The most widely used device is the Amplatzer PFO occluder (Abbott Vascular, Illinois, USA). The device is made of nitinol and consists of two disks with a 3-mm long connecting waist. Each disk has polyester mesh to prevent flow across the device. The device is available in 3 sizes: 18 mm, 25 mm, and 35 mm. The size is based on the RA disk size and decided based on the distance of the PFO from the aortic root and SVC orifice. The procedure is done under intracardiac echocardiography or TEE guidance. The device is delivered across the PFO using dedicated 8–9F delivery sheaths. NobleStitch EL device (HeartStitch, Inc., California, USA) uses a percutaneously delivered prolene sutures to appose the ostium primum and secundum and is in investigational stages.

Evidence from initial studies was conflicting. However, three recent trials that compared PFO closure to medical therapy for cryptogenic stroke (one trial each for Amplatzer device and Gore device, while the third allowed the physician to choose from a variety of devices) showed lower rates of recurrent stroke with device closure, although, rates of AF in patients undergoing device closure were higher.^{26–28} A meta-analysis of all available RCTs showed that device closure decreases the risk of recurrent stroke by nearly two-thirds. However, the absolute annual risk of recurrent stroke with medical therapy alone was low (1.17%) and the number needed to treat (NNT) with device closure to prevent one stroke was 176. The benefit depends upon the size of the shunt with greater risk reduction in patients who have a large shunt (presence of >30 microbubbles in LA within three cycles after right atrial opacification) with a NNT of 96 but no benefit in patients with a small shunt. Device therapy resulted in a four-times higher annual risk of AF [risk ratio = 4.68, 95% confidence interval (CI) 2.19–10.00, p <0.001, heterogeneity I² = 27.5%] with a number needed to harm of 85.²⁹ However, other studies have shown that such AF generally occurs early (<45 days) as a single episode of paroxysmal AF and less than 4% of the patients with AF progress to permanent AF.³⁰ There was no difference in the rates of major bleeding and procedure-related complications in various trials ranged

from 2.4 to 5.9%. Other meta-analyses have reported higher rates of absolute risk reduction ranging from 1.8 to 2.2%.^{31,32} Further, the risk of AF may depend upon the device used with one trial using a particular device showing no increase in rates of AF.²⁷ Another small trial compared PFO device closure with antiplatelet therapy in patients with high-risk PFO defined as PFO with an atrial septal aneurysm, hypermobility (phasic septal excursion into either atrium ≥ 10 mm), or PFO size (maximum separation of the septum primum from the secundum) more than or equal to 2 mm. There was no recurrence of stroke at the end of 2 years in the device group compared with a rate of 12.9% in patients on medication alone.³³

Interatrial Shunt Device

Heart failure with a preserved ejection fraction (HFpEF) comprises nearly 50% of all patients with heart failure. The pathophysiologic basis is abnormal left ventricular relaxation resulting in elevation of LA pressure, pulmonary congestion, and leading to symptoms. The interatrial shunt device (Corvia Medical) was designed to percutaneously create an iatrogenic defect in interatrial septum with the objective of decompressing LA and reducing LA pressure. Eligible candidates are patient with NYHA class II–IV symptoms, LV ejection fraction more than or equal to 40% and elevated pulmonary capillary wedge pressure (PCWP ≥ 15 mmHg resting or \geq during 25 supine bicycle exercise). The device is made of nitinol with an outer diameter of 18 mm and creates an 8 mm atrial septal defect. It is deployed by a standard interatrial septal puncture using a preloaded 16 Fr delivery system.

Limited evidence is available for the use of this device. A phase I study showed a success rate of 94% (64 out of 68 patients) and no major device-related complications during 6 months follow-up with reduction in resting PCWP in over 50% of the patients.³⁴ A phase II sham-controlled RCT with 44 patients showed a significant reduction in PCWP during exercise and no major adverse cardiac, cerebrovascular, and renal events at 1 month.³⁵

Another device which has been developed is the V-Wave shunt device (V-Wave, Caesarea, Israel). It is an hourglass-shaped implant with a nitinol frame, PTFE encapsulation and a one-way bioprosthetic valve (porcine pericardium) to prevent paradoxical embolism. A proof-of-concept cohort study in patients with heart failure with reduced ejection fraction (EF <40%; n = 10 patients) showed improvement in NYHA class in eight patients and reduction in PCWP by 6 mmHg at 3 months.³⁶

Robotic Percutaneous Coronary Intervention

Robotic PCI was developed to reduce the risk of radiation exposure and orthopedic injuries to PCI operator. The robotic system consists of a bedside robotic arm and a radiation shielded physician workstation located in the cath lab. The robotic arm has a disposable cassette in which the angioplasty equipment including wires, balloons, and stents are loaded.

Vascular access is obtained manually, the coronary artery is engaged with the guide catheter by the operator, and the guide catheter is connected to the Y-connector of the robotic arm. The guidewire is advanced through the opposite end of the robotic arm into the guide catheter. Thereafter, the guidewire is advanced under robotic control. Angioplasty catheters are loaded manually and are then advanced by robotic assistance. The workstation has a console with three joysticks for manipulating the wire, balloon catheter, and guide catheter. It also displays hemodynamic data, vital parameters, and fluoroscopic image with the facility of computerized angiographic analysis. Corindus CorPath 200 (Corindus Vascular Robotics, Massachusetts, USA) was approved by the FDA in 2012 and the second-generation system CorPath GRX has been recently approved.

The PRECISE (Percutaneous Robotically Enhanced Coronary Intervention) trial was a multicenter registry study of 164 patients which showed that robotic PCI is feasible and safe in simple lesions without an increase in patient radiation or contrast use.³⁷ The CORA-PCI (Complex Robotically Assisted Percutaneous Coronary Intervention) study evaluated CorPath 200 in a real-world cohort of 315 patients. Technical success with robotic PCI was 91.7%, manual assistance was required in 11.1% of cases, and manual conversion in 7.4%. Clinical success, stent use, and fluoroscopy time were similar between robotic and conventional PCI. However, procedure time was longer in the robotic group ($44:30 \pm 26:04$ mins vs. $36:34 \pm 23:03$ mins; $p = 0.002$).³⁸ There is also some evidence to suggest a trend toward decreased geographic miss with robotic PCI, as the robotic system allows sub-millimeter movements of angioplasty equipment.

The greatest drawback of this system is the absence of tactile feedback. It also does not allow the use of over the wire equipment such as over the wire balloons, microcatheters, and rota-ablation catheters and hence, has limited utility for complex lesions. Further, simultaneous balloon inflation as needed in dedicated bifurcation lesions is also not possible. While the angioplasty equipment can be advanced using the robotic arm, balloon and stent inflation is done by the operator. Lastly, the robotic PCI increases the operator learning curve, procedure time, and cost. Robotic systems have also been studied for electrophysiologic radiofrequency ablation procedures.

Quantitative Flow Ratio

Fractional flow reserve (FFR) is considered the reference standard for evaluation of intermediate coronary stenosis but requires expensive pressure wires, use of intravenous adenosine, and increases the procedure time. Quantitative flow ratio (QFR) is a computer-derived FFR calculated from three-dimensional quantitative angiography (3D-QCA) without the use of adenosine. A diagnostic angiogram is performed in two projections which are at least 25° apart and 3D-QCA reconstruction done. The contrast flow velocity is estimated by frame count during baseline conditions. The QFR is then calculated using complex computerized equations that derive the pressure drop across a lesion based

on the geometry of the stenosis as assessed by 3D-QCA.³⁹ A prospective study of 308 patients showed that QFR had a higher sensitivity and specificity for detecting hemodynamically-significant stenosis when compared with QCA considering FFR as gold standard (sensitivity: 94.6% vs. 62.5%, difference: 32.0%, $p < 0.001$; specificity: 91.7% vs. 58.1%, difference: 36.1%, $p < 0.001$). The overall patient-level diagnostic accuracy of QFR was 92.4%.⁴⁰

Coronary Lithoplasty

Coronary lithoplasty is a novel technique to tackle calcified coronary lesions. The lithoplasty system consists of a 6F compatible balloon angioplasty catheter that is introduced on a standard guidewire to the target lesion. The catheter contains electrohydraulic lithotripsy emitters which convert electrical energy into acoustic pressure pulses that disrupt coronary calcium. The balloon is connected to the generator, inflated at a pressure of 4 atmosphere and prespecified lithotripsy pulses delivered. Optical coherence tomography studies have shown that lithoplasty results in circumferential fractures in superficial and deep calcium increasing the minimum luminal area.⁴¹ Limited observational data (DISRUPT-CAD study, $n = 60$ patients) available for the device shows good procedural success rates, with rates of stent delivery being 100% and with no flow-limiting dissections, abrupt closure or perforation being reported. The device is approved by FDA for peripheral interventions and has received the CE approval for coronary interventions.⁴²

Coronary Sinus Reducer for Refractory Angina

Coronary sinus reducer (CSR) is a novel treatment option for patients with refractory angina who are not candidates for revascularization. Data from animal studies has shown that obstruction of the coronary sinus increases the coronary venous pressure, redistributes the blood from ischemic to nonischemic zones, and reduces myocardial ischemia. Surgical narrowing of the coronary sinus improves myocardial perfusion. Percutaneous implantation of CSR is based on the same principle by creating a focal narrowing in the coronary sinus by utilizing an implantable device.

The CSR (Neovasc Medical, Inc., Or Yehuda, Israel) is a balloon-mounted, bare metal, stainless steel stent which on expansion is shaped like an hourglass (the balloon has the same shape). The device is available in a single size and is suitable for variable anatomies. The procedure is performed under fluoroscopic guidance via right jugular venous approach. The coronary sinus is cannulated using a diagnostic 6F multipurpose or Amplatz catheter, a selective angiogram is done to assess anatomy and a 9F-guiding catheter is advanced over the diagnostic catheter. The device is advanced over a coronary guidewire and balloon inflated at 2–6 atmospheres. The procedure is done on an outpatient basis, and dual antiplatelet therapy is advised for 6 months after the procedure.⁴³ The device received CE approval in November 2011 but is not currently approved by the FDA.

The best available evidence for CSR comes from a small RCT comparing CSR to placebo. There was a significantly greater number of patients who experienced a reduction in Canadian Cardiovascular Society angina scale by 2 classes (35% vs. 15%; $p = 0.02$) and improvement in the quality of life as assessed by Seattle Angina Questionnaire after CSR implantation. However, the trial did not show any difference between the two groups in exercise time or provable ischemia as assessed by dobutamine echocardiography, and cardiovascular outcomes were not assessed.⁴⁴ Compassionate use of the CSR for patients with microvascular angina has also been reported, with limited data available on the same.

Percutaneous Ventricular Restoration

Percutaneous ventricular restoration (PVR) involves delivery of a ventricular partition device to isolate the aneurysmal LV apex from the remaining cavity, thereby, decreasing LV volume, restoring geometry and improving ventricular mechanics. The Parachute device (CardioKinetix Inc., California, USA) consists of an occlusive PTFE membrane bonded to a self-expanding nitinol frame in the shape of an inverted umbrella. It has 16 metallic struts with 2 mm anchors at the wide end which engage the myocardium and a collapsible foot which rests on the LV apex. The device is available in eight sizes. It is delivered by retrograde transaortic access with a 14–16F guide catheter by using a screwing delivery system which has an inflatable balloon for expanding the device and engaging the myocardium. Preprocedure screening is done by TTE and all eligible patients should undergo contrast-enhanced CT for evaluating cardiac anatomy. Anatomic criteria for device therapy are ejection fraction less than 40% with akinetic or aneurysmal apex, LV end-diastolic diameter greater than 55 mm, LV wall thickness greater than 3.5 mm, apical dimensions 4 × 5 cm, and normal trabeculations and papillary muscles.⁴⁵

Evidence for the use of parachute device is available from observational studies. The largest study, PARACHUTE III ($n = 100$ patients) demonstrated procedural success rate of 97% with major periprocedural adverse events at 7% with one death. At the end of 1 year, there was significant LV volume reduction, improvement in 6MWD and mean NYHA class.⁴⁶ A large pivotal RCT to test the efficacy of PVR is currently underway.

Endogenous Tissue Restoration

Percutaneous valve implantation has revolutionized the management of valvular disorders. However, the implanted prostheses are xenografts made from native animal valves or pericardium that incite a chronic inflammatory reaction and undergo structural degeneration requiring repeat interventions. Endogenous tissue restoration (Xeltis BV, Eindhoven, Netherlands) is a novel technology for valve replacement that aims to provide a synthetic bioresorbable scaffold which allows the endogenous host tissue to regenerate. Unlike standard bioresorbable polymers, such as polyglycolic acid, these scaffolds are made of a special supramolecular

polymer which is electrospun into matrices allowing space for native tissue to regrow. The technology has been used to develop extracardiac Fontan conduits, valved pulmonary conduits for right ventricular outflow tract reconstruction, and aortic valves.⁴⁷ The Fontan conduit has been studied in five children and 2-year follow-up results showed good hemodynamic and structural performance. The pulmonary valved conduit has undergone a successful preclinical study and has been successfully implanted in 12 children with good periprocedural outcomes and long-term results are awaited. A preclinical animal study of the aortic valve has shown good hemodynamic results with only mild AR being reported.⁴⁸ These valves may usher in a new frontier in valve replacement therapy in the coming years.

Pulmonary Artery Denervation

An imbalance between the local vasoconstrictor and vasodilator tone, and an exaggerated local baroreflex has been implicated in increasing the pulmonary artery pressures (PAP) in patients with idiopathic pulmonary artery hypertension. Pulmonary artery denervation (PADN) was initially studied in animals where it was successful in abolishing the elevation of PAP that occurs after occlusion of an interlobar artery.⁴⁹ Animal studies also showed that there is an immediate decrease in mean PAP and pulmonary vascular resistance and this is associated with histologic changes in the adventitial nerves.⁵⁰ Ablation is done using a dedicated 7Fr PADN radiofrequency catheter with 10 ablation electrodes arranged in a circular fashion. The catheter is introduced into the main pulmonary artery (MPA) in an 8 Fr sheath and ablation is given at three levels: proximal to the bifurcation in the MPA, distal to the bifurcation in the right pulmonary artery, and distal to the bifurcation in left pulmonary artery.

The first-in-man study of PADN in 13 patients with idiopathic pulmonary arterial hypertension not responding to medical therapy showed a significant reduction in mean PAP (55.5–36.5 mmHg, $p < 0.01$) and improvement in 6MWD (324 ± 21 m to 491 ± 38 m, $p < 0.006$) over a period of 3-months.⁵¹ The phase II results of PADN study showed that there was a hemodynamic success (defined as a reduction in mean PAP by at least 10% of baseline) in 94% patients. There was an absolute decrease in mean systolic PAP and mean PAP of -10 mmHg and -7 mmHg, respectively, within 24 hours with no major periprocedural complications. At 6 months there was a significant decrease in mean PAP (44.8 ± 16.4 vs. 53.1 ± 19.1) and PVR (8.4 ± 5.4 Woods units vs. 13.2 ± 6.9 Woods units), increase in 6MWD by a mean of 94 ± 73 m, and WHO functional class improved in 63.6% patients.⁵² A small study in 16 patients with chronic thromboembolic pulmonary hypertension with residual hypertension after pulmonary endarterectomy also showed a reduction in mean PAP (37.3–24.6 mmHg; $p = 0.01$) and decrease in PVR ($672 \text{ dyn}\cdot\text{s}\cdot\text{cm}^{-5}$ to $386 \text{ dyn}\cdot\text{s}\cdot\text{cm}^{-5}$; $p = 0.02$).⁵³

Renal Denervation

Renal denervation targets the renal sympathetic nervous system supply by percutaneous radiofrequency ablation in

the renal arteries. The procedure was developed as a treatment option for resistant hypertension. Initial studies showed a significant reduction in systolic blood pressure (SBP) and excellent procedural safety, but the sham-controlled SYMPLICITY HTN-3 trial showed no significant difference in mean office SBP or mean ambulatory blood pressure after 6 months.⁵⁴ The SYMPLICITY HTN-3 trial, however, had several limitations confounding the interpretation and generalization of results. The enrolled patients had treatment-resistant hypertension and underwent frequent drug changes during the study period. The ablation catheter (Simplicity Flex Catheter, Medtronic, Inc., California, USA) used was unipolar, required precise positioning and multiple ablations from distal to proximal, such that the complexity of the procedure may have resulted in incomplete denervation.⁵⁵

