ OCT has a 10 times higher axial (\approx 10 µm) and lateral resolution (\approx 30 µm), but lower penetration depth compared with IVUS (1–3 mm vs. 8–10 mm). Another limitation is scattering of NIR light and its high-signal attenuation by the blood cells in the lumen. Therefore, it requires catheter to be flushed with high viscosity solution (iso-osmolar contrast) and temporary complete removal of the blood from the lumen during imaging by the contrast injection. This ensures a very high contrast between lumen and the intimal interface.

PREPARATION OF IMAGING SYSTEM AND IMAGE ACQUISITION

The OCT system consists of the Dragonfly Imaging Catheter, Drive-motor and Optical Coupler (DOC), and Ilumien Optis Integrated computer system (Light-Lab Imaging Inc., St Jude Medical, MA) to acquire images and analyze as well as perform automatic or manual measurements after completion of image acquisition.

The Dragonfly Imaging Catheter is a 0.014 inch wire compatible 2.7 F rapid exchange intravascular catheter with an external sheath and an internal rotating fiber optic imaging core, which emits the infrared light as well as captures the reflected backscattered light waves. The imaging core is driven by a stainless steel torque wire connected to the DOC and pulled back automatically after activation along the length of the imaging window of the external sheath.

At present, in order to provide adequate and rapid injection of contrast during image acquisition, a guide catheter with at least a 6 F size without side holes and coaxially alignment in the coronary artery is recommended. The outer sheath is flushed with 3–5 cc of contrast medium so no blood elements can enter between the optical probe and the sheath. The OCT catheter is connected to the DOC. The catheter is advanced over the wire. The Dragonfly Duo Intravascular Imaging Catheter has three radiopaque markers at the distal tip, imaging lens and 50 mm proximal to the lens (Fig. 1). The lens marker is placed just distal to the intended segment to be studied. If blood is detected inside the sheath of the imaging catheter, purge it with 3 cc attached syringe with contrast, then enable live view. Autocalibrate the catheter by making sure the calibration markers are at the outer edge of the sheath. Enable pullback recording while injecting contrast medium (12–20 cc at rate of 4 cc/sec manually or automatically). Catheter pullback is activated automatically by detection of contrast medium at the lens and the probe is rapidly pulled back by the DOC inside the sheath in 2.5 seconds. When the pullback is finished, the OCT probe returns to its initial position and if needed, a new imaging run can be initiated. The acquired images are available for immediate

review and analysis in short axis, long axis, and 3D view. The current generation imaging display system can coregister the angiography and OCT images for better understanding of coronary anatomy and lesion characteristics.

OPTICAL COHERENCE TOMOGRAPHY INTERPRETATION IN INTRACORONARY IMAGING

Optical coherence tomography images have been validated against histology for accurate analysis of normal vessels as well as plaque composition, including fibrous cap thickness, lip core assessment, macrophage accumulation, calcification, and neovascularization.⁴ OCT has been found to have a 10 times higher axial ($\approx 10 \mu\text{m}$) and lateral resolution ($\approx 30 \mu\text{m}$), but lower penetration depth (1–3 mm) compared with IVUS.⁵ Therefore, visualization of the complete depth of a lesion is difficult especially in the presence of lipid-rich tissue.

The different vascular tissue layers have variable back-scattering and attenuation properties as they interact with infrared light. High backscattering by a tissue gives it a high-pixel intensity [bright picture, Internal and external elastic lamina (EEL), fibrous tissue] whereas low backscattering will be seen as a darker, low pixel intensity region (media layer and calcium). The second interaction that defines tissue is attenuation. A high attenuation means the light cannot penetrate to deeper tissue (lipids and red thrombus) whereas low attenuation means light passes through the tissue to deeper layers that can be seen in images (calcium, fibrous tissue). Other features used in image interpretation are homogeneous versus heterogeneous composition (fibrous plaque and lipid versus calcium respectively), sharp versus diffuse edges (calcium versus lipids). Further, due to high axial and longitudinal resolution, OCT allows for measurement of thickness and arc of tissues. OCT has also been used to identify atherosclerotic plaque with high-risk features such as thin fibrous cap, cholesterol clefts and increased macrophage infiltration (irregular bright structures in intima).⁶ The ability of OCT to detect the composition of tissue is based on the certain characteristic light interaction patterns.⁷ Normal coronary arterial segments in OCT images appear as a three-layer structure with bright internal and EEL with a thin layer of low-intensity media in between. The adventitia is identified with the tissue beyond EEL and vasa vasorum within it. Abnormal segments can be classified as:

- *Fibrous plaque*: Finely textured homogeneous, high back-scattered (signal-rich bright image) with low attenuation, (bright image with visualization of intima, media, and adventitia in the entire vessel thickness)
- *Calcific plaque*: Sharply bordered region with heterogeneous low backscatter and low attenuation (heterogeneously darker region with sharp borders and visible deeper layers)
- *Lipid-rich plaque*: High attenuating, signal poor region with poorly defined borders. High backscatter on the surface and poor backscatter under it. The intima

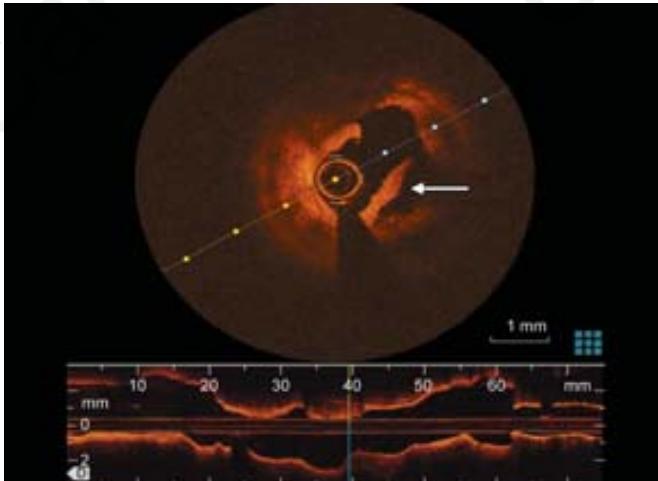

FIG. 1: Ruptured plaque.

media may not be visible beyond the lipid content of plaque (bright fibrous cap with diffuse homogeneous darker image underneath and indistinct edges and no visualization of deeper structures)

- *White thrombus:* Low attenuating, poorly defined mass “floating” with high backscatter, in the vessel (bright tissue with irregular edges seen on the surface with complete visualization of deeper structures). The white thrombus consists of platelets and white blood cells
- *Red thrombus:* High backscatter on the surface with high attenuating irregular mass attached to vessel wall that casts a shadow on wall behind mass (a bright surface structure with darker deeper nonvisible tissue). The red thrombus is rich in fibrin and red blood cells.