The SPYRAL HTN-OFF MED was a sham-controlled proof-of-concept RCT designed to assess the effects of renal denervation on SBP in treatment naïve patients. The trial used an advanced, easy-to-use, self-positioning catheter (Symplicity Spyral Catheter, Medtronic, Inc., California, USA) with multiple electrodes, giving simultaneous four-quadrant ablations which were done in the main and side branches. The 3 month results of the trial showed significant decrease in office and 24-hour ambulatory blood pressure in the renal denervation group: 24-hour SBP -5.5 mmHg (95% CI -9.1 to -2.0 ; $p = 0.0031$); 24-hour diastolic blood pressure (DBP) -4.8 mmHg (-7.0 to -2.6 ; $p < 0.0001$); office SBP -10.0 mmHg (-15.1 to -4.9 ; $p = 0.0004$); and office DBP -5.3 mmHg (-7.8 to -2.7 ; $p = 0.0002$). No significant changes were seen in the sham-control group. No major adverse events were observed in either group.⁵⁶ The SPYRAL HTN-ON MED trial was a similarly designed study (sham-controlled proof-of-concept RCT; $n = 80$) but evaluated renal denervation in patients with uncontrolled hypertension on antihypertensive therapy. At 6 months, the change in blood pressure was significantly greater in the renal denervation group than the sham-control group: office SBP (difference -6.8 mmHg, 95% CI -12.5 to -1.1 ; $p = 0.0205$) and 24-hour SBP (difference -7.4 mmHg, -12.5 to -2.3 ; $p = 0.0051$). No major adverse events were observed.⁵⁷

A recently developed technology utilizes endovascular ultrasound energy for thermal ablation of renal sympathetic nerves (Paradise renal denervation system, ReCor Medical, California, USA). The catheter is placed percutaneously in the renal arteries, centered with a water-filled cooling balloon and achieves a circumferential ring of ablation. The RADIANCE-HTN SOLO study was a single-blinded sham controlled RCT ($n = 146$) evaluating this technology which showed significantly greater reduction in daytime ambulatory SBP with renal denervation [-8.5 mmHg, standard deviations (SD) 9.3] than with the sham procedure (-2.2 mmHg, SD 10.0; baseline-adjusted difference between groups: -6.3 mmHg, 95% CI -9.4 to -3.1 , $p = 0.0001$). There were no major adverse events in either group.⁵⁸

CONCLUSION

Several upcoming technologies are set to revolutionize interventional cardiology. Foremost among them are

devices for percutaneous mitral and tricuspid valve repair. PFO occlusion has shown benefit in the management of cryptogenic stroke. Interatrial shunt device offers a novel treatment strategy for patients with HFpEF. QFR allows physiologic assessment during routine coronary angiogram using special software. Renal artery denervation has witnessed renewed interest with encouraging results from recent trials. Pulmonary artery denervation offers a new therapeutic option for patients with pulmonary hypertension. Finally, in the future, prosthetic implants may be replaced by the endogenous tissue restoration which allows regeneration of native tissue over bioresorbable scaffolds.

Intervention in Structural Heart Disease

TAVR: Indications and Limitations in Clinical Practice

Tarun Chakravarty, Matthias Raschpichler, Chinar Patel, Raj Makkar

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) is a minimally invasive treatment option for severe aortic stenosis (AS). The first case of TAVR in a human was performed in 2002 by Professor Alain Cribier.¹ With improved TAVR device technology, increasing operator experience, refinement in procedural techniques and patient selection, the field of TAVR has rapidly evolved. TAVR is now routinely performed for the treatment of severe symptomatic AS. A total of 54,782 TAVR procedures with commercially approved devices were performed in the United States from 2012 through December 2015.² In this chapter, we review the clinical evidence supporting the current indications for TAVR,^{3–9} as well as limitations of this technology.

ELIGIBILITY FOR TRANSCATHETER AORTIC VALVE REPLACEMENT

The clinical trials evaluating the safety and efficacy of TAVR have enrolled patients, based on their surgical risk profile. The surgical risk in patients with severe symptomatic AS was assessed based on the Society of Thoracic Surgery (STS) risk score as well as presence of comorbidities that may not be captured in the STS score, for instance, extensively calcified (porcelain) aorta, cirrhosis, chest wall deformity or deleterious effects of chest wall irradiation, oxygen-dependent respiratory insufficiency, and/or frailty. Based on the surgical risk, the patients in clinical trials were stratified, according to surgical risk, into extreme risk/inoperable (STS score $\geq 15\%$; or risk of morbidity and mortality $\geq 50\%$),^{3,8} high risk but operable (STS $\geq 10\%$; or 30-day mortality/morbidity $\geq 50\%$),^{4,7} intermediate risk [STS 4–8% in PARTNER (Placement of Aortic Transcatheter Valves) 2A or STS 3–15% in SURTAVI (Surgical Replacement and Transcatheter Aortic Valve Implantation) trial]^{9,10} and low risk (STS <2% in PARTNER 3 or STS <3% in Evolut low-risk trial). The risk adjudication in all randomized controlled trials (RCTs) was performed by two cardiothoracic surgeons.

Randomized Clinical Trials (Table 1)

Extreme Risk to Inoperable Patients

The PARTNER 1B trial randomized 358 extreme risk to inoperable patients to transfemoral TAVR with Edwards SAPIEN valve ($n = 179$) (Edwards Lifesciences Inc., Irvine, CA) or standard therapy (including balloon aortic valvuloplasty) ($n = 179$).³ The primary end point was rate of death from any cause. At 1 year, the rate of death from any cause was 30.7% with TAVR, as compared with 50.7% with standard therapy ($p < 0.001$). TAVR, compared with standard therapy, was also associated with a significant reduction in the composite rate of death/rehospitalization as well as significant improvement in quality of life. At 5 years, all-cause mortality was 71.8% in the TAVR group versus 93.6% in the standard treatment group ($p < 0.0001$).⁵

Following the results of the PARTNER 1B trial, a prospective nonrandomized registry of self-expanding CoreValve (Medtronic Inc., Minneapolis, MN) was initiated to evaluate the effectiveness of CoreValve for the treatment of extreme/prohibitive risk patients with severe AS.⁸ To estimate the rate of death or major stroke in patients with AS at prohibitive risk for surgery treated with standard therapy, an objective performance goal (OPG) of 43% was determined from a meta-analysis of seven balloon aortic valvuloplasty studies as well as the results of the PARTNER 1B trial. The rate of all-cause mortality or stroke at 1 year observed during the study was 26.0% versus 43.0% with the OPG ($p < 0.0001$).

High Risk but Operable Patients

The PARTNER 1A trial randomized 699 high-risk patients with symptomatic severe AS to TAVR with Edwards SAPIEN valve ($n = 348$) or surgical aortic valve replacement (SAVR) ($n = 351$).⁴ The primary end point was death from any cause at 1 year. The rate of death from any cause after 1 year was not different after TAVR and SAVR, 1 year death rate being 24.2% and 26.8%, respectively ($p = 0.44$). At 5 years, the rate of death was 67.8% in the TAVR group compared with 62.4% in

TABLE 1: Summary of randomized clinical trials and prospective registries of transcatheter aortic valve replacement

	30-day outcomes					1-year outcomes		2-year outcomes		5-year outcomes	
	Mortality	Stroke	Moderate to severe PVL	Pacemaker	Major vascular complication	Mortality	Stroke	Mortality	Stroke	Mortality	Stroke
Extreme risk studies											
PARTNER 1B	5.0%	6.7%	11.8%	3.4%	16.2%	30.7%	10.6%			71.8%	16.0%
CoreValve extreme-risk study	8.4%	4.0%	11.4%	21.6%	8.2%	24.3%	7.0%				
High-risk studies											
PARTNER 1A	3.4%	4.7%	12.2%	3.8%	11.0%	24.2%	6.0%			67.8%	10.4%
CoreValve high-risk study	3.3%	4.9%	9.0%	19.8%	5.9%	14.2%	8.8%				
Intermediate risk studies											
PARTNER 2A	3.9%	5.5%	3.7%	8.5%	7.9%	12.3%	8.0%	16.7%	10%		
SURTAVI trial	2.2%	3.4%	10.0%	25.9%	6.0%	6.7%	5.4%	11.4%	6.2%		
Sapien 3 study	1.1%	2.7%	1.2%	10.2%	6.1%	7.4%	4.6%				

PVL, paravalvular leak.

the SAVR group ($p = 0.76$). There were no cases of structural valve deterioration requiring surgical valve replacement in either group. Moderate or severe aortic regurgitation was more frequent in the TAVR group, noted in 40 (14%) of 280 patients in the TAVR group and two (1%) of 228 in the SAVR group ($p < 0.0001$), and was associated with increased 5-year risk of mortality in the TAVR group (72.4% for moderate or severe aortic regurgitation versus 56.6% for those with mild aortic regurgitation or less; $p = 0.003$).⁶

A similar randomized trial of 795 high risk but operable patients with symptomatic severe AS randomized patients to TAVR with CoreValve ($n = 394$) or SAVR ($n = 401$), primary end point of the study being rate of death at 1 year.⁷ In the as-treated population, the rate of death at 1 year was significantly lower in the TAVR group than in the surgical group (14.2% vs. 19.1%) ($p < 0.001$ for noninferiority; $p = 0.04$ for superiority). The results were similar in the intention-to-treat analysis.

Intermediate-risk Patients

The PARTNER 2 trial randomized 2,032 intermediate-risk patients with symptomatic severe AS to TAVR with SAPIEN XT valve (Edwards Lifesciences Inc., Irvine, CA) or SAVR.¹⁰ The primary end point was all-cause mortality or disabling stroke at 2 years. There was no significant difference in the rates of death or nondisabling stroke at 2 years between TAVR and SAVR groups (19.2% vs. 21.1%, $p = 0.25$). Patients undergoing TAVR had large aortic valve areas and lower rates of acute kidney injury, severe bleeding, and new-onset atrial fibrillation; surgery resulted in fewer major vascular complications and less paravalvular aortic regurgitation. In conclusion, TAVR was noninferior to SAVR for the treatment of symptomatic severe AS in intermediate surgical-risk patients.

Like PARTNER 2 trial, SURTAVI trial randomized intermediate-risk patients to TAVR with self-expanding

CoreValve/Evolut-R ($n = 879$) or SAVR ($n = 867$).⁹ The primary end point was death or disabling stroke at 2 years. At 2 years, there was no difference in the incidence of primary end point between TAVR and SAVR groups (12.6% vs. 14%, $p > 0.999$). TAVR was associated with lower aortic valve mean gradients, lower incidence of acute kidney injury, atrial fibrillation and higher incidence of permanent pacemaker (PPM) and residual aortic regurgitation.

Low-risk Patients

The PARTNER 3 trial (NCT02675114) randomized low-risk patients to TAVR with SAPIEN 3 valve or SAVR. The Medtronic Evolut low-risk study (NCT02701283) randomized low-risk patients with symptomatic severe AS to TAVR with Evolut valve or SAVR. Both the trials have completed enrollment; results are pending.

TRANSCATHETER AORTIC VALVE REPLACEMENT FOR DEGENERATIVE BIOPROSTHETIC AORTIC VALVES

Transcatheter aortic valve-in-valve (ViV) implantation has become the preferred treatment for degenerated bioprosthetic aortic valves, especially in patients at intermediate to high risk for redo surgery. The largest body of evidence supporting ViV as a treatment alternative for these patients comes from the Valve-in-Valve International Data (VIVID) registry.¹¹ In a VIVID registry report of 459 patients with degenerated bioprosthetic valves undergoing ViV implantation, 30-day mortality and major stroke rate was 7.6% and 1.7%, respectively. Survival at 1 year was 83.2%. Patients in the stenosis group had worse 1-year survival [76.6%; 95% confidence interval (CI), 68.9–83.1%] in comparison with the regurgitation group (91.2%; 95% CI, 85.7–96.7%) ($p = 0.01$). Patients with small valves had worse 1-year survival (74.8%,

95% CI, 66.2–83.4%) versus with intermediate-sized valves (81.8%; 95% CI, 75.3–88.3%) and with large valves (93.3%; 95% CI, 85.7–96.7%) ($p = 0.001$). These outcomes are comparable to the outcomes of TAVR for the treatment of native AS. The PARTNER 2 ViV trial and continued access registries enrolled 365 high-risk patients with symptomatic degeneration of surgical aortic bioprostheses.¹² At 30 days, all-cause mortality was 2.7%, stroke was 2.7%, major vascular complication was 4.1%, conversion to surgery was 0.6%, coronary occlusion was 0.8%, and new pacemaker insertion was 1.9%. 1-year all-cause mortality was 12.4%. At 1 year, mean gradient was 17.6 mm Hg and effective orifice area was 1.16 cm².

CURRENT GENERATION COMMERCIALLY AVAILABLE TRANSCATHETER AORTIC VALVE

The randomized TAVR trials were performed with the early generation TAVR valves. The current generation TAVs used in contemporary clinical practice, including balloon-expandable SAPIEN 3 and self-expanding Evolut PRO valves, have only been studied in prospective registries. Nevertheless, these registries have demonstrated excellent procedural outcomes with the SAPIEN 3 and Evolut valves.

SAPIEN 3 Valve

In the SAPIEN 3 study, 1,077 intermediate-risk patients with severe symptomatic AS underwent TAVR with SAPIEN 3 valve.¹³ Compared to the previous generations of balloon-expandable valves, the SAPIEN 3 valve system (Edwards Lifesciences Inc., Irvine, CA) has improved geometry of the trileaflet bovine pericardial valve; different cobalt alloy frame, which is longer than the early version of the balloon-expandable valve system (SAPIEN XT valve) with more open outlet cells and denser inlet cells; a polyethylene terephthalate fabric skirt sewn to the bottom portion of the interior and exterior of the frame [providing an external circumferential seal to reduce paravalvular leak (PVL)]; four valve sizes (20 mm, 23 mm, 26 mm, and 29 mm diameters); and lower profile delivery catheters with more precise valve positioning inserted through 14 or 16 French expandable sheaths for transfemoral access. At 1 year, mortality was rate 7.4%, disabling stroke rate was 2.0%, moderate-severe PVL rate was 2.0% and aortic valve reintervention rate was 1%. Following propensity score matching with intermediate-risk patients who underwent SAVR in the PARTNER 2 clinical trials, TAVR with SAPIEN 3 valve was both noninferior (pooled weighted proportion difference of -9.2%; 90% CI -12.4 to -6; $p < 0.0001$) and superior (-9.2%, 95% CI -13.0 to -5.4; $p < 0.0001$), compared to SAVR.

Evolut PRO Valve

Medtronic Evolut PRO valve (Medtronic Inc., Minneapolis, MN) was designed with an external pericardial wrap with the intent to reduce PVL while maintaining the benefits of a low profile, self-expanding, and repositionable supra-annular

valve. In the Medtronic Evolut PRO study, 60 patients with severe symptomatic AS underwent TAVR with Evolut PRO valve.¹⁴ At 30 days, mortality rate was 1.7%, disabling stroke rate was 1.7% and more than and equal to moderate PVL rate was 0%.

INDICATIONS FOR TRANSCATHETER AORTIC VALVE REPLACEMENT

Based on the available evidence from RCTs as well as large multicenter registries, TAVR is recommended for symptomatic patients with severe AS and a prohibitive risk for SAVR who have a predicted post-TAVR survival greater than 12 months. TAVR is a reasonable alternative to SAVR for symptomatic patients with severe AS and an intermediate surgical risk, depending on patient-specific procedural risks, values, and preferences. For severely symptomatic patients with bioprosthetic aortic valve stenosis judged by the heart team to be at high or prohibitive risk of reoperation, and in whom improvement in hemodynamics is anticipated, a transcatheter ViV procedure is reasonable. Although guidelines do not recommend for or against TAVR for the treatment of specific anatomic subsets, for instance, bicuspid AS or pure native aortic regurgitation, it may be reasonable to perform TAVR in experienced centers for these indications in carefully screened high-risk patients.

LIMITATIONS OF TRANSCATHETER AORTIC VALVE REPLACEMENT

With contemporary device technology and improved procedural techniques, TAVR is successfully performed by transfemoral approach in most patients with excellent procedural outcomes. The main limitations of TAVR include need for PPMs, strokes, valve thrombosis, and lack of data on long-term durability. The need for alternate access, PVL, vascular complications, and bleeding complications has become less frequent with the newer generation TAVR devices.