Artifacts seen with OCT can include residual blood in the vessel lumen or swirl; blood inside the probe; non-uniform distortion; fold over, saturation or sew-up artifact; and Z-offset drift. All of these artifacts are relatively uncommon with the exception of residual blood in the lumen and blood inside the probe. The first one is easily remedied with better contrast injection, and the second one by simply flushing the OCT catheter. Some of the artifacts in OCT are due to guidewire, stent struts (ghost reflection artifacts) or due to catheter and/or arterial rapid movement [stitching artifact/image malalignment (Fig. 2)].⁷

Vulnerable Plaque Assessment

Optical coherence tomography has an advantage over IVUS for identification of vulnerable plaque. High-resolution images of bright fibrous tissue obtained by OCT make it possible to accurately measure the thickness of the fibrous cap in μm . Further, easy identification of a lipid core with thin fibrous cap ($<65 \mu\text{m}$) defines a thin-cap fibroatheroma (TCFA) as vulnerable plaque (Figs. 3 and 4). In addition, OCT may be able to identify the mechanism of acute coronary syndrome (ACS) by identification of plaque erosion (intact intima with white thrombus) versus plaque rupture (loss of integrity of intimal layer with white or red thrombus in the lumen).

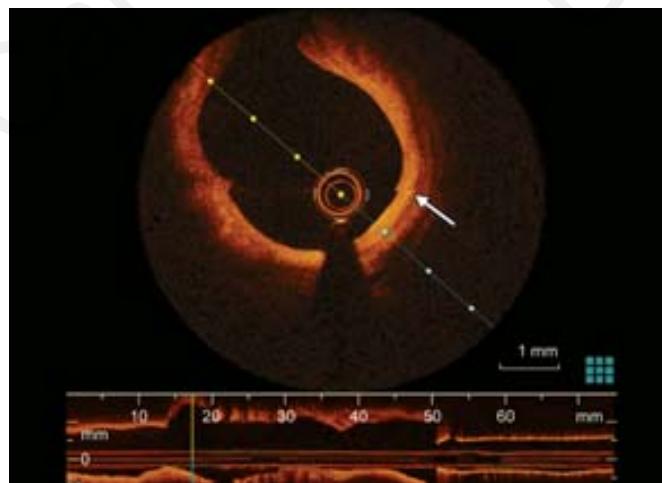

FIG. 2: Stitching artifact.

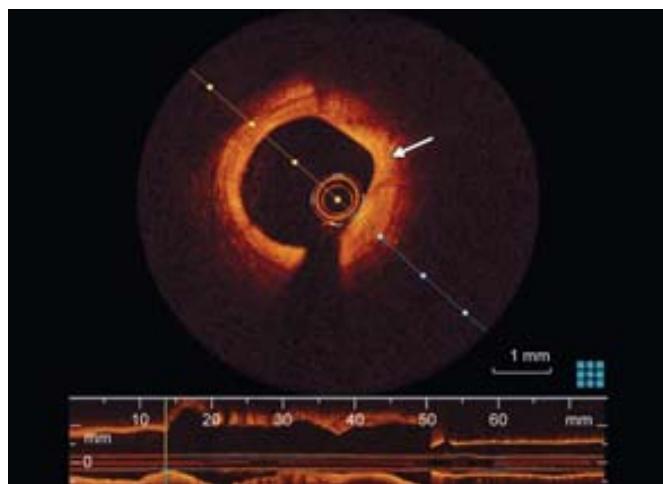

FIG. 3: Fibrotic plaque with thick fibrous cap.

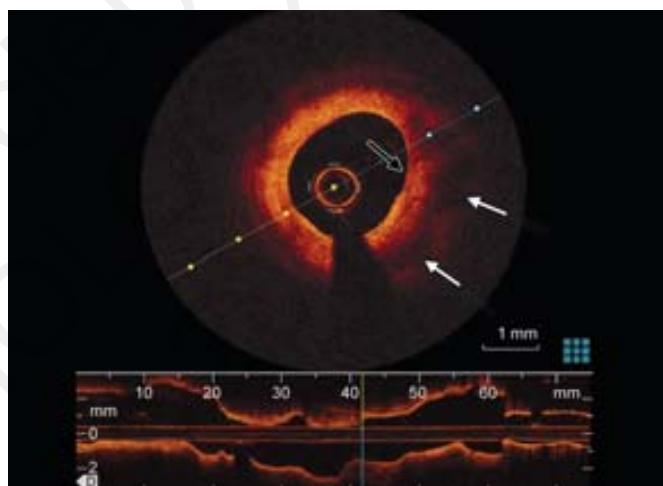

FIG. 4: Fibrotic plaque with lipid core (white arrows) and thin fibrous cap (black arrow).

OPTICAL COHERENCE TOMOGRAPHY VERSUS INTRAVASCULAR ULTRASOUND

Optical coherence tomography as an imaging modality has certain distinct advantages and disadvantages compared to IVUS, which may be useful in evaluation of specific clinical settings.

Advantages

- Optical coherence tomography images are easy to interpret and system interface is superior due to very rapid automatic analysis and display of stents with lumen profile
- Near-field spatial resolution is 10 times higher compared with IVUS, which allows for more accurate assessment of vulnerable plaque, coronary dissection, stent edge dissections, tissue coverage of stent struts, and stent malapposition (Fig. 5)
- Determination of calcium thickness (which is not possible with IVUS); total calcium arc more than 180°

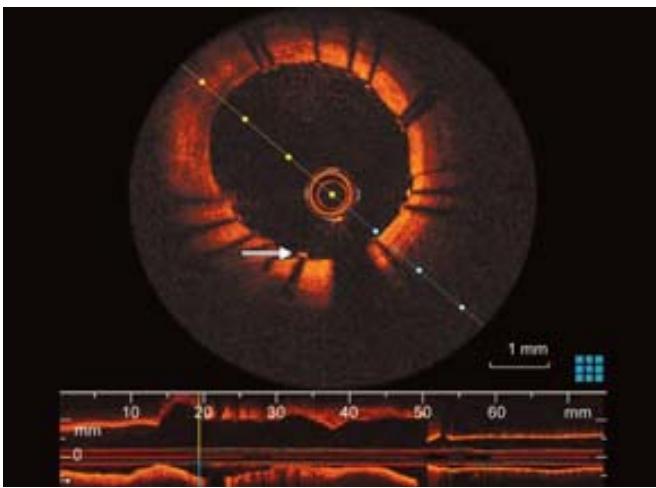

FIG. 5: Stent strut malapposition.

and increased calcium thickness more than 0.5 mm are all associated with greater risk of stent under-expansion. Therefore, one may need to aggressively predilate after rotational atherectomy, prior to stent placement

- Accuracy of identification of white and red thrombus (identification of mechanisms of ACS), stent failure (stent thrombosis and restenosis)
- Guidance of bioresorbable scaffold implantation
- Optical coherence tomography offers better accuracy for stent apposition and edge dissection during PCI
- Optical coherence tomography offers the ability to measure full volumetric lumen analysis due to high resolution of longitudinal view compared with IVUS, resulting in greater accuracy for selection of stent size.⁸