Permanent Pacemaker Implantation

The incidence of PPM implantation varies according to the transcatheter valve type, rates being higher with self-expanding valves compared to balloon-expandable valves. The rate of PPM implantation was 3.5% with the first generation Edwards SAPIEN valve,^{3,4} 8.5% with the second generation Sapien XT valve¹⁰ and 13% with the current generation SAPIEN 3 valve.¹³ The rates of PPM implantation were higher with the self-expanding CoreValve/Evolut valve; rates being 19.6% in the CoreValve high-risk study⁷ and 26% in the SURTAVI intermediate-risk study.⁹ The highest PPM rates are associated with implantation of a mechanically expanding Lotus valve, rates being 35.5% in the randomized controlled REPRISE trial.¹⁵ With improved implantation techniques, especially high deployment of the valves, the PPM rates have come down with all valve types. While pacemaker implantation does not impact mortality after TAVR, it is

not benign. The need for PPM implantation after TAVR is associated with prolonged hospitalization; increased risk of rehospitalization; less improvement in ejection fraction in patients with depressed ejection fraction at baseline; and increased procedural costs.^{16,17}

Stroke

Stroke after TAVR is associated with increased mortality, worse quality of life and increased healthcare costs. In the PARTNER 1 TAVR trials using first generation Edwards SAPIEN valve, stroke rates were higher with TAVR compared to SAVR (5.4% vs. 2.4% at 30 days). With improved TAVR technology, better patient screening and improved procedural understanding, stroke rates after TAVR have decreased significantly. The Medtronic high-risk CoreValve study that was initiated after the PARTNER 1 trial demonstrated a lower stroke rate with TAVR, compared to SAVR; although the differences were not significantly different (4.9% vs. 6.2%). PARTNER 2A trial comparing TAVR with Sapien XT valve with SAVR demonstrated similar stroke rates between TAVR and SAVR. The SURTAVI trial comparing TAVR with CoreValve versus SAVR in intermediate-risk patients demonstrated lower strokes rates with TAVR (3.4% vs. 5.3%). Strokes continue to be a devastating complication of TAVR. The SAPIEN 3 registry of intermediate and high-risk patients demonstrated a stroke rate of 2.7% at 30 days after TAVR, disabling stroke rates being 1.0%.¹³ The use of cerebral embolic protection devices to decrease periprocedural strokes after TAVR is an area of ongoing research. The SENTINEL trial compared cerebral embolic protection with the Sentinel device, randomizing patients in a 1:1:1 manner to Sentinel device with magnetic resonance imaging (MRI),

Sentinel device with no MRI imaging or TAVR without the use of Sentinel device.¹⁸ The use of Sentinel device during TAVR was associated with a significant reduction in stroke rates at 72 hours post-TAVR. Based on these data, the Sentinel device was approved by the Food and Drug Administration (FDA) for use during TAVR. A significant proportion of patients develop new onset atrial fibrillation after TAVR, which is also a significant predictor of strokes after TAVR. In conclusion, the stroke rates have decreased with contemporary valve types and procedural techniques, being comparable, if not lower than the stroke rates after SAVR. These stroke rates can potentially be reduced further with the use of cerebral protection devices, detection and treatment of new onset atrial fibrillation and optimization of postprocedural antiplatelet and antithrombotic therapy.

Valve Thrombosis

Subclinical leaflet thrombosis was recently reported in 10–15% of patients undergoing TAVR. Subclinical leaflet thrombosis is missed routinely on transthoracic echocardiography (TTE); is readily detected with contrast computed tomography (CT) of the valve; is less common in patients on anticoagulation; resolves with the initiation of anticoagulation; and is associated with increased aortic valve gradients compared to patients with no subclinical leaflet thrombosis (although the gradients are still within the expected range after TAVR) (Fig. 1).^{19–22} In a registry of 931 patients undergoing contrast CT after bioprosthetic aortic valve replacement, subclinical leaflet thrombosis was more frequent in transcatheter valves, compared to surgical valves.²⁰ Most of the small studies did not notice a relationship between valve thrombosis and stroke rates; however, the two largest studies reported

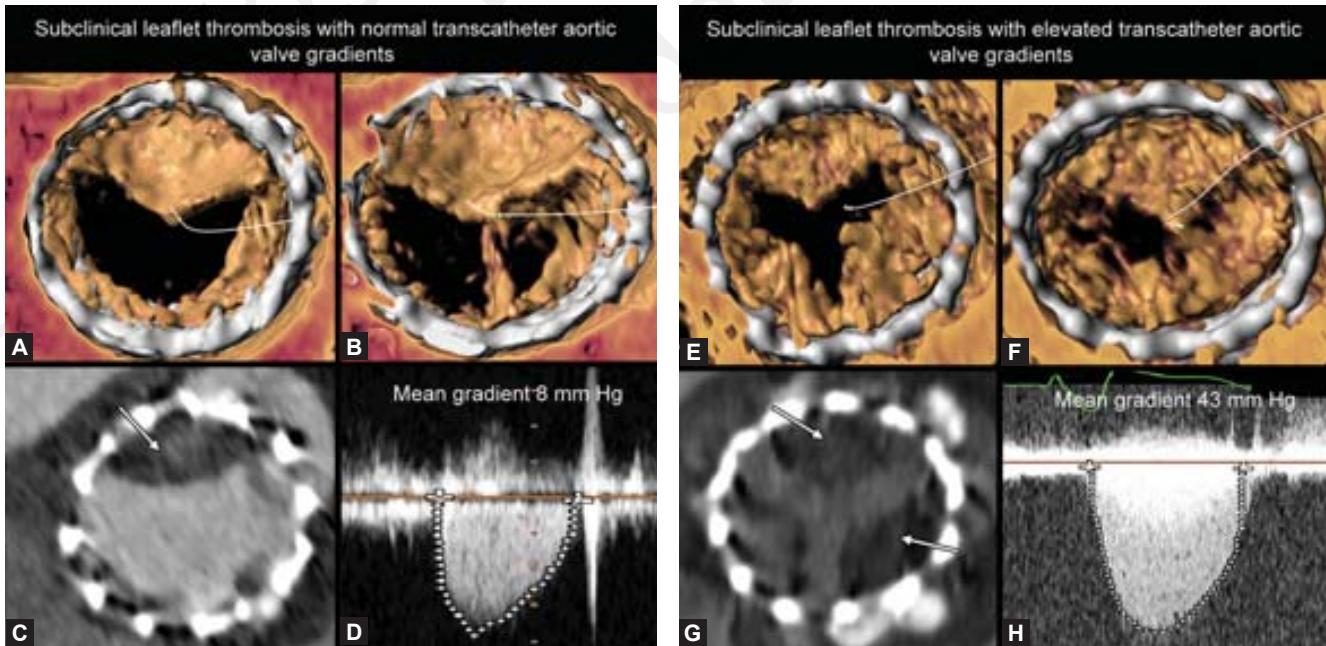

FIG. 1: Subclinical leaflet thrombosis, associated with normal gradients and elevated aortic valve gradients. (A–D) Reduced leaflet motion during systole (A) and diastole (B); in the presence of hypoattenuation associated leaflet thickening (C) and normal aortic valve gradients (D). (E–H) Reduced leaflet motion during systole (E) and diastole (F); in the presence of hypoattenuation associated leaflet thickening (G) and normal aortic valve gradients (H).

an increased incidence of transient ischemic attacks with subclinical leaflet thrombosis (although the stroke rates were not different). While subclinical leaflet thrombosis is frequent, clinically significant valve thrombosis of TAVs resulting in heart failure or thromboembolic complications is rare, occurring in only up to 0.5% of the patients after TAVR.²³ Whether subclinical leaflet thrombosis is an innocent imaging finding; or if it really impacts valve hemodynamics, clinical outcomes and valve durability needs to be determined with prospective randomized trials with long-term follow-up. The role of routine anticoagulation after TAVR for the prevention of subclinical leaflet thrombosis and its impact on clinical outcomes is being evaluated in the GALILEO trial (NCT02556203) and ATLANTIS trial (NCT02664649).

Valve Durability

Transcatheter aortic valve replacement was initially performed in high-risk patients, who had limited life expectancy due to the presence of comorbidities. In the PARTNER 1 trial of inoperable patients with severe AS, only 1 out of 169 patients who did not undergo TAVR was alive at 5 years. In the PARTNER 1 trial of high-risk patients, 67.8% of the patients undergoing TAVR had died by 5 years. Given the high mortality in the high-risk patients undergoing TAVR in the early TAVR era, there is paucity of evidence on the long-term durability of TAVs. Nevertheless, the limited datasets available on valve durability of TAVR valves are reassuring, within the limitations of poor long-term survival in majority of patients. A report from the 5-year follow-up from the PARTNER 1 trial (with 5-year follow-up echocardiograms available in 424 patients undergoing TAVR) demonstrated valve durability of Edwards SAPIEN valve, without structural valve degeneration at 5 years. Long-term durability of TAVs will be available from the low-risk and intermediate-risk study, with longer life-expectancy.

Other Limitations

The rates of vascular complications, bleeding complications, need for alternate access, and paravalvular regurgitation have become less common with improved device design; smaller caliber delivery systems; improved patient screening; and improved operator experience. The newer TAVs (SAPIEN 3, Evolut PRO, and Lotus) have moderate-severe PVL rates of less than 2–3%. The incidence of vascular complications and bleeding complications; as well as the need for alternate access, continues to decline with the availability of 14 French delivery systems.

CONCLUSION

In summary, TAVR is a breakthrough technology and is the standard of care for the treatment of severe symptomatic AS in high-risk patients; an alternative to SAVR for intermediate-risk patients or for the treatment of high-risk patients with degenerative bioprosthetic aortic valves. With device iterations, accumulating clinical experience, and better patient screening, the incidence of complications after TAVR continues to decline.

Imaging for Transcatheter Aortic Valve Implantation: Practical Aspects

Kinjal Banerjee, Nyal Borges, Parth Parikh, Samir Kapadia

INTRODUCTION

Transcatheter aortic valve implantation (TAVI) has dramatically changed management of patient with severe aortic stenosis (AS). Patients previously considered inoperable are often excellent candidates for TAVI. The indications for transcatheter aortic valve replacement (TAVR) have now been expanded to patients with high- and intermediate-surgical risk for surgical aortic valve replacement (SAVR) as well. Without direct visualization and access to the valve, multimodality imaging plays an immense role in accurate planning and successful execution of the procedure.

PLANNING PHASE

The process begins with the evaluation of a patient with severe AS as a candidate for TAVR. Broad objectives in the planning phase include the following described here.

Patient Selection

While the indications for TAVI are expanding, appropriate patient selection is an essential part of a successful procedure. The first goal is to establish severe AS and indications for a valve replacement. Ruling out other severe valvular lesions is also an important part of establishing suitability for TAVI. Patient with concomitant severe mitral pathology may benefit more from a combined open surgical procedure.

Elderly patients with significant calcific AS often have concomitant multi-vessel coronary artery disease. A patient who may need coronary artery bypass graft (CABG) now or in the near future may benefit from a combined open surgical procedure.

Transthoracic Echocardiography

By the time a patient is seen by a Heart Team, the patient usually has had a transthoracic echocardiography (TTE) (Fig. 1). A two-dimensional TTE provides an initial assessment of severity of AS, morphology of the aortic valve, and

coexisting valve lesions like mitral regurgitation (MR). It also provides an estimation of left ventricular (LV) and right ventricular (RV) function, among other parameters. This is a good starting point, and is enough to give a rough idea of patient suitability for TAVI. It is best to consider the TTE as a firewall to exclude patients who are not candidates for TAVI and thus to avoid further, potentially unnecessary, testing. The most important information that TTE provides is with regards to severity of AS. Aortic valve area and peak and mean gradients are important measurements. In patients with low-gradient AS careful measurement of flow should be undertaken. Patients with low flow (35 mL/m^2) are defined as low-flow AS patients. Some elderly patients, particularly men above 80 years of age with low-flow low-gradient AS should be screened for TTR amyloid using pyrophosphate scan or cardiac magnetic resonance imaging (MRI). Patients with amyloidosis have worse prognosis with or without TAVI. In some patients with advanced amyloidosis, TAVI may not help to improve symptoms particularly if AS is not critical.

Cardiac Catheterization

Most centers routinely obtain a diagnostic cardiac catheterization prior to TAVI. This serves several purposes. First, a diagnostic coronary angiogram assesses coronary pathology and helps decide the need for intervention. The optimal timing of intervention for coronary lesions is a matter of debate. However, for patients with multi-vessel disease, a combined CABG and aortic valve replacement (AVR) may be a more suitable procedure. Further, a combined TAVR and percutaneous coronary intervention (PCI) has been shown to be feasible and safe. However, patients with a low ejection fraction less than 30% and high STS score more than or equal to 10 have been shown to have higher risk of 30-day mortality after PCI. Second, it serves as a secondary modality to evaluate LV hemodynamics. Invasive pressure measurements are not routinely necessary with high quality echocardiographic Doppler estimation, but may serve to provide additional assessment.

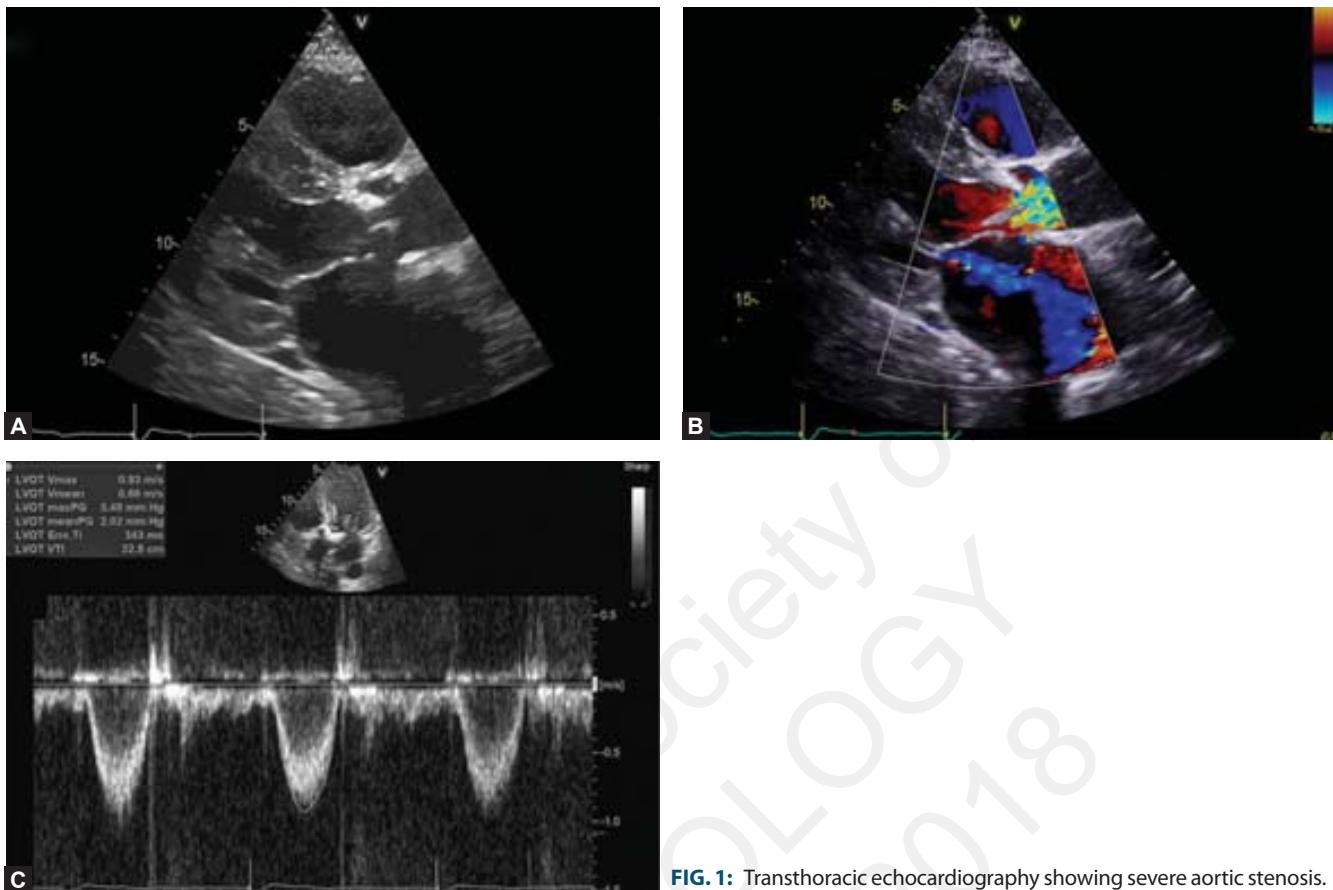

FIG. 1: Transthoracic echocardiography showing severe aortic stenosis.

Transesophageal Echocardiography

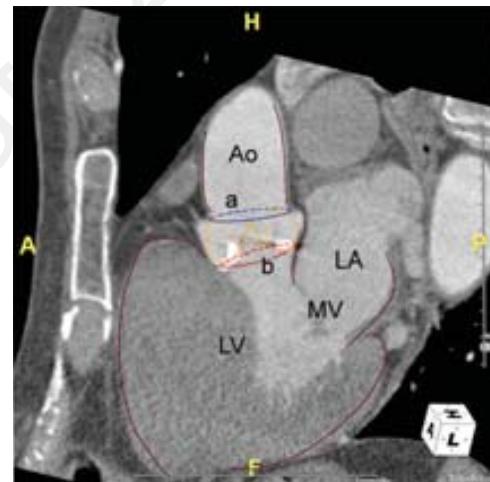

Preprocedural transesophageal echocardiography (TEE) with three-dimensional imaging may be used to further assess the aortic root, especially in the setting of morphological anomalies of the aortic valve. It may serve to help annular sizing in patients unable to undergo a contrast-enhanced computed tomography (CT) scan due to renal impairment. However, in many centers cardiac MRI can be performed to evaluate the aortic annulus. Therefore, TEE is sparingly used for preprocedural planning at this time.