Disadvantages of Optical Coherence Tomography

- Additional contrast load in patients with renal insufficiency increases the risk of contrast-induced nephropathy
- Swirling artifacts created by inadequate clearance of blood from the arterial lumen by inadequate injection, larger arterial lumen size or rapid blood flow
- Since contrast detection at the optical probe is necessary to initiate pullback, predilation of the lesion may be necessary preintervention in cases with obstruction by the catheter
- Inability to assess aorto-ostial lesions (left main or right coronary artery) as proper catheter engagement is needed for adequate contrast flush
- Depth penetration is limited, so the recommended size of the vessels is less than 3.5 mm
- Optical coherence tomography cannot identify EEL area accurately in lipid-rich plaques or larger arteries. IVUS enables better EEL visibility compared to OCT, and therefore leads to “more aggressive” stent sizing with larger minimum stent area (MSA) during PCI compared to OCT^{9,10}
- There is limited clinical outcome data for OCT-guided versus angiography-guided PCI. The only major study

looking at this is a recently published observational trial.¹¹

CORRELATION OF OPTICAL COHERENCE TOMOGRAPHY WITH FRACTIONAL FLOW RESERVE

Although OCT is an excellent tool to assess atherosclerosis, it is limited in its inability to assess the functional significance of moderate coronary atherosclerotic lesions. Although, minimal luminal area (MLA) or minimal luminal diameter (MLD) by OCT has limited correlation with fractional flow reserve (FFR), except in the case of the left main coronary artery.¹²⁻¹⁴ OCT-derived MLA thresholds have reasonably high-positive predictive value (80–92%) but lower negative predictive value for physiological significance of coronary artery stenosis (66–89%).¹⁵⁻²⁰ Therefore, PCI based on OCT-derived MLA alone is not routinely recommended.

CLINICAL UTILITY OF OPTICAL COHERENCE TOMOGRAPHY IMAGING

Clinical utility of OCT in diagnosis of coronary artery disease is limited to:

- Angiographically ambiguous lesions (e.g., dissection, thrombus, calcified nodule)
- Assessment of left main stenosis (except ostial) especially with distal lesions in the left anterior descending (LAD) or left circumflex (LCX) arteries, which may make FFR assessment difficult or uncertain.
- Suspected culprit lesion of ACS to identify plaque erosion versus rupture, which may identify some erosion in patients, who can be treated medically without stent implantation.
- Rate of periprocedural complications with stent implantation (malapposition, stent thrombosis, no reflow).
- Complex bifurcation lesion for preprocedure planning.

Utility of Optical Coherence Tomography in Procedural Planning of Percutaneous Coronary Intervention

The use of OCT or IVUS should be considered for PCI planning and optimization in patients undergoing interventions for chronic total occlusion, long lesions, left main lesions, bifurcation stenting with two stents, and in calcified lesions. If OCT is used in such scenarios, the guidelines recommend a set of parameters for stent selection and optimization.

Lesion Preparation

As stated earlier, OCT has higher tissue penetration into calcium compared to IVUS.^{21,22} Accurate assessment of thickness and length of calcified plaque can guide decision making about lesion preparation. Regular or scoring balloons can fracture thin, concentric calcium. On the other hand, for concentric and thicker calcified plaque, atherectomy versus aggressive predilatation with noncompliant balloons

may be considered. For lipid-rich plaque, predilation with an undersized balloon or a direct stenting strategy may be employed.

STENT SELECTION (DIAMETER AND LENGTH)

Stent Diameter

Stent underexpansion is an important predictor of early stent thrombosis and restenosis after drug-eluting stent (DES) implantation. Based on the currently available data from the ILUMIEN III trial and OPINION (the OPTical frequency domain imaging vs. INtravascular ultrasound in percutaneous coronary Intervention) study, the best approach for stent size selection by OCT is to use distal lumen reference (less aggressive to more aggressive: mean distal lumen diameter, mean distal EEL diameter if two orthogonal measurements feasible or a single distal EEL diameter).^{23,24} The stent size can be chosen as 0.25 mm up if one uses lumen diameter versus rounded down if one uses EEM diameter (3.30 mm mean lumen diameter will need 3.5 mm stent vs. 3.30 mm EEL will need 3.0 mm stent). Subsequent dilatation of the mid and proximal part of the stent can be done to optimize stent expansion in these segments. Intravascular imaging results in implantation of larger diameter and length of stent, and larger final in-lesion minimum lumen diameter compared with angiographic guidance.^{25,26} When comparing IVUS versus OCT guidance, if you size by distal lumen diameter, OCT guidance leads to around 10% lower diameter; a small but significant difference in the average stent size (OCT 2.92 ± 0.39 mm versus IVUS 2.99 ± 0.39 mm, $p = 0.005$) with no effect on long-term angiographic follow-up. If one uses EEM diameter then there is no difference in stent size when using OCT vs. IVUS guidance.²⁴ It has also been shown that luminal volumetric dimensions measured by OCT resulted in smaller MSA and lower stent expansion with OCT compared to IVUS.⁹ Other studies have shown that OCT guided PCI resulted in smaller MSA, smaller stent diameters, and smaller maximum balloon diameters compared to IVUS guided PCI.^{10,24,27} One strategy that has been suggested for OCT-guided PCI is to measure reference diameters pre-PCI to guide stent sizing, deploy the stent, assess angiographic success (postdilate if needed), and then repeat OCT prior to completion of procedure.²³

Stent Length Selection

Optical coherence tomography can aid in stent length selection by showing regions of the coronary artery with eccentric calcification or lipid-rich plaque (>50%) at the proximal or distal edge of the proposed stent implantation. As such defining the normal coronary segment helps avoid edge dissection and stent complications. The coregistration of angiography and OCT can be used as a clinical tool to optimize stent implantation by selecting appropriate landing zone and length of the stents, thereby resulting in a trend toward reduced major stent edge dissection.

OPTIMIZATION AFTER STENT DEPLOYMENT

Stent Expansion

Whether adequate stent expansion should be defined by imaging modalities as absolute area or relative area (relative to reference segments) remains controversial. In general, greater achievable absolute stent expansion by OCT or IVUS results in improved long-term stent patency and better clinical outcomes. Based on the available data, large percentage of patients (~50%) do not achieve strict predefined relative reference criteria for stent expansion in randomized controlled trials with both IVUS and OCT. These did not translate proportionally into worse clinical outcomes. Therefore available evidence would suggest that an absolute MSA of more than 4.5 mm^2 by OCT and more than 5.5 mm^2 by IVUS and relative MSA more than 80% of the mean reference segment area should be considered adequate stent expansion in non-LM lesions. This cutoff may not be achievable in small vessels or may result in stent under-expansion in large vessels. In left main coronary artery (LM), based on IVUS studies the MSA should be more than 7 mm^2 for distal LM and more than 8 mm^2 for proximal left main. OCT with lumen profile in longitudinal view allows easy detection of stent under-expansion with rapid automatic calculation of the luminal stent area at the potential under-expanded stent site in reference to distal and proximal reference segment. OCT-angiography coregistration can help in identification of the under-expanded stent segments, which can then be postdilated appropriately. Accurate postdilation of only the under-expanded stent segment helps to avoid unnecessary postdilatation, especially near stent edges, thereby lowering the risk of edge dissection.²⁸

Stent Malapposition

Acute stent malapposition (the lack of contact of stent struts with the vessel wall) is common as detected by OCT, with studies showing an incidence of 39–84% compared to IVUS (~15%).^{29–32} OCT has a better resolution than IVUS to measure accurately the axial distance of stent strut from the vessel wall [incomplete stent apposition (ISA) distance] and its longitudinal extent. It is more common when stent is placed in a tortuous segment of the artery. Acute stent malapposition may resolve by neointimal tissue growth if the ISA distance is less than 0.4 mm and the length of malapposition is less than 1 mm.³³ However, the findings of three large OCT registries of stent thrombosis have shown higher incidence of malapposition in acute, subacute as well as late stent thrombosis.³⁴ Therefore, it may be prudent to avoid extreme malapposition and correct it safely at the time of stent implantation when anatomically feasible. Late acquired malapposition (due to positive remodeling) is difficult to diagnose unless intravascular imaging was done at the time of initial stent placement; but has been identified as a cause of late and very late stent thrombosis.

Tissue Prolapse

Optical coherence tomography is superior in detection and identification of tissue characteristics of the material found protruding through stent struts into lumen (tissue prolapse). It is more common in patients undergoing PCI for ACS with plaque rupture than chronic stable plaques or ACS with plaque erosion. Although, large tissue prolapse (definition unclear) is related to acute stent thrombosis and periprocedural complications but there are no guidelines for the management of small tissue prolapse.³⁵

Edge Dissection

Optical coherence tomography due to its high resolution is ideal in identifying edge dissections as well as in-stent dissections. Based on the randomized and observational studies of routine OCT imaging post stent implantation, minor edge dissections are very common (20–40%), do not portray adverse clinical outcomes and do not require routine additional intervention. In contrast large edge dissections with more than 60° arc, more than 2 mm length, involving the medial or at the distal edge should be treated with additional stenting.^{36,37} Identification of intramural or extramural hematoma at the stent edge by OCT should also be treated to reduce acute stent thrombosis.

Bioabsorbable Stent Implantation

Due to currently available technology of bioabsorbable stent (thick stent struts and low radiopacity), proper identification of lesion morphology by OCT is very important in stent selection. OCT also provides the poststent implantation optimization to avoid stent underexpansion and malapposition.

CONCLUSION

In comparison to IVUS, OCT imaging clearly has an advantage in assessment of plaque morphology; is as good as IVUS in guiding the optimization of PCI procedure; is better in evaluation of stent-related complications but has limited clinical data to date. However, the coronary images obtained are simple to acquire and can be learned to interpret. Familiarity with image interpretation and advancement in technology such as coregistration of angiography, 3D OCT and FFR as well as 3D reconstruction of implanted stent will only further enhance our comfort for its use in routine clinical practice because it clearly has a role in improvement in short- and long-term clinical outcomes in patients with coronary artery disease.

Stem Cells in Cardiovascular Disease: Is there an indication?

Vijay Iyer

INTRODUCTION

Cardiovascular disease remains the leading cause of death worldwide, getting 17 million people each year.¹ The World Health Organization estimates that by 2020 this number reached 24 million.^{2,3} With complex multifactorial pathologies, including both genetic and environmental factors, cardiac disease continues to be difficult to prevent. Current strategies against cardiac vessel disease into prevention, i.e., the effectiveness of drug strategies, vary among individuals, and surgical intervention is not be applicable to all patients. New approaches need to be established to better understand the mechanism for coronary vessel disease and improved diagnostic and therapeutic 70s, particularly in the context of heart failure (HF), lifestyle changes, and pharmacological and/or surgical intervention.

Over the last 20 years, there has been interest in harnessing and promoting the innate and regenerative ability of injured organs to treat disease. The exciting preclinical findings in stem cell biology and the growing expertise and cell isolation and handling has increased interest in cell-based therapy for cardiovascular disease.⁴ In more than 200 clinical trials and 50 meta-analysis we have improved our understanding off the potential use of stem cells for improving cardiac function. Despite the lack of a trial that conclusively demonstrates clinical efficacy, this safety and feasibility of several different cell types are now established. This field is now placed to anchor the next phase of trials that most likely will pave the pathway for a cell-based therapy with efficacy.

There is a dire need for therapies for cardiovascular disease due to the increasing number of patients worldwide. HF continues to be a major problem worldwide and despite the use of evidence-based therapies, such as angiotensin-converting enzyme inhibitors, beta-blockers, and mineralocorticoid receptor antagonist and angiotensin receptor neprilysin inhibitors mortality continues to be unacceptably high. Furthermore, drug therapy for HF is efficacious only in a subset of patients with no appropriate therapy for preserved ejection fraction or for worsening chronic HF.

The traditionally held opinion was that the heart is a terminally differentiated organ with little to no regenerative capacity. This changed after the identification of a small resident population of multipotent cardiac stem cells (CSCs) reframing the heart has an organ that the capacity for self-renewal. It is now understood that although they are terminally differentiated cells, there is a 1-2% cardiomyocyte turnover per year in childhood.^{5,6} However, the heart is unable to adequately compensate in the face of overwhelming cardio myocyte loss seen in acute myocardial infarction (AMI) and HF. Stem cells, defined by the inability to self-renew and differentiated into at least one of the cell type were investigated as a means to directly replace lost myocardium and stimulate endogenous repair. This review will focus on the clinical data available from trials in stem-cell therapy.

CHALLENGES IN CELL THERAPY

The field of stem-cell therapy applied to clinical cardiovascular problems as some significant challenges. The challenges are listed in box 1.⁷

The potency of injected cells is often poor diminishing their inability to be effective in larger animal studies and in humans. Current approaches have attempted to precondition these cells by culturing them in hypoxic medium, by the addition of several growth factors like transforming growth factor (TGF), vascular endothelial growth factor (VEGF), and fibroblast growth factor (FGF) as well as the proto-oncogene Pim-1. Additional approaches have been combined two different types of cell types to improve the potency.

A second major problem with cardiac regeneration therapy has been the poor engraftment under tension-off the administered cells. The approaches being used to overcome these include repeated injections of cell types in therapy, the administration of cells by electro anatomic directed trans-endocardial injection instead of coronary artery infusion, the use of a bio-matrix to enhance cell engraftment.

BOX 1**Challenges in cell therapy for cardiovascular disease**

- Selection of cell recipient
- Selection of cell donors
- Selection of appropriate cells
- Route and method of delivery
- Retention of stem cells
- Optimizing cell potency
- Determining the optimal dose and number of doses of cells
- Creating bio scaffolds to help delivery of cells
- Standardization of preclinical studies to help measure the appropriate end points in clinical trials
- Determining the optimum timing of cell administration.

CELL TYPES AND MECHANISMS

The early studies of therapy hypothesized that transplanted cells could differentiate into myocytes and therefore regenerate the myocardium. This however appears to be a rare event in larger animal studies and in humans.^{8,9} Even in the studies that have shown improvement in myocardial function, i.e., little evidence that cells have engrafted.⁹ This has shifted the focus to paracrine mechanisms as the main mode of benefit from stem cells.¹⁰ The multitude of mechanisms proposed include secretion of growth hormones, cytokines, metalloproteinase, exosomes, and mitochondrial transfer. A number of adverse cardiac remodeling events occur in damaged myocardium that include imbalanced extracellular matrix turnover and fibrosis, acute and chronic inflammation, oxidative stress, abnormal energy metabolism, and oxygen consumption, increased apoptosis, endothelial dysfunction and reduced vasculogenesis, all of which are targets for stem-cell therapies. It is very likely that different cell types have different mechanisms by which they may have a positive benefit. Preclinical studies to investigate these are continuing.