PLANNING PHASE: PROCEDURAL PLANNING

Once indications for AVR have been firmly established, and TAVR is considered, more concrete anatomical information is needed to plan the procedure. Special emphasis is placed on detailed aortic root anatomy (Fig. 2), to aid in valve sizing, coronary anatomy in relation to aortic valve and annular calcification. Evaluation of access for TAVI is another important goal for preprocedural planning.

Computed Tomography Imaging Protocol: Basics and Objectives

To obtain optimal images of the aorta, several conditions should be met. Firstly, iodinated contrast provides good delineation of the aorta and blood vessels. Imaging must

LA, left atrium; LV, left ventricle; MV, mitral valve; Ao, aorta.

FIG. 2: Basic anatomy of the aortic root. A, Sinotubular junction; B, Aortic annular plane defined by lowest point of three cusps.

be obtained in the arterial phase to allow acquisition of the aorta, down to the iliac and femoral arteries. In patients with a contraindication to iodinated contrast, e.g., renal disease, noncontrast CT images may suffice for access evaluation in many patients but root assessment is not possible with noncontrast CT alone. As indicated above, TEE or cardiac MRI may be considered. Second, electrocardiographic (ECG) gating is necessary to eliminate motion artifacts, and

also allows measurement of the aortic annulus in specific phases of the cardiac cycle. Some centers prefer prospective ECG gating, where the patient is exposed to X-rays only during a specific phase of the cardiac cycle. While this generates similar image quality and reduces radiation exposure, images are often restricted to a single phase of the cardiac cycle and lacks the flexibility of retrospectively gated images. Images are reconstructed using multiplanar views for accurate measurement of annulus (Fig. 3) Images are obtained in 0.5 mm thickness for the annulus but 3 mm thickness may be adequate for access evaluation in abdomen and pelvis. Annular measurements are usually taken in systolic phase of the cardiac cycle. Centerline reconstructions allow imaging of the aorta, iliac, and femoral arteries in planes perpendicular to blood flow irrespective of curvature of these arteries.

The following measurements are necessary for the aortic root:

- **Aortic annulus:** The aortic annular is defined as the plane that passes through the lowest point of all three aortic cusps. The area of the aortic annulus is measured as a polygon, and then converted to a diameter. Similarly, the diameter is also estimated by measuring the perimeter of the aortic annulus. This measurement is extremely critical as it provides vital information for sizing of the prosthetic transcatheter heart valve (THV). Incorrect sizing can have devastating consequences, with undersized valves at risk for paravalvular leakage (PVL) and embolization, while oversized valves may cause conduction anomalies or even an annular rupture. Area-based sizing is considered standard and reproducible, and tend to yield more conservative estimates of annular size for balloon expandable valves. For self-expanding valves, where valves conform to annulus, perimeter-based sizing is used more commonly. The degree of oversizing is an important parameter in procedure planning, and is associated with procedural success and complications. Recommended oversizing ratios vary by valve models and technologies
- **Height of coronary ostium:** The distance from the aortic annulus plane to the opening of the left main coronary artery is an important measurement. Ensuring adequate clearance of the coronary ostium allows the valve to be implanted without impinging on coronary blood flow, and allows the coronary arteries to be accessed in the future. Other measurements used to assess ostial clearance are mean sinus of Valsalva diameter and sinus or annulus diameter ratio. Effaced sinuses with low coronary arteries and bulky calcification of leaflets have been associated with higher risk of coronary occlusion with TAVR
- **Valve morphology:** A gross assessment of the valvular morphology is essential to a successful procedure. Calcification of the aortic root may put the patient at risk for PVL, conduction abnormalities or even annular rupture. Specific measures can be taken in patients with bicuspid valves to appropriately select and place the valve
- **Sinotubular junction (STJ) and ascending aorta:** The STJ diameters are a sizing parameter for self-expanding valves which extend proximally beyond the STJ. Severe calcification of the STJ and ascending thoracic aorta puts the patient at risk of multiple complications, including aortic wall dissection, rupture, and embolic complications
- **Concomitant cardiac pathology:** Pathology involving the mitral valve, left ventricular outflow tract (LVOT), or interventricular septum may complicate, or exclude the option of, TAVI for a patient. Similarly, the presence of an intraventricular thrombus is also a contraindication for TAVI
- **Access feasibility:** Transfemoral TAVR requires a sheath of 14F-18F sheath dependent on specific TAVR device. The arterial phase of the CT scan is used to assess the descending aorta and the iliac and femoral arteries. Excessive tortuosity, significant calcifications, atherosclerotic occlusive disease or aneurysmal changes put the patient at some risk of access-related complications like bleeding, hematoma or pseudoaneurysms, as well as embolic complications including stroke. If transfemoral

access is unsuitable, the patient may be a candidate for an alternative access route, the most common of which is trans-subclavian followed by transaortic access. Transapical access is also used sometimes but it is rare these days with availability of TAVI devices requiring smaller access.

- Estimation of aortic valve plane for device implantation using fluoroscopy. Identification of a plane perpendicular to the native annulus (coplanar angulation) may reduce the need for multiple dye injections during the procedure to align fluoroscopic imaging to the valve.

PROCEDURE PHASE

Being a minimally invasive transcatheter procedure, intra-procedural imaging plays an essential part of the entire procedure. The main aims of intraprocedural imaging are:

- Procedural guidance, appropriate positioning of THV across the valve and deployment
- Identification of complications intraoperatively, with the potential to intervene immediately.

Fluoroscopy

Fluoroscopy is the primary imaging modality used for guidance during the procedure. Identification of a coplanar angle during procedural planning can reduce both dye injection and radiation exposure during aligning the fluoroscope to an optimal angle perpendicular to the native valve. Biplane fluoroscopy can provide an additional dimension to imaging, and allow guidance in two separate orthogonal planes. Dye injections allow visualization of aorta and aortic valve (Fig. 4), and allow positioning of the THV across the native aortic valve (Fig. 5A). The depth of implantation is estimated as the depth of the distal edge of the valve from the noncoronary sinus. The valve is expanded (for balloon-expandable valves) or deployed (for self-expanding valves) under real-time fluoroscopic guidance (Figs. 5B and C). Once the valve is deployed, further dye injections allow visualization of the positioned valve in relation to the aortic

root (Fig. 6). Retrievable valves can be repositioned before they are released from the deployment catheter. Further, aortic regurgitation (AR) can be assessed by regurgitation of dye from the aorta into the LV cavity. A final dye injection is usually recorded at the end of valve deployment to document procedure success, lack of significant AR, and final implantation depth. As the catheter is withdrawn, dye is injected into the iliofemoral system to ensure there are no vascular complications.

Role of Transesophageal Echocardiography during Transcatheter Aortic Valve Implantation

Transesophageal echocardiography may be used to provide an additional layer of real-time guidance during the procedure. It allows high-resolution imaging of the aortic valve, and can aid with positioning of the valve prior to deployment. Three-dimensional reconstruction provides an anatomically correct image of the aortic valve and aortic root both before and after deployment of the valve. In the event of PVL, TEE can precisely localize the regurgitant jet and allow assessment of severity. Mild PVL is common after TAVI, but moderate or severe PVL need intervention, typically a balloon postdilation. Rarer complications like a valve embolization, new wall motion abnormality, pericardial effusion, severe valvular regurgitation, rupture of the annulus or dissection of the aorta can be rapidly identified by intraprocedural TEE.

There is a growing trend of performing TAVI under conscious sedation without general anesthesia. This serves to reduce anesthesia-related complications and to shorten hospital stay after the procedure. Therefore, in the current era TEE is not performed at the time of procedure. In this situation TTE is a must. Just after valve deployment TTE is performed to rule out pericardial effusion, PVL and new wall motion abnormalities. TAVI should not be performed without availability of echocardiographic machine in the cath laboratory.

Note rapid pacing via temporary wire placed in right ventricle.

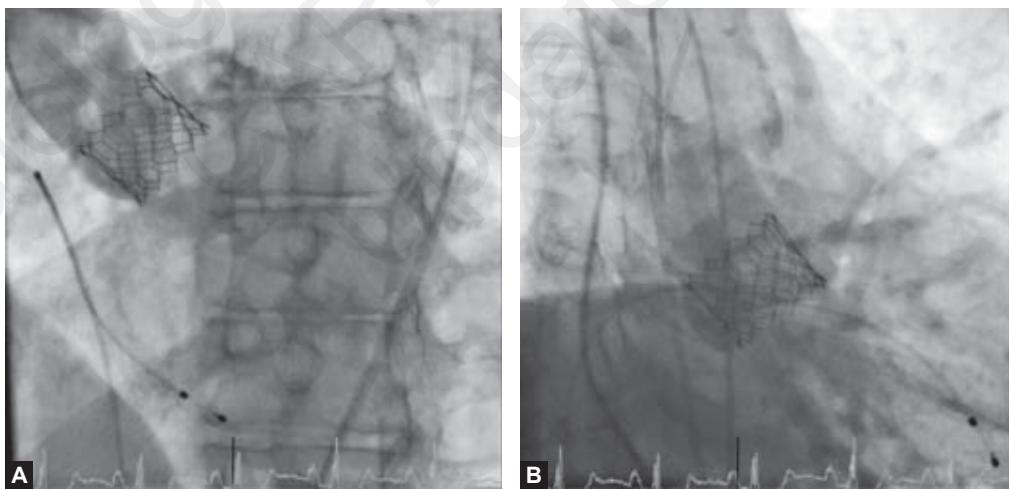

FIG. 6: Aortogram after valve deployment to check positioning of the valve, implantation depth, and aortic regurgitation. The coronary ostia may be engaged and separate images obtained if there is suspicion for coronary obstruction.

POSTPROCEDURE FOLLOW-UP

Patients undergoing TAVI need follow-up after the procedure. Parameters to monitor include:

- Valve gradient and effective orifice area for baseline assessment and for future diagnosis of worsening valve function

- *Aortic regurgitation:* Central and paravalvular
- *Other complications:* Leaflet thrombosis, device migration, and endocarditis
- *Changes in cardiac structure and function:* Effect of valve replacement on LV hypertrophy, mitral valve function, and other cardiac pathology.

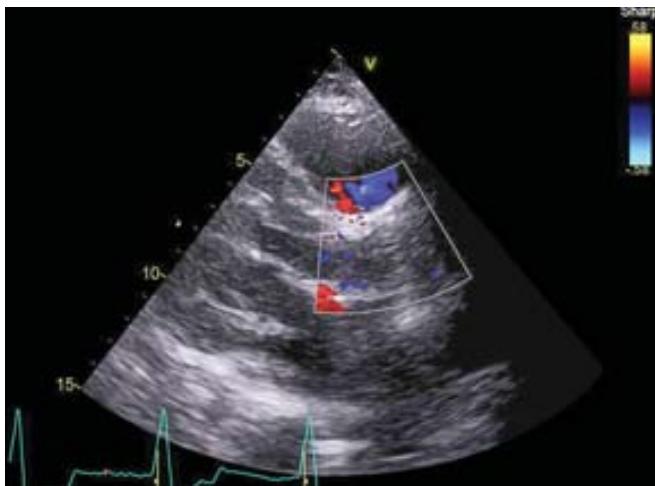

FIG. 7: Transthoracic echocardiogram obtained postprocedure, showing valve *in situ* and no aortic regurgitation.

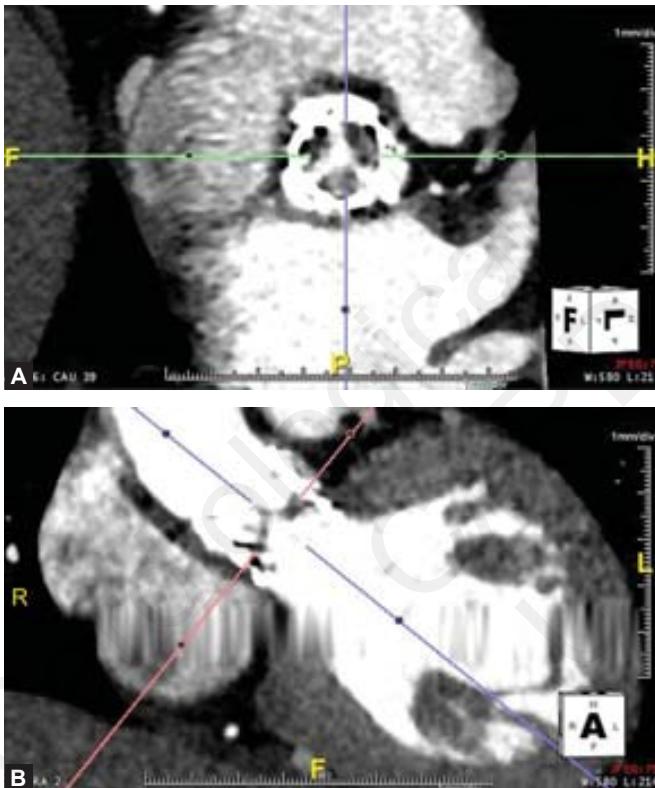

FIG. 8: Post-transcatheter aortic valve replacement CT imaging with contrast showing hypoattenuated leaflet thickening.

Transthoracic echocardiography is adequate for follow-up in most patients (Fig. 7). If valve gradient is increasing or there is valvular AR, hypoattenuated leaflet thickening (HALT) is suspected. HALT is properly diagnosed with contrast gated CT scan imaging in all cardiac cycles (Fig. 8). TEE is not as sensitive as CT but can be used in patients with severe renal insufficiency.

CONCLUSION

Successful TAVI is dependent on appropriate patient selection, thorough procedure planning, and real-time guidance during the procedure. At each of these stages, imaging plays an important role. TTE provides a basic starting point in confirming the indications of AVR. CT scanning plays a vital role in access planning and valve sizing. Fluoroscopy forms the mainstay of intraprocedure real-time guidance, and for assessment of immediate postprocedure complications. TEE and MRI serve as backup imaging modalities when standard imaging is not possible, or further detail is necessary.

Alcohol Ablation for HOCM: Progress over the Past Two Decades

Hubert Seggewiss, Angelika Koljaja-Batzner

INTRODUCTION

Hypertrophic cardiomyopathy (HCM) is the most common genetic heart disease with an estimated incidence between 0.2 and 0.6%.^{1,2} The most important pathophysiologic finding is left ventricular obstruction with significant impact on symptoms and prognosis of the patients.³ In 1995, alcohol septal ablation was introduced as new treatment option and alternative to surgical myectomy in symptomatic patients with hypertrophic obstructive cardiomyopathy (HOCM).⁴ In this chapter, we describe the developments of the treatment within the last two decades.

HISTORICAL DEVELOPMENT OF PERCUTANEOUS SEPTAL ABLATION

After introduction of percutaneous treatment of coronary artery disease in the late 1970s advances in interventional techniques widened the therapeutic options into the field of valvular and structural heart diseases. Three observations were important for the development of percutaneous septal reduction therapy in HOCM.

Sigwart et al. reported on impaired systolic wall motion by temporary balloon occlusion of coronary arteries.⁵ Come et al. observed disappearance of left ventricular obstruction in patients with HOCM following myocardial infarction.⁶ Finally, Brugada et al. successfully treated malignant ventricular tachycardia by septal artery occlusion with alcohol injection into septal branches.⁷ Simultaneously, performed animal studies showed that use of absolute alcohol resulted in more homogeneous scars.

All these observations led to the primary idea of percutaneous treatment of septal hypertrophy in HOCM patients by G Berghofer (personal communication).⁸ He developed the hypothesis that occlusion of a septal coronary branch supplying the hypertrophied septal area with consecutive therapeutic infarction may result in gradient reduction. Identification of the target septal branch should

be done by echo contrast study during temporary balloon occlusion of the target branch. Berghofer discussed that the definitive septal branch occlusion should be performed either chemically by alcohol injection or mechanically by deployment of coils. Unfortunately, Berghofer could not transfer his idea into clinical practice.