The paracrine mechanism of stem cell benefit was derived from early studies that showed that bone marrow-conditioned medium, i.e., cell-free medium in which bone marrow cells had been cultured, acquired VEGF and monocyte chemoattractant protein from the cultured cells.¹¹ Additionally, the transendocardial injection of autologous bone marrow into place with induced myocardial ischemia increased collateral perfusion and improved function in the ischemic myocardium presumably because of the above-mentioned growth factors.¹² Additional studies, both in small and larger animals with coronary occlusion suggested that cell-free mesenchymal cell culture medium alone was able to provide the same benefit as the stem cells themselves. All of these together have supported the paracrine mechanism of action of stem cells.

It is now believed that the transfer of cytokines, chemotherapy cues, and growth factors from stem cells is mediated by small extracellular vesicles called exosomes.¹³ These are of endosomal origin within a lipid bilayer and are between 30 and 120 nm in diameter. Some current

approaches are targeting exosomes as possible drug delivery vehicles that can be produced in robust quantities *in vitro* by immortalized stem cells.

Early studies are stem cells in clinical trials were primarily derived from adult sources such as bone marrow and adipose tissue. There were often delivered as unfractionated populations of cells or as purified unmodified single cell types. The early trials of unfractionated bone marrow mononuclear cells which is a heterogeneous population comprising mesenchymal stem cells, endothelial progenitor cells and hematopoietic stem cells were largely neutral but safe.¹⁴

The next generation of cell therapies included progenitor cells isolated from cardiac tissue, allogeneic cell products, human pluripotent stem cells, and stem cells that have been lineage directed via chemical or genetic treatments to take on a specific cell phenotype. This group includes c-Kit+ (CD 117+) CSCs and cardiosphere-derived cells (CDC). CSCs are derived from adult hearts and displays strong paracrine signaling and demonstrate multi-lineage trans-differentiation *in vitro*.¹⁵ CDCs are a heterogeneous population of cells derived from myocardial tissue that form self-adherent clusters *in vitro* and include both CSCs and supporting cells among others. Lineage-directed cells are those that have been treated to express a specific phenotype. These bone marrow-derived mesenchymal stem cells were treated with a cocktail of trophic factors to elicit a cardiac phenotype. The cells are typically isolated from young healthy donors and can be saved for later delivery and delivered as an off-the-shelf product, eliminating the need for long waiting periods required to expand autologous cell populations.¹⁶ More recent approaches have included pluripotent cells such as embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs).

CLINICAL TRIALS WITH STEM CELLS

There have been a number of clinical trials utilizing stem cells in AMI, ischemic cardiomyopathy, and nonischemic dilated cardiomyopathy. These trials are summarized in Tables 1–3.¹⁷

Clinical trials in stem-cell therapy in cardiovascular medicine often preceded a clear understanding of the mechanism of actions of the cell types being utilized. The consequence of this was that the endpoints chosen in these trials were probably inadequate or inappropriate. A number of these trials utilized surrogate endpoints. A surrogate endpoint is a functional or biochemical marker that substitutes for a clinical endpoint but is expected to predict clinical benefit based on evidence. The benefit of a surrogate endpoint is that it can overcome some of the financial burden associated with large sample size needed for clinical endpoints.

In HF trials a number of endpoints having utilized that include left ventricular ejection fraction (LVEF), left ventricular end-systolic, and end-diastolic volume. These surrogate endpoints often predict mortality in HF trials.¹⁸ In addition patient functional status and quality of life (QoL) or important markers and HF trials and often reflect the symptomatic burden of the HF syndrome. A number of tools having utilized to assess QoL among HF patient's and include

allo, allogeneic; ADRCs, adipose derived regenerative cells; auto, autologous; BMMNCs, bone marrow mononuclear cells; BM-MSCs, bone marrow derived mesenchymal cells; CDCs, cardiosphere derived cells; cMRI, cardiac magnetic resonance imaging; CPCs, circulating progenitor cells; CT, computed tomography; echo, echocardiography; EDV, end diastolic volume; EF, ejection fraction; ESV, end systolic volume; IC, intracoronary; IV, intravenous; LV, left ventricle; LVEF, left ventricular ejection fraction; n, number of patients; NA, not assessed; NS, not significant; NYHA, New York heart association; QoL, quality of life; SPECT, single-photon emission tomography; TESI, transendocardial stem cell injection.

the Minnesota living with HF questionnaire and the Kansas City cardiomyopathy questionnaire. Markers of symptoms and functionality such as the New York Heart Association class and the Canadian cardiovascular society score for angina are also important endpoints especially in refractory angina trials. The measurement of infarct size has been an important endpoint in some AMI trials. The assessment of this is typically done with echocardiography or magnetic resonance imaging. The use of serum markers like B-type natriuretic peptide and N-terminal pro B-type natriuretic peptide is also being utilized in the HF trials.

Most trials that have been recently designed have measured a multitude of endpoints that will allow us to understand how best to design the next phase of clinical trials. The utilization of surrogate endpoints in early face trials is reasonable but the next phase of trials will need to measure heart endpoints such as mortality, cardiovascular events and hospitalizations. These will obviously require adequately powered longitudinal placebo control studies.

Trials in Acute Myocardial Infarction

Early trials in cell-based therapy were in the clinical area of AMI. Most trials were designed around the concept of cardioprotection with the intent of using intracoronary infusion of stem cells in addition to percutaneous intervention in the setting of AMI. The early trials used bone marrow derived mononuclear cells which were harvested from patient's 1–12 days after percutaneous intervention

and delivered the same day. TOPCARE-AMI and BOOST evaluated bone marrow to mononucleosis is delivered an average of 5 days after AMI.^{19,20} Trials reported improvement in LVEF in the treatment during a short follow-up period. REPAIR-AMI was the largest trial for AMI and was designed to assess the efficacy of bone marrow mononuclear cells. This study randomized patients receiving cells or placebo 3–7 days after AMI. At 4 months, LVEF was significantly improved with an average 5.5% in the cell therapy group compared with only 3% in the placebo group. At 1 year the composite of death, myocardial infarction and need for repeat revascularization, was lower in the cell therapy group. This effect on mortality, but not improvement in LVEF was maintained at 5 years.

A number of subsequent trials including TIME, Late TIME, SWISS-AMI, BOOST-2 and MiHeart/AMI have not been able to demonstrate improvement severe left ventricle systolic function and response to cell therapy.^{21–25} Most of these trials used different populations of bone marrow-derived cells. Significantly these trials utilized cardiac magnetic resonance imaging (MRI) as the standard for assessing left ventricular systolic function. Subsequent treatment analysis have shown that trials of utilized echocardiography as a marker of LVEF demonstrated improvement in left ventricular systolic function one that have utilized cardiac MRI (disease which is considered medical center for evaluating left ventricular function) have not demonstrated a benefit of several therapy in improvement in left ventricle systolic function in the setting of AMI. These findings suggest that the trials to follow should

utilize cardiac MRI as the preferred modality of assessing left ventricular systolic function both for regional and global function.