It took some years until Kuhn et al. published their studies of the effect of temporary balloon occlusion in patients with HOCM in the early 1990s.⁹ In the meantime Sigwart has treated patients with the alcohol ablation. He published the results of the first three patients in 1995.⁴ The first publication of the new treatment option for symptomatic patients with HOCM opened the discussion about the long-term effect of the induced myocardial scar.¹⁰ Despite the discussion septal ablation became popular worldwide.^{8,11-13} Introduction of myocardial contrast echo guidance in 1996 by Faber et al. was the major step for this acceptance as first choice treatment in most patients.¹¹

INDICATION FOR SEPTAL ABLATION

Symptomatic (dyspnea, angina, exercise-related syncope) patients with significant obstruction (>30 mm Hg at rest and >50 mm Hg at provocation) despite optimal medical therapy (beta-blocker or verapamil without vasodilating drugs) should be considered for septal reduction treatment. From the morphologic standpoint patients isolated non-systolic anterior motion (non-SAM)-related mitral valve disease should primarily undergo myectomy. But, clearly SAM-related outflow tract gradient with consecutive mitral regurgitation and patients with mid-cavitary obstruction can be successfully treated by percutaneous transluminal septal myocardial ablation (PTSMA).¹⁴ Patients with additional cardiac diseases are primarily candidates for combined surgical therapy although combined interventional treatment can be performed, especially in patients with coronary artery disease.¹⁵ Patients with prior myectomy and insufficient result had been successfully treated.¹⁶ In summary,

indication for septal ablation is an individual decision taking into account clinical and morphologic aspects as well as the patient's choice after detailed information about the different treatment options.

TECHNIQUE OF SEPTAL ABLATION

First of all, it has to be stated that treatment of symptomatic patients with HOCM is an elective procedure in order to improve the quality of life. Therefore, achievement of a satisfactory result and avoidance of complications are equivalent therapeutic aims. An indispensable requirement is that alcohol septal ablation should be performed only by an experienced multidisciplinary team in the treatment of HCM including an experienced interventional cardiologist who is familiar in the management of all potential interventional complications and an experienced echocardiographer. Due to the large number of anatomic variations a certain number of procedures are necessary in order to maintain the interventional skills.¹⁷

After introduction of percutaneous septal alcohol septal ablation for treatment of symptomatic patients with HOCM a large number of technical variants have been used and described.¹⁸ As in most centers we use echocardiographic guided ablation which was introduced as PTSMA.¹⁹

A diagnostic catheterization is required to exclude coronary artery disease in symptomatic patients, define a potential target septal branch, and measure left ventricular outflow tract gradient (LVOTG). Simultaneous pressure recording of aortic and left ventricular pressures (Fig. 1) is necessary in order to measure accurate LVOTG at rest, during Valsalva maneuver, and postextrasystolic beat (Brockenbrough phenomenon), especially in patients with atrial fibrillation.

To perform PTSMA, we prefer two arterial accesses. A coronary angioplasty guide catheter is inserted via the right femoral artery and a special pigtail catheter via the left femoral artery. Simultaneous recording of the aortic pressure through the guide catheter and the left ventricular pressure through the pigtail catheter enables earliest diagnosis of hemodynamic changes during ablation, especially potential complications like pericardial tamponade.

Up to 50% of the treated patients develop temporary complete heart block at any time of the procedure. Therefore, placement of a temporary pacemaker lead is mandatory in patients without pacemaker or implantable cardioverter defibrillator (ICD). To avoid rarely observed loss of capture after alcohol injection, especially in high risk patients [previous myectomy, baseline left bundle branch block (LBBB), septal pacing], output increase of permanent

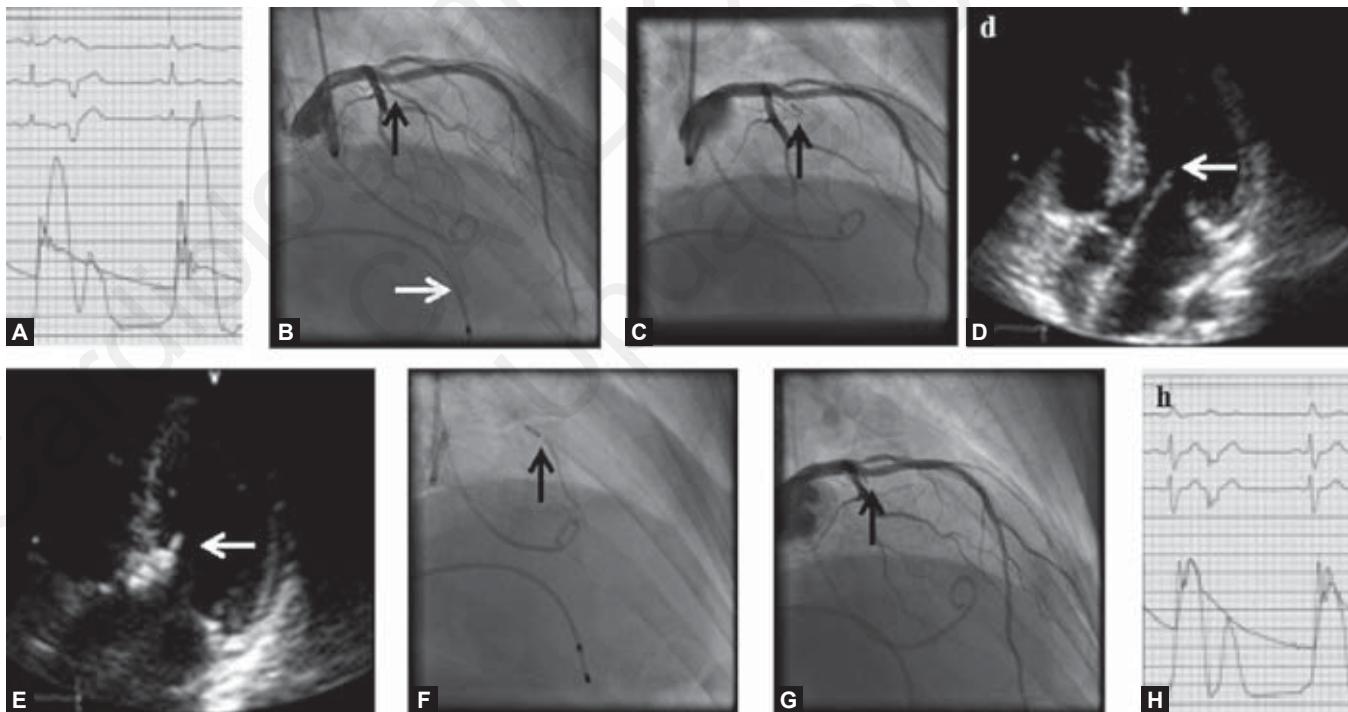

FIG. 1: Echo-guided septal ablation (percutaneous transluminal septal myocardial ablation); **A**, Simultaneous pressure recording of left ventricular outflow tract and aorta at rest and post extrasystole; **B**, Baseline coronary angiography of the left coronary artery with estimated target branch (black arrow) and temporary pacemaker lead (white arrow); **C**, Placement of the "over-the-wire" balloon into the target septal branch (black arrow); **D**, Modified baseline four-chamber view in transthoracic echocardiogram with systolic anterior motion (SAM) septal contact (arrow); **E**, Echo contrast depot in the basal septum at SAM septal contact (arrow); **F**, Injection of contrast dye through the central lumen of the "over-the-wire" balloon (arrow); **G**, Occluded septal branch (branch) after balloon withdraw 10 minutes after last alcohol injection; **H**, final hemodynamic measurement with gradient at rest and post extrasystole.

pacemaker or ICD is recommended. Weight adjusted heparin at the beginning of the procedure as well as opiate analgesia before alcohol injection are administered intravenously as a routine.

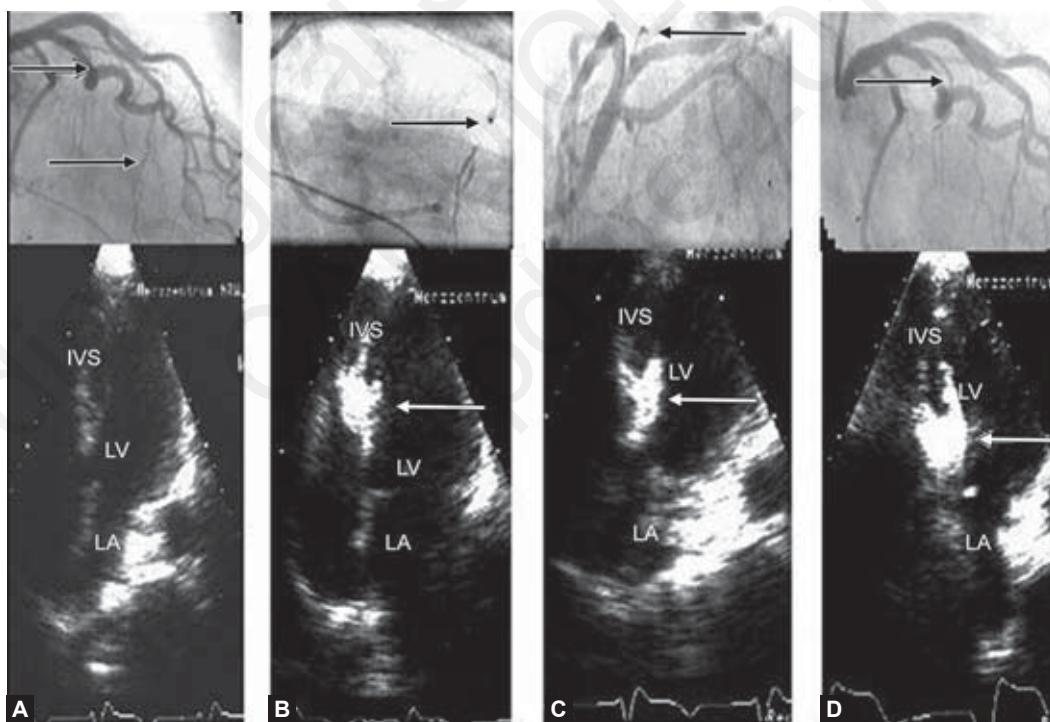

Left coronary angiography [usually in right anterior oblique (RAO) cranial view] permits the identification of possible target septal branches. In patients with left ventricular outflow tract obstruction commonly the first large septal branch or one of its side branches is considered as target vessel. Nevertheless, the diagonal and intermediate branches and rarely, the right coronary artery should also be carefully inspected for the existence of atypically originating septal branches.

An angioplasty floppy guidewire with standard length is advanced in the supposed target septal branch. Sometimes, it may be necessary to try differently shaped wires due to the enormous variety of septal branches anatomy. A mildly oversized short (6–10 mm) over-the-wire (OTW) balloon is advanced into the septal branch and inflated. Inflation pressures above the nominal pressure should be avoided as they result in compression of the central lumen of the catheter. Usually, balloon sizes are 1.5–2.5 (rarely 3.0) mm. The occluded balloon should avoid alcohol spilling to the left anterior descending (LAD), thus avoiding infarction of

non-target myocardial areas. Avoidance of the parent vessel dissection can be achieved by positioning the balloon distally the origin of the target branch.

Identification of the target septal branch is the most critical part as alcohol misplacement could lead to necrosis in unwanted left and right ventricular areas like free-walls or papillary muscles with potential mitral or tricuspid valve regurgitation. Furthermore, an excessive anatomic variation with potential collateralization in the septal artery system has been described.²⁰ Postmortem studies have shown that, the first septal branch supplies the right ventricular free wall in 2 out of 10 patients and led to incomplete supply of the basal septum in 4 out of 10 patients.²¹ In 1996, Faber et al. had detected alcohol misplacements in the septal area during the early series. Therefore, they invented echocardiographic guidance of the procedure in August 1996 which was presented at the American Heart Association (AHA) annual scientific meeting in 1996. (Fig. 2) Each predicted target septal branch should be tested with myocardial contrast echocardiography.^{11,22,23}

After balloon placement and before inflation, multiple transthoracic echocardiographic views (parasternal, apical, and subcostal) are taken and recorded. Thereafter, the balloon catheter is inflated and the guidewire withdrawn. About

IVS, intraventricular septum; LV, left ventricle; LA, left atrium.

FIG. 2: First ever echo-guided septal ablation (upper line angiography, lower line transthoracic echocardiography); A, Angiographic documentation of atypical (upper arrow) and typical (lower arrow) septal branches. Echocardiographic four-chamber view [intraventricular septum (IVS), left ventricle, left atrium]; B, Contrast injection through "over-the-wire" balloon in the typical branch (black arrow) with echo contrast depot in the mid-septal intraventricular septum (IVS) (white arrow); C, Contrast injection through "over-the-wire" balloon in the atypical branch (black arrow) with echo contrast depot in the subaortic IVS (white arrow); D, Final angiography with occlusion of the atypical septal branch (black arrow) and perfect located alcohol depot (white arrow).

1–2 mL of echocardiographic contrast agent is injected through the balloon catheter with simultaneous transthoracic echocardiography repeating the previous recorded views in order to exclude misplacements which may lead to complications in case of alcohol injection. After withdraw of the mostly used contrast agent Levovist® (Bayer, Germany) from the market, we compared different echocardiographic contrast agents in vitro and during septal ablation. Finally, cooled (4°C) agitated gelatine polysuccinate (Gelafundin®, B Braun, Melsungen, Germany), a colloid plasma volume substitute, offers the best contrasting properties and stability.²³ The use of Gelafundin® gives reliable information regarding contrast opacification of any other cardiac structure (right ventricle, papillary muscle, and other areas of left ventricle). After confirmation with myocardial contrast echocardiography, selective angiography of the target septal branch through the inflated balloon catheter should document the adequate sealing of the septal branch and exclude filling of any other coronary artery through septal collaterals.^{24,25} Diagnostic accuracy of this important step will be improved by increasing the frame rate during contrast injection. In case of retrograde filling of the LAD or any other vessel the collateralizing septal branch can be occluded by a monorail balloon.²⁴ After identification of the ideal septal branch up to 2–3 cc of absolute alcohol is slowly injected through the central lumen of the OTW balloon under continuous fluoroscopic—to exclude instability and dislocation of the balloon, hemodynamic, and electrocardiographic control. Injection rate is 1 cc/min followed by angiographic control of the left coronary artery after each cc of alcohol. Injected alcohol amount should be 1 cc/1 cm septal thickness.²⁶

Any catheter dislocation or resistance during injection should lead to immediate cessation of injection to avoid alcohol spilling. The balloon is left in place for 10 minutes after final alcohol injection. Shorter time have been associated with higher complication risk due to alcohol backflow.²⁷

After balloon retraction, a final angiogram documents occlusion of the septal branch without complications of any other vessel. Thereafter, final measurement of LVOTG at rest and provocation are repeated. As we are aware of hemodynamic remodeling and scar formation with further gradient reduction up to 12 months after alcohol injection we plan ablation of further septal branches only in patients with combined subaortic and mid-cavitory obstruction in one session to reduce the risk of complications and keep to therapeutic scar as small as necessary.

After removal of the right femoral artery sheath and arterial closure with a closure device, the patient will subsequently stay in the coronary care unit for at least 48 hours under constant hemodynamic and rhythm control. Cardiac enzyme measurements every 6–8 hours allow documentation of peak creatine kinase (CK) value. In absence of third-degree atrioventricular (AV) block, the temporary pacemaker will be removed the morning after the procedure. In case an ongoing heart block requiring temporary pacing the jugular or subclavian venous access is preferable in order to reduce the risk of lower limb venous thrombosis. After 48 hours we

decide on implantation of a permanent pacemaker or ICD in case of increased risk of sudden cardiac death according to the clinical risk stratification models.^{28–30} Hospital discharge usually takes place after 1 week of permanent electrocardiographic monitoring being aware of the risk of late heart block.

The described actual technique is the result of permanent steps to reduce complications and improve hemodynamic and clinical results. Main steps of this improvement were the introduction of echo contrast guidance and reduction of the amount of alcohol. Other discussed technical aspects like, intracardiac echocardiography or preinterventional computed tomography (CT) coronarography for choosing the target septal branch did not gain widespread acceptance.

ACUTE RESULTS AND COMPLICATIONS

Since, the first report of percutaneous treatment of symptomatic patients with HOCM by Sigwart a large number of consistent reports have shown acute hemodynamic success in more than or equal to 90% of the patients mainly treated with the echocardiography-guided technique.^{4,8,11–13,26,30–37}

Faber et al. reported in the first series of 61 patients with echo-guided septal ablation compared to the initial 30 patients with nonecho-guided ablation a superiority with respect to acute gradient reduction (>50% gradient reduction 92% vs. 70%) and need for permanent pacemaker implantation (7% vs. 17%). Reduction of LVOT obstruction resulted in symptomatic improvement and in increased of exercise capacity.¹⁹

From the very beginning of percutaneous septal ablation concerns about the risk of procedure-related acute and late complications had been discussed. Despite the reduction of reported complication rates due to increased experience of the interventional cardiologists it should be addressed that avoidance of complications should be the main goal of this elective procedure beside the achievement of a good hemodynamic and clinical success. Up to now there is an open discussion about the numbers of required procedures to achieve and maintain large enough experience to perform safe procedures.

The most common complication after alcohol septal ablation is complete heart block requiring permanent pacing. Despite the reduction of heart block after introduction of echo-guided ablation up to 50% of patients may develop conduction problems in the first hours after alcohol injection, which resolves spontaneously in most cases (either in the cath laboratory or in the coronary care unit). This is due to the close proximity of the first septal branch with the His bundle or the right bundle branch.^{38,39} As pointed out before placement of a temporary pacemaker before alcohol injection is an absolute requirement of the procedure because the development of heart block is not predictable.

Faber et al. developed a scoring system based on ECG parameters, hemodynamic variables and myocardial enzyme release for the prediction of pacemaker dependency after alcohol septal ablation which turned out to be a sufficient help in clinical routine.⁴⁰ Patients with pre-existing left

bundle branch block are at higher risk to develop complete heart block as nearly 50% of the patients develop complete right bundle branch block. In such patients implantation of a permanent pacemaker before alcohol septal ablation can be discussed. As pointed out before preprocedural ICD implantation is certainly reasonable in case of an increased risk of sudden cardiac death according to the commonly used risk stratification models.

Advances of the initial technique of alcohol septal ablation with the addition of myocardial contrast echocardiography and use of lower alcohol volumes resulted in a reduced need for permanent pacing after the intervention. Finally, about 10% of the patients will require a permanent pacemaker.^{11,41-43}

Like any interventional procedure alcohol septal ablation may be complicated by technical problems. Reported complications include coronary dissection, coronary spasm, ventricular fibrillation, cardiac tamponade mainly due to temporary pacemaker lead, pulmonary embolism, cardiogenic shock, stroke, and problems with the puncture site.³³ As in our personal experience in about 2,000 ablations without coronary spasm and ventricular fibrillation we would postulate that leakage and misplacement of alcohol are the main reasons for these reported complications. Therefore, special care should be taken to avoid alcohol leakage to the LAD due to retrograde flow through an incompletely sealed septal branch or through collateral flow to other septal branches that could lead to an unwanted infarction.^{24,25} Dislocation or rupture of the balloon during alcohol injection as well as too early deflation and retraction of the balloon after alcohol injection are also possible causes of alcohol spilling.^{27,44} These complications can be avoided by careful intervention following a strict interventional protocol (use of slightly oversized balloon, careful angiographic exploration of the septal branch, thorough observation of the balloon during slow alcohol injection, well-timed deflation 10 minutes after alcohol injection).²² The described complications associated with the technical part of the procedure are influenced by the considerable learning curve and are rare in high-volume centers.^{36,45} In addition, it should be mentioned that the procedure can and should be abandoned if the operator has the impression of a potential complication.

FOLLOW-UP RESULTS

From the very beginning of PTSMA follow-up studies have shown ongoing hemodynamic and clinical improvement with further reduction of the left ventricular outflow tract obstruction during the first year due to postprocedural remodeling.³¹

The mean residual LVOTG decreased from 60–70 mm Hg to 15–20 mm Hg. Patients with higher residual gradients have an increased all-cause mortality at follow-up.^{35,43,46} Mainly due to the anatomic variation of the septal artery system²¹ 14% of patients may require a second ablation to get an adequate result.⁴⁷

Successful ablation results in reduction of SAM-related mitral regurgitation and pulmonary artery pressure.^{11,31} Hemodynamic improvement after ASA is associated with symptomatic improvement and increased exercise capacity. The subjective improvement has been verified by objective measurements of exercise performance on cardiopulmonary exercise testing.^{26,48}

With introduction of septal ablation for symptomatic patients with HOCM, concern was raised on the potential negative effect of creating a myocardial scar in patients who were already at risk for ventricular arrhythmias.¹⁰ This presumption was supported by initial case reports of ventricular arrhythmias occurring after septal ablation.⁴⁹

We reported on an up to 8 years follow-up in the first 100 consecutive symptomatic patients treated with echocardiography-guided technique. Only one sudden cardiac death was observed, and event-free survival at 5 years was 82%.³¹ A more recent study on 178 consecutive patients treated with septal ablation provided similar results. Survival after 1, 5, and 10 years were 97%, 92%, and 82%, respectively, and did not differ from survival in an age- and sex-matched general population. The only independent predictor of all-cause mortality was age at the time of ablation.⁵⁰

A study on 470 consecutive patients treated with echo-guided ablation between 1996 and 2010 in Germany and Denmark addressed the question of sudden cardiac death during follow-up. Before ablation, 25% of the patients had more than or equal to 2 risk factors for sudden death with a significant reduction to 8% after ablation. The observed 10-year survival was 88%, and survival free of sudden death was 95%, which was similar to that of a matched general population.⁴³

Veselka et al. reported on the results of the Euro-ASA registry in which 1,275 patients underwent the procedure in 10 European tertiary referral centers in 7 countries. The 10-year overall survival was 77%, whereas sudden death-free survival was 90%. Follow-up in this study exceeded 7,000 patient-years with a sudden death rate of 0.6% per year. The combined rate of sudden and cardiovascular mortality was relatively low at 1.2% per patient-year.³⁵ In summary, an expected increase of cardiac mortality after septal ablation has not been observed.

CONCLUSION

In patients with symptomatic HOCM despite optimal medical therapy PTSMA has been established as effective alternative to the previous gold standard surgical myectomy. The optimal therapy of an individual HOCM patient should be found in the context of a HCM team, consisting of experts of both treatment methods and the disease itself. Decisive criteria are anatomical findings as well as cardiac and noncardiac comorbidities. Both methods should not be regarded as competing, but complementary treatment methods. Procedural success is related to the experience of the surgeon or interventionalist.

Percutaneous Management of Paravalvular Leak: Patient Selection and Outcomes

A Sreenivas Kumar, Ramakrishna Janapati

INTRODUCTION

Paravalvular leak (PVL) is defined as an abnormal retrograde flow between the implanted prosthetic valve and annulus of the native valve. The prosthetic valve regurgitation includes regurgitation through the valve (transvalvular) as well as paravalvular regurgitation (also known as paravalvular leak). PVL can occur after (1) surgical valve replacement; (2) surgical valve repair; or (3) after percutaneous valve implantation. PVL is a rare complication associated with surgical or percutaneous valve implantations. Previous studies reported an incidence of PVL around 2–10% in aortic valve replacements and 7–17% in the mitral valve (MV) implantation.^{1,2} Only 1–5% of patients with PVLs can have serious clinical manifestations^{3,4} and majority of the PVL had benign clinical course. Definitive treatment of significant PVL requires redo surgical repair or replacement, but it is associated with significant morbidity and mortality. Percutaneous treatment of PVL has been rapidly evolving therapy for significant PVL. With increasing operator experience and better availability of percutaneous closure devices, the transcatheter treatment of PVL was associated with lower morbidity, mortality, shorter duration of procedure time and hospitalization.⁵

ETIOLOGY OF PARAVALVULAR LEAK

Paravalvular leak results from the incompetent seal between the native annulus and prosthetic sewing ring. Several factors increase the risk of PVL that includes abnormal pressure or traction forces on implanted prosthesis, slow resorption of annular calcium, postoperative infections, continuous suturing of mitral prosthesis, smaller size prosthetic valve, and location of valve implant. PVL can occur early after surgery or it may be delayed complication and early occurrence usually associated with technical aspects. Delayed PVLs can result from infective endocarditis with suture dehiscence and slow resorption of annular calcium.^{6,7}

CLINICAL DIAGNOSIS

The most common presenting symptoms and signs of significant PVL includes that of congestive heart failure (CHF) from fluid overload in 90% of cases and hemolytic anemia in 30–40% cases. Anemia may be the presenting sign due to intravascular hemolysis. Majority of patients had New York Heart Association (NYHA) class III or more symptoms. Clinical examination had a limited sensitivity and specificity in detecting significant PVL. Mitral PVLs may present with a pansystolic murmur heard over the left sternal border, with radiation of murmur depending on the direction of regurgitant jet. In aortic PVLs, a high-pitched decrescendo early diastolic murmur heard at the neoaortic area. Hemolytic anemia is more commonly observed in patients with smaller size leaks with high-velocity jets, pre-existing anemia, and with increased red blood cells (RBCs) fragility due to folate or iron deficiency. Hemolysis can be diagnosed by a serum lactate dehydrogenase (LDH) level more than 450 U/L and any two of the four following criteria: blood hemoglobin less than 13.8 g/dL for men or less than 12.4 g/dL for women, serum haptoglobin less than 50 mg/dL, and reticulocyte count more than 2%.⁸ In addition, plasma free hemoglobin levels more than 40 mg/dL are suggestive of intravascular hemolysis. Plasma N-terminal pro-brain natriuretic peptide (NT-proBNP) is usually elevated (>400 pg/mL) in patients with CHF and increases as the severity of aortic or mitral regurgitation increases.^{9,10}

IMAGING

Imaging provides a pivotal role in diagnosis of PVL, and to detect the size, extent location, number of leaks. Imaging also plays an essential role during and after procedure to assess the success of the procedure and residual leaks. Imaging is useful to assess the left ventricular (LV) function, to detect any active infective endocarditis, excessive rocking motion

of the prosthetic valve and severity of regurgitation. In most cases echocardiography is useful for definitive diagnosis of PVL. Other imaging modalities that are increasingly used for evaluation of PVL are cardiac computed tomography (CT) and magnetic resonance imaging (MRI).

Echocardiography

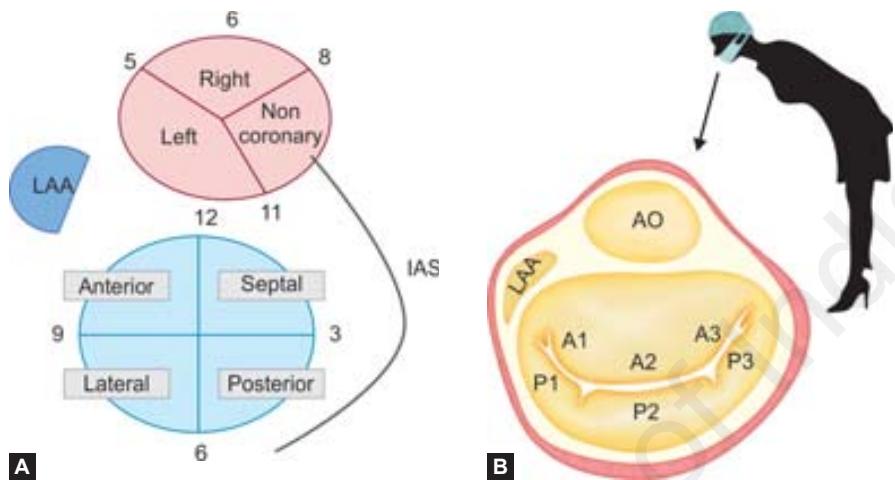

Echocardiogram is the mainstay of imaging modality for diagnosis of PVL and both transthoracic and transesophageal echocardiography (TEE) are utilized for evaluation of prosthetic valves. TTE provides both functional and anatomic information of prosthetic valve. TTE is routinely used for assessment of prosthetic valve mobility, chamber size, and function and transvalvular gradients. However, TTE is limited by acoustic shadowing, metallic artifacts, and with limited imaging windows in postoperative patients. TEE provides better spatial resolution of prosthetic valve function and evaluation of prosthetic valve leaks, and is superior to TTE especially for imaging of mitral prosthesis. For aortic PVL the

acoustic shadowing prevents the assessment of posteriorly located PVL by TTE parasternal long-axis view and anteriorly located PVL by TEE midesophageal views. Three-dimensional (3D) TEE provides better assessment of PVL size and shape when compared to two-dimensional (2D) TEE.¹¹ 3D TEE is most useful for intraprocedural guidance and it provides superior assessment over 2D TEE during procedure. Several studies had used different grading schemes for assessment of severity of PVL and most commonly used in the previous studies was a 3-class grading system (mild, moderate, and severe) and some other studies had used a 4-class grading scheme (grades 1, 2, 3, 4) similar to native valve regurgitation. More recently a unified 5-class grading system was proposed which classifies PVL as trace, mild, mild-to-moderate, moderate, moderate-to-severe, and severe. The PVL severity was classified based on several qualitative and quantitative parameters such as vena contracta width, jet density, jet deceleration time, diastolic flow reversal in the descending aorta regurgitant volume, and regurgitant fraction (Table 1).

TABLE 1: Parameters to define the severity of mitral and aortic PVL

Mild mitral PVL	Severe mitral PVL
Normal sewing ring motion	Sewing ring motion usually abnormal
Jet features: Narrow jet width, infrequent multiple, no proximal flow convergence	Jet features: Wide jet width, frequently multiple, proximal flow convergence visible
% LVOT diameter <30%	% LVOT diameter ≥60%
Circumferential extent <10%	Circumferential extent ≥30%
Normal LV size	Moderately or severely dilated LV size
Vena contracta width <4 mm	Vena contracta width ≥6 mm
Incomplete or faint spectral Doppler	Dense spectral Doppler
Quantitative criteria for mild MVR PVL	Quantitative criteria for severe MVR PVL
RVol <30 mL	RVol ≥60 mL
RF <30%	RF ≥50%
EROA <0.1 cm ²	EROA ≥0.3 cm ²
Mild aortic PVL	Severe aortic PVL
Normal sewing ring motion	Sewing ring motion usually abnormal
Jet features: Narrow jet width, infrequent multiple, no proximal flow convergence	Jet features: Wide jet width, frequently multiple, proximal flow convergence visible
% LVOT diameter <30%	% LVOT diameter ≥60%
Circumferential extent <10%	Circumferential extent ≥30%
Normal LV size	Moderately or severely dilated LV size
Vena contracta width <4 mm	Vena contracta width ≥6 mm
Incomplete or faint spectral Doppler	Dense spectral Doppler
PHT >500 ms	PHT <200 ms
Diastolic flow reversal absent or brief	Holodiastolic flow reversal (end-diastolic velocity >20–30 cm/s)
Quantitative criteria for mild AVR PVL	Quantitative criteria for severe AVR PVL
RVol <30 mL	RVol ≥60 mL
RF <30%	RF ≥50%
EROA <0.1 cm	EROA ≥0.3 cm

AVR, aortic valve replacement; EROA, effective regurgitant orifice area; LVOT, left ventricular outflow tract; MVR, mitral valve replacement; PVL, paravalvular leak; PHT, pressure half-time; RF, regurgitant fraction; RVol, regurgitant volume.

LAA, left atrial appendage; IAS, interatrial septum; AO, aorta.

FIG. 1: Mitral and aortic valves from a surgeon's view.

For mitral PVL pulmonary venous flow reversal in systole was considered as a specific sign of severe mitral PVL.¹² Precise quantification of PVL can be difficult in majority of cases due to various artifacts.

To provide uniformity in reporting and for better communication between the interventionalist and echocardiographer, the leak location should be reported in a clockwise fashion from a surgical view of mitral and aortic valves (Fig. 1). For aortic valve the commissure between left and right coronary cusp was assigned at 5 o'clock position, between right and noncoronary at 8 o'clock and 11 o'clock position was assigned to the commissure between left and noncoronary sinuses. Most of aortic PVLs are located between right and noncoronary cusps.¹³ Similarly, for mitral PVL by rotating the TEE probe and echocardiographic image, the MV and aortic valve are oriented in a fashion that aortic valve is at the top of MV when viewed from atrium. The junction between aortic valve and anterior mitral annulus was assigned as 12 o'clock position and 6 o'clock was assigned to midpoint of posterior annulus. The interatrial septum and posteromedial commissure are at 3 o'clock and left atrial appendage and anterolateral commissure at 9 o'clock location. The aortomitral curtain at the 11 o'clock position is the most common location for mitral PVL followed by at 5 and 6 o'clock, representing the posterior wall of mitral ring.¹⁴

Computed Tomography

With advances in cardiac CT it is possible to assess the PVL in a greater detail. Retrospective electrocardiogram (ECG)-gated image acquisition with 3D or 4D-reconstruction utilizing volume rendering techniques has been used in PVL assessment.^{15,16} Better quality images were obtain when patient heart rates were slower, longer diastolic frames and in closed leaflet position. Even with CT imaging of PVL can produce hyperdense or hypodense image artifacts.

Cardiac Magnetic Resonance Imaging

Cardiac magnetic resonance imaging (CMR) is utilized for accurate quantification of regurgitation, quantification of antegrade and retrograde flow and for assessment of cardiac chamber size and function. Velocity-encoded phase-contrast magnetic resonance (MR) is utilized for reproducible assessment of regurgitant fraction and regurgitant volumes. CMR is especially useful for assessment of bioprosthetic valves, annuloplasty rings and metallic artifacts may impair mechanical valve assessment. With advances in MR technology it is now possible for 3D reconstruction of PVL with complex anatomy.¹⁷

Fluoroscopy

Prosthetic valves needs to be profiled in multiple angulated views to document the valve leaflet motion and for assessment of paravalvular regurgitations. Biplane imaging provides two orthogonal views simultaneously and useful for oblique and angulated projections. Left anterior oblique caudal fluoroscopic imaging differentiates medial versus lateral paravalvular defects, and right anterior oblique view differentiates anterior versus posterior location of PVL. Fluoroscopy is also useful to detect any impingement of PVL closure device on the prosthetic valves before releasing the closure device. Coronary angiogram should be done to locate the distal left anterior descending (LAD) near apex during Transapical access for PVL closure.