Bone marrow mononuclear cells have not shown much efficacy and recent trials suggesting that mesenchymal stem cells may be more appropriate candidates. A number of smaller phase II studies have shown promise in the utilization of mesenchymal stem cells in the setting of AMI.

Trials in Refractory Angina

With improvements in percutaneous revascularization as well as coronary artery bypass grafting the persistent problem of a large number of people who cannot be adequately revascularized and have refractory angina is growing. Stem cells at an attractive option for these patients since therapy shown to stimulate neoangiogenesis and improve perfusion. This population of cells studied with a CD34 positive circulating progenitor cells that showed a reduction in angina frequency compared to the placebo group after 12 months. The RENEW trial utilizing autologous CD34 positive cells isolated from peripheral blood enrolled 112 patients and demonstrated improvement in total exercise time at 3 months and an reduction in angina frequency at 6 months compared to patients treated with placebo only.²⁶⁻²⁸

There has been subsequent treatment and allergies all 6 trials using stem cells refractory angina utilizing CD34 positive cells suggesting a reduction in number of angina episodes and improved exercise tolerance as well as myocardial perfusion. Therefore, despite the fact that no single trial has shown an improvement in mortality this may be a therapeutic option for some patients for refractory angina.

Trials in Ischemic Cardiomyopathy

Ischemic cardiomyopathy offers the most promising area of therapeutic benefit with cell-based therapy. Most of these patients have a chronic syndrome secondary to loss of myocyte function and the cellular renewal of degenerated myocytes in this setting is most likely to offer both a mortality and symptomatic benefit.

Clinical trials and ischemic cardiomyopathy utilized a number of different kinds of cell types that include bone marrow-derived mononuclear cells and second-generation cells. Early trials also utilized skeletal myoblasts that were injected into the myocardium at the time of coronary artery bypass surgery. However, the cells were shown to be extremely arrhythmogenic and this approach has since been abandoned.²⁹

The earliest trial of bone marrow-derived mononuclear cells in congestive HF patient's utilized direct injections after electromechanical mapping into areas of infarct. These trials suggested an improvement in left ventral systolic function by 9% and reduction in left ventricle and systolic volume and scar sites.^{29,30} The endpoint of exercise capacity was also significantly improved at 6 months and 12 months. A number of the other trials have been summarized in table 1. Meta-analysis of trials utilizing bone marrow-derived mononuclear cells in ischemic cardiomyopathy does reveal

an improvement in left ventricle systolic function. The cells however may not have significant efficacy in older patients as a consequence more recent trials are investigating more purified cell types, allogeneic transplants and combination of cells.

Mesenchymal some cells from the bone marrow are also excellent candidates for regenerative therapy since the exhibit a fourfold constellation of phenotypic activity that includes immunomodulation, antipyretic effects, stimulation of new angiogenesis, and activation of endogenous cardiac repair pathways. Most of these effects are thought to be because of paracrine mechanisms. The early trials involving autologous mesenchymal stem cells are summarized in table 2.³¹⁻³³ Subsequently, allogeneic stem cells were also tested these trials collectively showed improvements in left ventricular remodeling improvements in QoL, functional status, and in some cases also improvement in left systolic function. Stem cells derived from umbilical cord who also been tested in trials with variable results.

Adipose-derived regenerative cells were tested in a number of trials that were essentially neutral or negative.

Cardiac stem cells similar to mesenchymal stem cells secrete cytokines and growth factors. Incomplete clinical models there appeared to be beneficial and was subsequently tested in phase I trials in humans. In small numbers of patients improvements in left ventricle systolic function were seen. These trials were early and did utilize cardiac MRI for evaluation of left ventricular function and the newer trials utilizing CSCs will be testing these effects more rigorously.^{34,35}

Cardiosphere-derived cells are a promising mixture of cells that are rich in the CD-105 cell surfaces marker and demonstrate a paracrine effect, i.e., probably more potent than the CSCs. The CADUCEUS trial was a proof of clots of trial and 33 patient's vancomycin received autologous CDCs or standard of care. In no myocardial biopsies were performed to obtain samples and CDCs were grown. The cells were delivered within intracoronary infusion one and a half to 3 months after myocardial infarction. Cardiac MRI showed reductions in myocardial scar size in the treatment arm. A subsequent trial, ALLSTAR, utilized a similar strategy in patients with left ventricular dysfunction secondary to a myocardial infarction within the last 12 months. However, this trial was halted early due to lack of benefit.

Cardiopoietic stem cells are second-generation therapeutic cells that include mesenchymal stem cells that have been treated to optimize to cardioprotective functions. The cells were tested in patients with ischemic cardiomyopathy and ejection fraction of less than 35%. The composite endpoint that included mortality, worsening HF, 6 minute walk distance, left ventricular end-systolic volume and LVEF measured by echocardiography did not show any difference between the sham and the cell therapy groups. However, in those patients who had a baseline larger than left ventricular end diastolic volume there appeared to be a positive reduction in both end-diastolic and end-systolic volume in the cell treated. This further highlights that selective populations of patient's might benefit even within these clinical trials that have shown to be overall negative.¹⁶

A number of preclinical studies have shown that combinations of stem cell types especially mesenchymal stem cells and cardiopoietic stem cells have a synergistic effect in the cardiac repair process.⁴ These combinations are being tested in randomized controlled trials in patients with ischemic cardiomyopathy.

The interpretation of trials and ischemic cardiomyopathy is fraught with confusion because of the different endpoints being utilized. It is important to assess just mortality and LVEF improvements but also recurrent cardiovascular events, QoL, and functional status improvements since they're equally meaningful.

NONISCHEMIC DILATED CARDIOMYOPATHY

Nonischemic cardiomyopathy is marked by a significant immunological component, a lower scar burden and a larger proportion of dysfunctional viable myocardium. This makes it a potential therapeutic target for cell-based therapy. Cardiac MRI studies that have measured scar volume and the extent of dysfunctional viable myocardium have shown that dysfunctional viable myocardium is an independent predictive improvement in LVEF, wall motion score and end-systolic volume index. Stem-cell therapies are known to work in part because of immunomodulatory signaling and reversal of myocardial dysfunction. Theoretically, this would suggest that nonischemic cardiomyopathy would be a good therapeutic target for cell-based therapies. The number of trials in nonischemic cardiomyopathy is relatively smaller compared to those in AMI and ischemic cardiomyopathy and summarized in table 3.³⁶⁻⁴²

These trials included the use of bone marrow-derived mononuclear cells, CD34 positive cells from peripheral blood, allogeneic, and autologous bone marrow derived mesenchymal stem cells. Many of these trials have shown improvements in LVEF. The changes and left ventricular volumes have been more variable as have changes in functional status and functional capacity.