Multimodality Imaging

All the imaging modalities will complement each other whereas 2D or 3D TEE provides real time image guidance during PVL closure, and fluoroscopy will detect the prosthetic valve movement and impingement of device on prosthetic valve movement during procedure. For anteriorly located aortic PVLs intracardiac echocardiography (ICE) may be

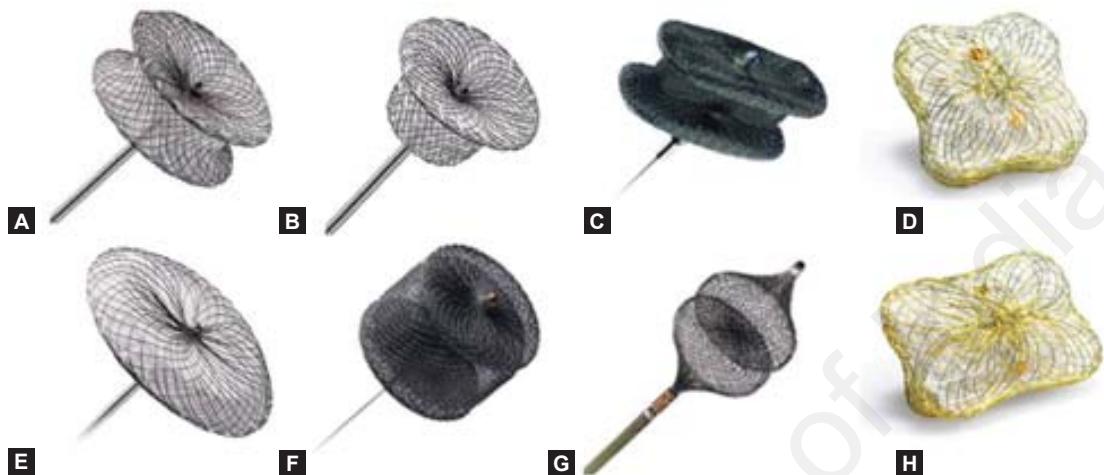

FIG. 2: Paravalvular leak closure devices: **A**, Amplatzer muscular ventricular septal defect occluder; **B**, Amplatzer duct occluder; **C**, Amplatzer vascular plug III; **D**, Occlutech paravalvular leak device (square-shaped design); **E**, Amplatzer septal occluder; **F**, Amplatzer vascular plug II; **G**, Amplatzer vascular plug IV; **H**, Occlutech paravalvular leak device (rectangular-shaped design).

helpful. Fusion imaging techniques may enable the real time display of 4D reconstructed CT images adjacent to or on overlaid on live fluoroscopy image thereby reducing the duration of procedure.

INDICATIONS FOR PARAVALVULAR LEAK CLOSURE

The percutaneous treatment of PVL is a Class IIa [American College of Cardiology/American Heart Association (ACC/AHA) 2014 guidelines] indication for high-risk surgical patients who had an indication for PVL closure.¹⁸

Absolute Indications¹⁹

- Symptoms of heart failure due to PVL
- Significant hemolysis due to PVL
- Moderate PVL with declining left ventricular ejection fraction (LVEF)
- Moderate PVL with progressive LV enlargement.

Relative Indications¹⁹

- Risk of endocarditis
- Asymptomatic mild or moderate PVL
- Mild or moderate PVL after transcatheter aortic valve implantation (TAVI).

Contraindications

- Active endocarditis
- Regurgitation involving one-third of prosthetic valve annulus
- Rocking motion of prosthetic valve.

DEVICES FOR PERCUTANEOUS PARAVALVULAR LEAK CLOSURE

The currently used PVL closure devices are made-up of woven nitinol mesh that can be retrievable and reposition-

able. Only very few purpose-specific devices exist. The AMPLATZER™ vascular plug III (AVP III; St Jude Medical) and the Occlutech PVL device (PLD; Occlutech, Germany) are the only two devices designed specifically for PVL closure. The other devices that are currently used off-label for PVL closure, have been designed for closure other congenital cardiovascular defects like atrial septal defect, ventricular septal defect, and patent ductus arteriosus (Fig. 2). The Amplatzer devices are the most commonly used for PVL closure worldwide. The AVP II device is most commonly used in the USA and while in Europe the most frequently used device is the AVP III; however, only Occlutech device is approved by the European commission for PVL closure.

TECHNIQUE OF TRANSCATHETER PARAVALVULAR LEAK CLOSURE

Generally procedure is performed under general anesthesia with 3D TEE as it takes long time for percutaneous PVL closure. In case of aortic PVL procedure can be completed under conscious sedation.

Mitral Transcatheter Paravalvular Leak Closure

The various approaches that had been used for mitral PVL closure includes antegrade-transseptal approach, retrograde transaortic approach, and transapical approach. Under fluoroscopic guidance in the most commonly used antegrade approach once successful transseptal puncture is made, a diagnostic catheter usually multipurpose or Judkins right catheter was advanced over the wire into left atrium (LA) (Fig. 3A). The mitral prosthetic valve is profiled in multiple angulated views usually in RAO (tangential view) and LAO caudal view (enface view for MV) to have a clear idea about the prosthetic valve motion. Systemic heparinization administered to prevent thrombus formation in catheters or

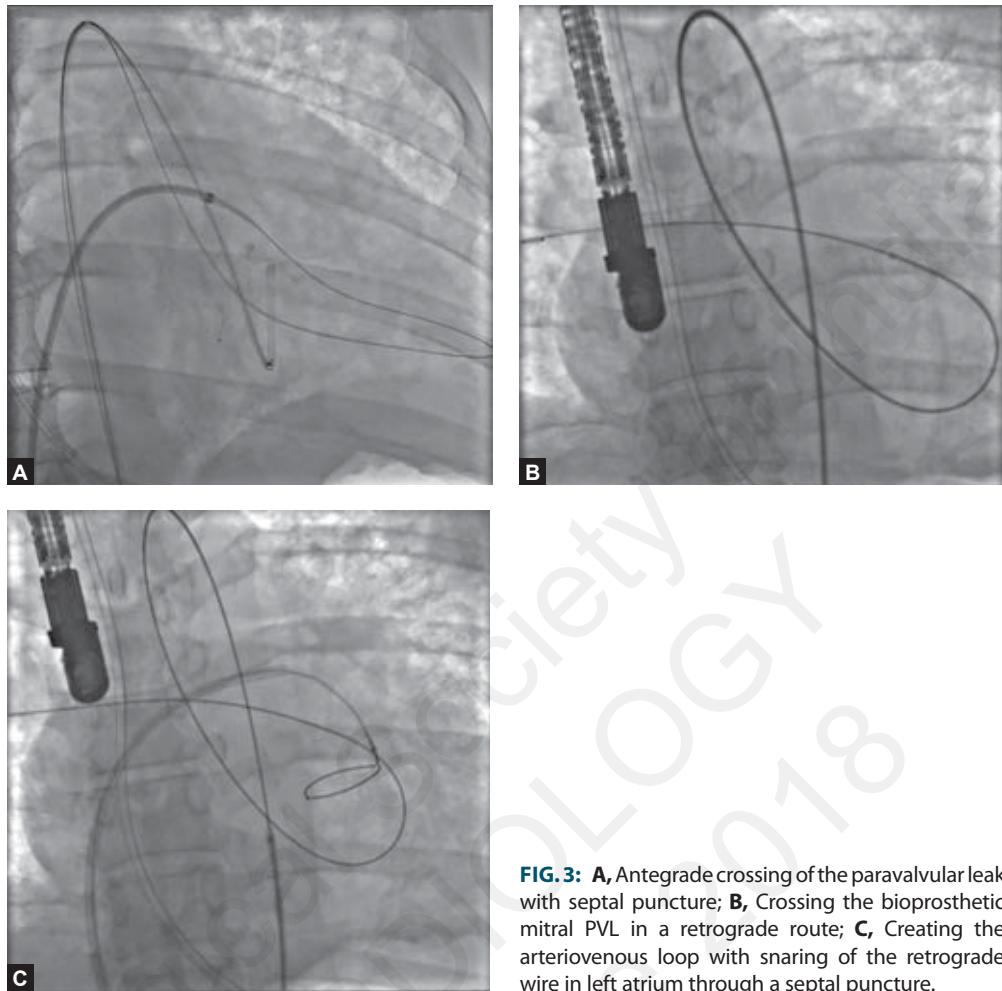

FIG. 3: **A**, Antegrade crossing of the paravalvular leak with septal puncture; **B**, Crossing the bioprosthetic mitral PVL in a retrograde route; **C**, Creating the arteriovenous loop with snaring of the retrograde wire in left atrium through a septal puncture.

over the valves. The PVL was crossed with a hydrophilic guide wire (Terumo wire) under TEE guidance. Sometimes it may be helpful to use a deflectable catheter (Agilis catheter, St Jude Medical) for crossing the PVL especially in septal PVL. The hydrophilic guide wire is exchanged for a stiffer (Amplatz Extra-Stiff) wire with forming a loop in LV. Sometimes the formation of a venoarterial loop may be required for additional support by snaring the wire in aorta or in LA. After this a 6F guide catheter (usually 6F multipurpose guide) was advanced over the wire into LV. An AVP device up to size 12 mm can fit in a 6F coronary guide catheter without excessive resistance. Based on the size of the defect single or multiple devices can be deployed sequentially through the same guide catheter. It is important to confirm the normal movement of mechanical leaflets before releasing the device. If the leaflet motion is impaired, the device needs to be repositioned or to choose a smaller device.

In retrograde transaortic approach the PVL is crossed from LV to LA with a hydrophilic guide wire over a diagnostic catheter usually a Judkins right catheter (Fig. 3B) or a flexible tip catheter. After crossing MV the wire is snared in LA through a transseptal puncture and an arteriovenous loop is created (Fig. 3C). Finally the device is deployed over the venous access catheter through the transseptal puncture.

For difficult cases like posterior, medially located defects and in patients with double-mechanical valve placement the alternative approach is through the LV apex. The advantage with transapical access is easy to cross the PVL and less difficulty in deploying the PVL devices. However, this approach is associated with higher procedural complications like coronary perforation, pericardial effusion, and the need for a separate device for apical access closure.

Aortic Paravalvular Leak Closure

Most of aortic PVLs are smaller than mitral PVL and are usually closed with a single-closure device. The most commonly used approach for aortic PVL closure is retrograde approach through the transfemoral access. In retrograde approach the coaxial system consisting of a 6F coronary guide catheter (multipurpose catheter) with 5F diagnostic catheter [Amplatz left (AL1) or Judkins right (JR)] and a 0.035 inch Terumo wire or flexible tip stiff wire is commonly used. After crossing the defect the coaxial system can be advanced into LV and device can be deployed. Alternatively, for difficult cases the guide wire can be exchanged for a stiffer wire (Amplatz Extra-Stiff) with a stable loop in LV or an arteriovenous loop may need to

be created for additional support as described for mitral PVL. The other approach is transapical access as described earlier.

Paravalvular Leak Closure after Transcatheter Aortic Valve Replacement

With increasing use of transcatheter aortic valve replacement (TAVR) for aortic valve replacement, PVLs can occur due to undersized prosthetic valve, malapposition of valve due to heavy calcification. The malapposition can be treated by balloon postdilation, whereas moderate-to-severe PVL can be treated by vascular plug or AVP IV device. The AVP IV device is smaller in size (4–8 mm) and is easier to deliver through a 4F catheter. With improved design of prosthetic valves with adequate sealing skirts the incidence of PVL had decreased considerably.

OUTCOMES AND COMPLICATIONS OF PARAVALVULAR LEAK CLOSURE PROCEDURES

Technical success of PVL closure was defined as correct placement of the device across PVL without any residual leak and without any prosthetic valve dysfunction. Clinical success was defined according to the clinical indication for PVL closure such that improvement in hemolysis and more than equal to 1-stage improvement in NYHA functional state. With increasing operator experience the technical success of PVL closure ranges between 77 and 90% across various studies and clinical success ranges between 67 and 77% depending on the indication of PVL closure.^{20,21} Successful device closure is associated with improved quality of life and reduction in overall mortality and morbidity.²² The reported major complications with transcatheter PVL closure include emergency cardiac surgery for failed device closures, mechanical valve interference, embolization of prosthetic device, stroke, worsening of hemolysis, and death during or immediately after the procedure.²³

MEDICAL THERAPY

For patients who were using anticoagulation prior to PVL closure to be continued after the procedure with metallic valves and patients with atrial arrhythmias. At least 3 months of dual antiplatelet therapy is recommended for bioprosthetic valve patients.

CONCLUSION

Transcatheter closure of symptomatic PVL is associated with less procedural morbidity and mortality rate than surgical closure of PVL. Successful percutaneous closure of PVL is associated with long-term mortality benefit in symptomatic patients. With improved design of newer devices, availability of exclusive devices for PVL and with increasing operator experience the technical and clinical success of percutaneous closure PVL is improving.

Left Atrial Appendage Closure Device for Stroke Prevention in Atrial Fibrillation

Balbir Singh

INTRODUCTION

Atrial fibrillation (AF) is the most common arrhythmia seen in clinical practice, and the incidence increases with age. It is associated with significant mortality and morbidity, mainly due to stroke and heart failure. AF is associated with five times higher stroke rates as compared to those without AF.¹ For prevention of this complication, treatment options have been either with warfarin or with the newer anticoagulant agents. This anticoagulant therapy has been proven to effectively prevent thromboembolic strokes, but the increased risk of serious bleeding prevents many patients from taking this therapy. Therefore, there is always a need for alternative therapies with lower bleeding risk.²

Percutaneous left atrial appendage (LAA) occlusion is an evolving therapy, which should be taken into consideration in those patients with AF with a high stroke risk and contraindications for oral anticoagulant (OAC).

This chapter aims at discussing the scope for LAA closure, the available LAA occlusion devices, and their clinical evidence until now.

EXISTING OPTIONS OF STROKE PREVENTION IN ATRIAL FIBRILLATION

Several randomized controlled trials have proved the efficacy of OACs in preventing strokes and reducing mortality, these

trials have also shown that antiplatelets are not useful for this purpose.

However, OACs are associated with increased bleeding to the tune of incidence of 2–4% per year which is substantial and also with some life-threatening bleeds like intracranial hemorrhage (ICH). There was a hope that the advent of new oral anticoagulants (NOACs) such as dabigatran, apixaban, or rivaroxaban would overcome these disadvantages; however, this has not been fulfilled entirely.³ Table 1 depicts the incidence of bleeds and compliance with these drugs.

RATIONALE FOR LEFT ATRIAL APPENDAGE OCCLUSION

The logic behind LAA occlusion is that the LAA is the primary site of thrombus formation in patients with nonvalvular atrial fibrillation (NVAF) as has been demonstrated on postmortem studies and transesophageal data. In 90% of patients with NVAF, the site of clot formation is the LAA.⁴ In view of this data, it appears LAA closure will provide protection against thromboembolic episodes in patients with NVAF. As a result, the European Society of Cardiology (ESC) guidelines for the management of AF (2012) recommend that LAA closure may be considered in patients with a high stroke risk and contraindications for long-term OAC administration (Class IIb, level of evidence B). The USA

TABLE 1: Incidence of bleeds and compliance with oral anticoagulants

Parameters	Warfarin	Dabigatran	Apixaban	Rivaroxaban
	(PROTECT AF)	(RELY)	(ARISTOTLE)	(ROCKET AF)
Age	71.7	71.5	70	70
Major/minor bleed	N/A	16.4	18.1	14.9
Major bleed (%)	4.1	3.1	2.1	3.6
Stroke (%)	2.7	1.1	1.3	1.7
Drug discontinuation	16–34	21	N/A	24

Food and Drug Administration (FDA) has also approved LAA closure device in recent past.

However, one must remember that many patients with NVAF have several comorbidities and could have atherosomatous changes in aorta or carotids which could lead to stroke mitigating the benefit of LAA closure.

IDENTIFYING THE RIGHT PATIENT FOR DEVICE CLOSURE

Left atrial appendage closure offers an alternative to patients of NVAF who are at risk of thromboembolism and are also at high risk for bleeds or contraindications to OACs. The patients who could be considered as high risk for bleeding are:

- Coagulopathies, low platelet counts, or other disorders
- Severe hepatic or renal dysfunction
- Known vascular malformations in intestine, brain, or retina which could potentially bleed.

Other groups of patients apart from those with high bleeding risk are those who develop ischemic stroke despite well-controlled OAC or NOAC therapy and high chance of therapeutic noncompliance to OAC or NOACs (Box 1).

BOX 1 Potential indications of left atrial appendage closure

- Serious bleed with oral anticoagulants like ICH, etc.
- Contraindications to OAC-like underlying coagulopathies
- Development of stroke or SE despite controlled anticoagulation
- Intolerant to oral anticoagulants
- Not compliant on drugs

ICH, intracranial hemorrhage; OAC, oral anticoagulant; SE, status epilepticus.

INTOLERANCE OR CONTRAINDICATIONS TO ORAL ANTICOAGULANT OR NEW ORAL ANTICOAGULANTS

Transesophageal echocardiography (TEE) helps to identify the anatomy of LAA and is essential preprocedure and also during the procedure; preprocedural TEE is used to screen suitable candidates and to define LAA morphology and dimensions and exclude LAA thrombus.² TEE has a major role in guiding proper placement of the device and for assessing procedural complications (Fig. 1).

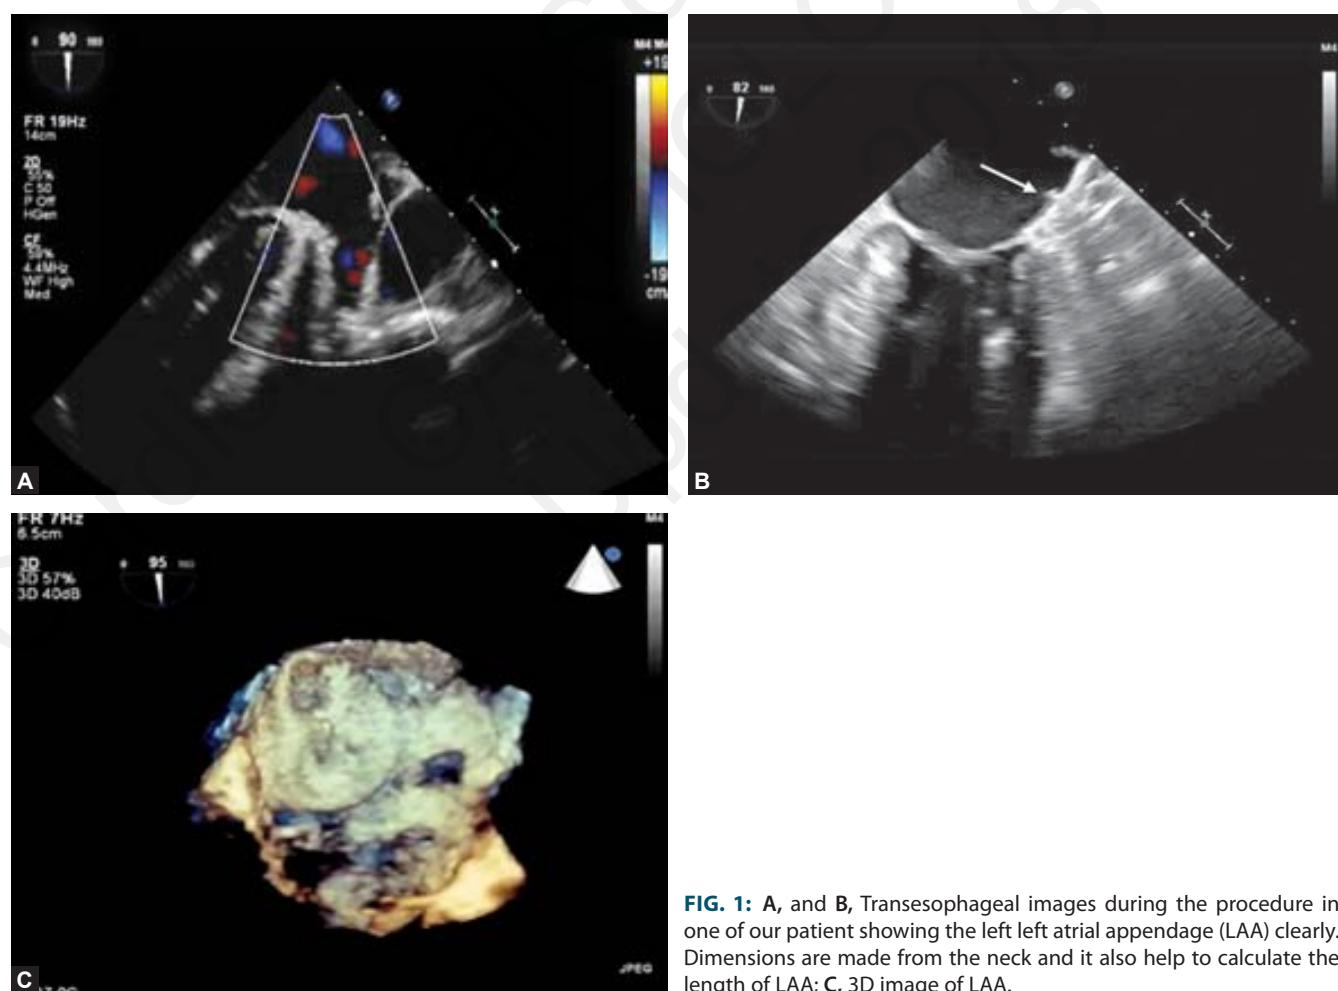

FIG. 1: A, and B, Transesophageal images during the procedure in one of our patient showing the left left atrial appendage (LAA) clearly. Dimensions are made from the neck and it also help to calculate the length of LAA; C, 3D image of LAA.

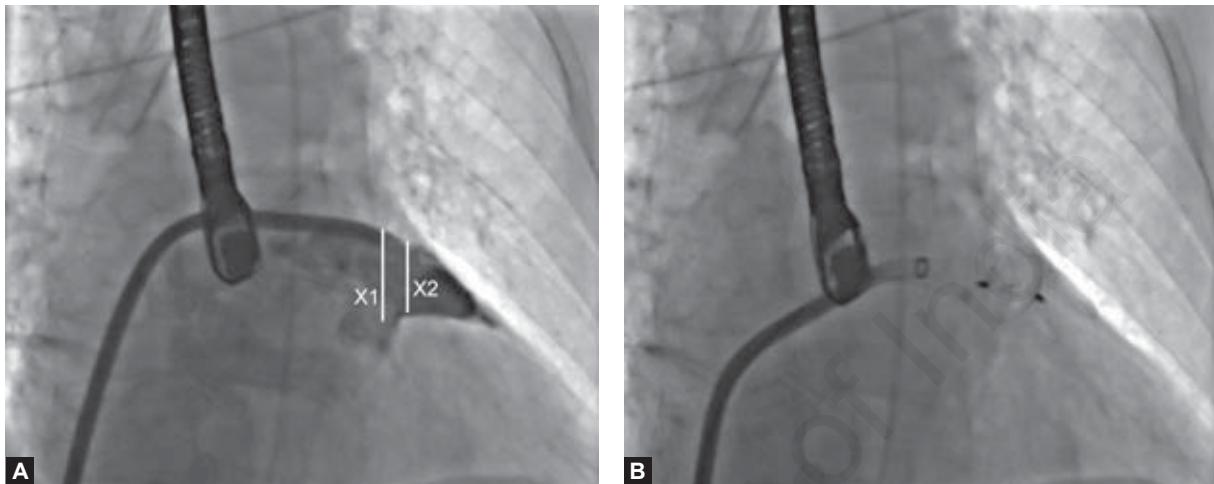

FIG. 2: The fluoroscopy images showing the deployment of the device.

DEVICE IMPLANTATION

Percutaneous LAA occlusion is usually performed under general anesthesia and with TEE and fluoroscopic guidance. The standard transseptal puncture techniques are used to position the delivery sheath and place the device in the LAA. Once in position, the device stability is confirmed by a fluoroscopy and TEE imaging. Finally, the device is released from the delivery cable by counterclockwise rotation at the shaft [these are steps for Amplatzer Cardiac Plug (ACP), St Jude Medical—Figure 2]. Until now, the WATCHMAN and ACP devices are widely used in clinical practice and WATCHMAN device is now FDA approved.

POSTPROCEDURAL TREATMENT

Dual antiplatelet therapy (DAPT) (aspirin and clopidogrel) is prescribed for the first 45 days after LAA closure and clopidogrel can then be stopped, antiplatelet therapy exists. In patients with a very high bleeding risk, it may be considered to low-dose NOAC may be needed if the device indication was for recurrent strokes despite NOACs.

CLINICAL TRIAL RESULTS⁴⁻⁹

The only prospective, randomized trial is the PROTECT AF trial in which 707 patients with NVAF were randomly assigned in a 2:1 ratio to either percutaneous LAA occlusion with the WATCHMAN device or to warfarin therapy. Patients with paroxysmal, persistent, or permanent NVAF were enrolled if they had a CHADS2 risk score more than or equal to 1. The trial demonstrated the noninferiority of WATCHMAN LAA occlusion compared with OAC therapy regarding the primary efficacy endpoint—a composite of stroke, systemic embolism, and cardiovascular death [relative risk (RR) = 0.62, 95% confidence interval (CI) 0.35–1.25]. The primary efficacy endpoint occurred in 2.3% of the device group versus 3.8% of the warfarin group (RR = 0.60, 95% CI 0.41–1.05),

demonstrating a 40% RR reduction in primary efficacy in the WATCHMAN group. Cardiovascular death occurred in 1.0% of the device group versus 2.4% of the warfarin group (RR = 0.40, 95% CI 0.21–0.72, $p < 0.05$). The rate of hemorrhagic stroke was 0.2% in the device group versus 1% in the warfarin group (RR = 0.18, 95% CI 0.04–0.60, $p < 0.05$).

More recent data, from the CAP registry ($n = 566$, WATCHMAN), the PREVAIL study ($n = 269$, WATCHMAN) and a large multicenter study involving the ACP device ($n = 969$) show improved procedural safety, the complication rates within 7 days were 4.1%, 4.4%, and 4.1%, respectively. These lower rates of complications are due to better operator experience of device implantation.

The PREVAIL study added information to the first PROTECT AF. The major findings of this trial were:

- Left atrial appendage occlusion with the WATCHMAN device was not noninferior to warfarin for the primary efficacy composite endpoint
- The WATCHMAN device was noninferior to warfarin for the occurrence of late ischemic events, such as ischemic stroke or status epilepticus.
- The WATCHMAN procedure met the prespecified success criterion for safety events.

A recent meta-analysis with the long-term 5-year outcomes of the PREVAIL trial, combined with the 5-year outcomes of the PROTECT AF trial, demonstrate that LAAC with the WATCHMAN device provides stroke prevention in NVAF patients to a similar degree as OAC with warfarin. It also reduces mortality and risk of hemorrhagic stroke.

DISCUSSION

Left atrial appendage closure has emerged in the last decade as a useful therapy in stroke prevention in NVAF. Since the initial publications, the complication rates have significantly reduced making the procedure more attractive.

The current guidelines only justify the use of this in patients with contraindications to OAC therapy or those with poor compliance or inability to take drugs.

The future studies will shed more light on the group which will benefit the most with these drugs.

CONCLUSION

Percutaneous LAA occlusion has been shown to be a safe, efficacious, and cost-effective strategy for stroke prevention in patients with NVAF with increased stroke and bleeding risk. It is now a commonly performed procedure in many centers in Europe and US, in our experience success was obtained in all eight patients where it was attempted, however, operator experience and technique are of paramount importance.

SECTION 11

Cardiac Imaging

Utility of Echo in Assessment and Management of Functional Mitral Regurgitation

Gonzalo Luis Alonso Salinas, Marina Pascual Izco, José Luis Zamorano

INTRODUCTION

Despite the decrease of rheumatic disease, mitral regurgitation (MR) is becoming more prevalent in parallel with population aging and the improvement and increased survival of patients with dilated cardiomyopathy (DCM) of any etiology. Approximately, 10% of the population over 75 years of age have significant MR.¹ This condition has a negative impact on prognosis, regardless of the etiology and comorbidity.

Surgical or percutaneous treatment would be performed only in patients with severe MR. Thus, a precise and accurate evaluation is required.

MECHANISM AND ETIOLOGY OF MITRAL REGURGITATION

According to MR mechanism, Carpentier classification² for mitral leaflets motion:

- *Type I:* Normal motion. MR is due to annular dilatation or leaflet perforation or tear
- *Type II:* Excess leaflet motion. The free edge of one or more leaflets overrides the plane of the annulus during systole (leaflet prolapse)
- *Type III:* Restricted leaflet motion.
 - Restricted in both systole and diastole
 - Restricted only in systole.

According to its etiology, if the disease is intrinsic to the valve and its structure is called primary MR; if there are no structural anomalies in the valvular apparatus is called secondary or functional MR. In this chapter, the focus will be the secondary or functional MR.

The etiologies of secondary or functional MR are mainly the ischemic heart disease and DCM. Secondary MR appears because, despite a normal and undamaged valvular apparatus, myocardial ischemia, DCM or severe left atrial (LA) dilation decreases the forces that help the mitral valve (MV) closure during the systole of the left ventricle (LV).³

Within these pathologies, ventricular remodeling produces an altered LV geometry with an altered subvalvular apparatus, there is an apical and posterior displacement of the papillary muscles and their corresponding chordae tendineae, which pulls the mitral leaflets and progressively decreases and cancels its coaptation surface.⁴ This traction or tethering that usually occurs during LV systole, can be asymmetric, caused by involvement of the posterior papillary muscle, which is visualized with the "Seagull Sign" (Fig. 1) or symmetric if it affects both papillary muscles equally.

ULTRASOUND ASSESSMENT OF FUNCTIONAL MITRAL REGURGITATION

Echocardiography (ECG) is, despite the development of other imaging techniques, the cornerstone of the study of MR. It helps us to describe the morphology of the valve, which can guide us about the etiology of MR, as well as the possibility of repair. In addition, it is a very reliable tool to quantify the severity of the regurgitation.

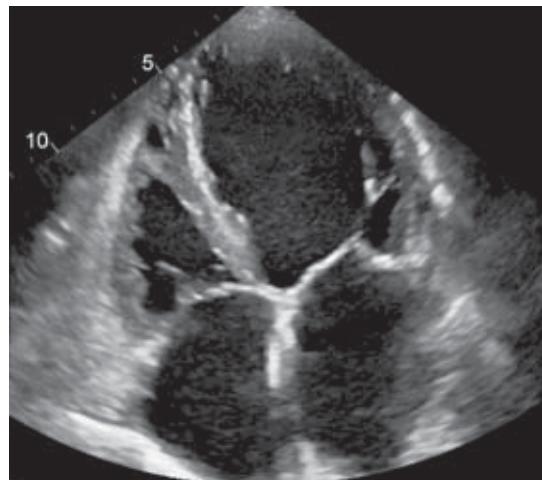

FIG. 1: Seagull's sign.

Morphological Evaluation of the Mitral Valve

Transthoracic Echocardiogram

Two-dimensional transthoracic echocardiogram (TTE) allows an accurate observation of the morphology of the MV. The location of the affected segments and the origin of the regurgitant jet, the description of the presence and extension of calcifications, as well as the anatomical changes within the valve or its annulus are fundamental parameters that we must describe to guide the management of the valve disease. Moreover, the presence of a damaged leaflet, the rupture of a papillary muscle and a large coaptation defect are specific findings of significant MR.

Recognize and identify the leaflet segments showed in each cardiac view seems fundamental. Parasternal short-axis view allows observation of the six segments of both mitral leaflets and using color Doppler technique, locates the origin of the regurgitant jet and/or the prolapsing segment. Parasternal long-axis view shows the segments A2 and P2, apical four-chambers the segments A3, A2, and P1 (from internal to external), and apical two-chambers P3, A2, and P1 in the same order.⁵

Transoesophageal Echocardiogram

Transesophageal echocardiogram (TEE) allows us to visualize the MV with higher resolution, being especially useful in those patients with a suboptimal acoustic window. MV is fully visualized in the transgastric view at 0° with the posterior leaflet in the upper part of the image and the anterior leaflet in the lower one. This view shows us the six segments, similarly to parasternal short-axis view in TTE. In sagittal view at 120° long-axis four-chambers we can visualize segments A2 and P2. From this plane, if we angulate the probe toward the aortic valve we can see A1 and P1, and if we do it toward the tricuspid valve, A3 and P3 segments. In sagittal view, from 60° to 90°, we can obtain a bicommissure vision and identify P3, A2, and P1 segments from left to right.⁵

Mitral Annulus

To describe the dilatation of the mitral annulus (MA), we use the MA/anterior leaflet ratio in parasternal long-axis view, considering the MA dilated if this ratio is greater than 1.3 in diastole. In addition, we should also measure the diameter of the ring, considering it dilated if it is greater than 35 mm. MA decreases its area in systole approximately 25% of its area in diastole.

Three-dimensional Image