FUTURE DIRECTIONS IN CELL THERAPY AND LESSONS LEARNED

It is important to recognize that cell-based therapy has only been investigated over the last 20 years. This is a relatively small period of time and the field is still very young. The early irrational exuberance has been tempered by some of the neutral and negative outcomes of trials. However, it is extremely promising that in most of these trials so far therapy has been shown to be extremely safe. In many of these trials that are somebody positive outcomes that give us hope for future trials. Preclinical work on understanding the mechanism of action continues to grow and will help us decide better trials with more specific endpoints that can be measured. The different kinds of stem cells being studied is also increasing. The iPSCs are specifically of great interest since they alleviate a number of ethical and availability concerns. The preclinical

work with the cells is progressing rapidly and clinical trials with the cells are very close.

The experience with the trial so far has enhanced our understanding of the paracrine mechanism of benefit from the cells as well as the possible need for repeated dosing like drug therapy. In conclusion stem-cell-based therapy for cardiovascular disease continues to remain an exciting area of research and in combination with advances in bioengineering scaffolds and the understanding from preclinical work, will most likely provide exciting results in the near future that will add to the armamentarium of therapies available for patients with cardiovascular disease.

It is important that there are no current guidelines which approve the stem cells for use routinely in cardiovascular disease. Therefore, patients should only be treated within the confines of appropriate randomized control trials.

Future of Interventional Cardiology

VK Bahl, Dinkar Bhasin

INTRODUCTION

It has been over 40 years since the first percutaneous coronary intervention (PCI) was done and 15 years since transcatheter aortic valve replacement was developed. These procedures have evolved considerably and have likely reached peak levels of safety and efficacy. The focus of interventional cardiology has now shifted to novel therapies for other forms of structural heart disease. Herein, we review the new interventional technologies on the horizon.

PERCUTANEOUS MITRAL VALVE THERAPIES

Surgical repair of mitral valve (MV) is often successful but, in contemporary practice, patients with severe mitral regurgitation (MR) have several comorbid conditions which increase the risk of surgical therapy. Hence, arises the need for safe and efficacious percutaneous therapies for MV. Technologies have been developed for both primary and secondary MR and these device systems target the various components of MV apparatus including the valve leaflets, annulus, chordae, and ventricular attachments. The most widely studied device is MitraClip (Abbott Vascular) which has been compared in a randomized control trial (RCT) to surgical therapy, while evidence for other devices is either preclinical or preliminary.

MitraClip involves implantation of 1–4 mm V-shaped clips across anterior and posterior mitral leaflets, approximating them and converting a single large regurgitant orifice into two small orifices. The procedure is done under transesophageal echo and fluoroscopic guidance. A 24Fr delivery sheath is introduced into left atrium (LA) via trans-septal puncture. A single clip is generally sufficient for functional MR while degenerative MV disease often requires at least two clips for additional stability. The EVEREST II trial compared MitraClip with surgical therapy and showed that with MitraClip there were increased rates 3+ to 4+ MR (12.3% vs. 1.8%; $p = 0.02$),

higher rates of surgery (27.9% vs. 8.9%; $p = 0.003$) but similar 5-year mortality rates (20.8% and 26.8%; $p = 0.4$).¹ Currently, MitraClip is considered a class IIb recommendation in patients who are not operable or at high risk with surgery.^{2,3} The PASCAL device (Edwards Lifesciences, California, USA) is a similar device that allows each MV leaflet to be grasped independently followed by apposition. It has been used on compassionate grounds in patients with severe MR which is not suited for repair with MitraClip.⁴

Devices targeting the chordal apparatus include the NeoChord DS1000 (Neochord, Inc.) and Harpoon TSD-5 devices (Harpoon Medical). Both are polytetrafluoroethylene (PTFE) sutures implanted on a beating heart using minimally invasive transapical approach and are tethered to the apical myocardium, thereby, preventing leaflet prolapse. Initial experience with the NeoChord device showed a reduction in MR severity to grade $\leq +2$ in over 85% of the patients and the device was CE approved in 2012.⁵

A wide range of percutaneous mitral annuloplasty devices have also been developed. The Cardioband (Valtech Cardio, or Yehuda) device is a polyester band with multiple 6 mm stainless steel anchors and is implanted via 25Fr trans-septal access system into the atrial aspect of the mitral annulus posteriorly. The band is tightened after implantation resulting in annular shortening.⁶ The Carillon device (Cardiac Dimensions) is another option for percutaneous annuloplasty that is delivered into the coronary sinus. It consists of a curvilinear nitinol wire with two self-expanding nitinol anchors at either end which are implanted in the coronary sinus and great cardiac vein, along the posterior atrioventricular groove resulting in the approximation of the posterior mitral annulus.⁷ Mitraign (Mitralign, Inc., Tewksbury, MA) is a suture-based annuloplasty technology. It involves delivery of a suture and pledgets along the posterior margins of the annulus (P1 and P3 scallops) from the left ventricle (LV) aspect using a deflectable catheter. The suture and pledgets are tightened resulting in narrowing of the anteroposterior dimension of MV annulus.

Percutaneous ventriculoplasty devices have been developed to improve LV geometry and decrease MR.⁸ VenTouch (Mardil Medical) consists of an inflatable chamber positioned along the external posterolateral aspect of LV by a left thoracotomy. Inflation of the device reduces LV and annular dimensions and improves leaflet coaptation. The Accucinch system (Ancora Heart) consists of multiple nitinol anchors connected by a nitinol wire and is delivered via retrograde access across the aortic valve into the base of the LV. Tightening of the nitinol wire cinches the basal LV and hence, the mitral annulus, thereby improving leaflet apposition.

Transcatheter MV replacement is a feasible option when percutaneous repair is not possible or has failed. However, unlike aortic valve replacement, MV interventions are more complex. The annulus is saddle-shaped increasing risk of paravalvular leak and annular calcification is rare, making anchorage of the valve difficult. Critical nearby structures such as the left ventricular outflow tract, conduction system, and the circumflex artery are at risk of iatrogenic damage. The use of transcatheter aortic valves such as the Sapien XT valve via transapical approach was associated with poor results, necessitating the development of special valves for the mitral position. The currently available valves include CardiAQ (CardiAQ Valve Technologies), Tiara (Neovasc Inc., British Columbia, Canada), Tendyne (Tendyne Inc.), and Medtronic-Intrepid (Medtronic Inc.). All valves are trileaflet bioprosthetic valves with self-expanding nitinol frame. Valve anchoring is either axial to the LV apex (Tendyne) or radial to the annulus with most devices having addition design features to reduce paravalvular leak. Delivery approaches vary among the devices being apical or trans-septal with delivery systems ranging in size from 26 to 42 Fr.⁹

Percutaneous Tricuspid Valve Therapies

The significance of functional tricuspid regurgitation (TR) has been highlighted in recent studies showing that it is associated with decreased long-term survival independent of left ventricular function, right ventricular function, or pulmonary hypertension.¹⁰ Surgery for severe TR is associated with a high mortality and medical management alone is often suboptimal. There is a growing unmet need for effective percutaneous tricuspid valve (TV) interventions for patients with functional TR. The major mechanisms of functional TR are annular dilation and leaflet tethering because of structural changes in the right ventricle. Several devices targeting these pathophysiologic mechanisms have been developed but the clinical experience is limited. Preoperative evaluation involves the use of multimodality imaging including transthoracic echocardiography (TTE), transesophageal echocardiography (TEE), and computed tomography (CT) for delineation of the anatomy of the valve and neighboring structures such as coronary sinus ostium and the right coronary artery. The procedures are done using TEE and fluoroscopic guidance.

Annuloplasty devices reduce the tricuspid annulus by percutaneous or minimally invasive procedures. The Trialign device (Mitralign, Inc., Tewksbury, USA) is similar to the

Mitralign device used for percutaneous MV annuloplasty. It percutaneously delivers pledges and sutures the antero-posterior and septoposterior commissures of the TV reducing the annulus size. A recent study with this device showed a 30-day success rate of 80% with a significant reduction in severity of TR and improvement in New York Heart Association (NYHA) functional class.¹¹ Tricinch (4Tech Cardio, Galway, Ireland) is another percutaneous device being studied for TV annuloplasty and consists of a stainless-steel cork-screw implant that is delivered trans cavally into the anterior TV annulus, and is connected by an adjustable Dacron band to a self-expanding nitinol stent implanted in the inferior vena cava (IVC). The implant tenses the TV annulus, decreases its dimensions, and decreases TR. The stent in the IVC maintains the tension. The Cardioband, used for percutaneous MV annuloplasty, has also been implanted for the TV annuloplasty.

The FORMA repair system (Edwards Lifesciences, California, USA) is a novel coaptation device which aims to reduce the effective regurgitant orifice area by providing a structure on which the TV leaflets can coapt. It consists of a rail which is screwed to the RV apex and a spacer anchored to this rail, which facilitates coaptation. The spacer consists of foam-filled polymer balloon with holes in its shaft and undergoes passive expansion after deployment. A recent study of 18 patients reported a success rate of 89% with no major peri-procedural complications and reduction in severity of TR in 46% at 1-year. Significant improvement in NYHA class and 6-minute walk distance (6MWD) were reported.¹²

MitraClip has been used in the tricuspid position for clipping the anterior and posterior tricuspid leaflets and reducing the regurgitant orifice. Observational data from 64 patients showed that the procedure was successful in 97% and reduction of TR severity by at least 1 grade occurred in 91% of the patients. There was a significant improvement in the NYHA class and 6MWD.¹³

Caval valve implantation involves heterotopic valve implantation in the IVC and the superior vena cava (SVC) in contrast to orthotropic valve implantation which is done at the site of normal TV. The valves do not prevent TR but decrease the hemodynamic consequences and right-sided congestive symptoms. However, they are only useful for patients with pulsatile blood flow in the vena cava and evidence of systolic flow reversal. The Tric Valve (P&F Products & Features Vertriebs GmbH, Austria, and Braile Biomedica, Brazil) consists of two self-expanding bioprosthetic valves made of bovine pericardium on a nitinol frame. One valve is implanted in the SVC-right atrium (RA) junction and other at the IVC-RA junction above the diaphragm to avoid hepatic vein compromise. The procedure is straightforward but the valve has only been used on a compassionate basis in severely ill patients, often with multiple comorbidities, and systematic data are lacking. Commercially available balloon-expandable valves used to treat aortic stenosis, such as Edwards Sapien XT or Sapien 3 (Edwards Lifesciences, California, USA) valve, have also been implanted in the vena cava to decrease

regurgitant flow. This procedure requires prestenting of large-sized vena cava to stabilize the valves and is generally done only for the IVC. These valves have also been used for valve-in-valve and valve-in-ring procedures for patients who have previously undergone TV replacement and TV repair, respectively.¹⁴

Left Atrial Appendage Occlusion

Warfarin therapy decreases the risk of stroke in patients with atrial fibrillation (AF) by over 60% compared to placebo.¹⁵ Over 90% of the thrombi in nonvalvular AF form in the left atrial appendage (LAA) and the majority of the AF-related strokes occur from embolism of LAA thrombi.¹⁶ Percutaneous LAA occlusion was developed as a treatment option for stroke prevention in patients who have AF but cannot tolerate long-term oral anticoagulation. Eligible candidates include patients with prior severe bleeding (intracranial bleed or severe gastrointestinal bleed), patients requiring combined use of dual antiplatelet therapy and anticoagulation, patients with labile international normalized ratio (INR) values, patients with thrombocytopenia or other coagulation defects, poor compliance with anticoagulant therapy, and patients with recurrence of stroke on oral anticoagulation. The procedure is contraindicated in patients with absolute contraindications to anticoagulation as postprocedure anticoagulation is necessary. The Watchman device (Boston Scientific, Minnesota, USA) is the only device tested in RCTs and approved by FDA for percutaneous LAA occlusion.

The Watchman device is a self-expanding nitinol cage covered with a PTFE membrane and has ten fixation anchors for holding the device in the LAA. The device is available in 5 sizes from 21 to 33 mm (in 3 mm increments); the size corresponds to the width of the expanded device at its shoulders. Preprocedural evaluation requires baseline TEE and CT imaging to assess LAA anatomy and rule out pre-existing thrombi. The device is selected based on the maximum width of LAA ostium; 8–20% compression of the original device size is acceptable. Implantation is done via antegrade access across the atrial septum using a 14 Fr delivery sheath. Aspirin (81–100 mg) is started one day before the procedure and warfarin is added postprocedure to maintain an INR between 2–3 for at least 45 days or longer depending upon TEE assessment after that interval. After stopping warfarin, clopidogrel is added to aspirin and continued until 6 months after implantation, and thereafter aspirin (300–325 mg) is continued indefinitely.^{17,18}

Two RCTs (PROTECT-AF and PREVAIL) have evaluated the Watchman device in comparison to oral anticoagulation.^{19,20} Meta-analysis of these trials demonstrated that the Watchman device was noninferior to warfarin therapy for postprocedure ischemic stroke or systemic embolism.²¹ Significantly lower rates of nonprocedure related [hazard ratio (HR) = 0.48; p = 0.0003] major bleeding, hemorrhagic stroke (HR: 0.20; p = 0.0022), and all-cause mortality (HR: 0.73; p = 0.035) were observed in the device group. Recent observational studies have reported procedural success rates of more than 98% and rates of major periprocedural

complications being less than 2% (pericardial tamponade in ~1% patients).²² The Amplatzer Amulet LAA occlusion device (Abbott Vascular, Illinois, USA) is currently being studied in a noninferiority trial comparing it with the Watchman device.

Patent Foramen Oval Occlusion

Cryptogenic ischemic stroke is diagnosed when the recognizable causes of stroke have been excluded including atheroembolism, cardioembolic stroke, small vessel disease, coagulation disorders, and arterial dissection. The prevalence of patent foramen ovale (PFO) in cryptogenic stroke is 40–50%.²³ The reference standard for noninvasive detection of PFO is TEE with a bubble contrast study. Transcranial Doppler has a sensitivity of 97% and specificity of 93%.²⁴ The sensitivity and specificity of TTE with harmonic imaging and using bubble contrast is 91% and 93%, respectively.²⁵ Percutaneous PFO occlusion has emerged as a treatment option for patients with cryptogenic stroke and PFO.
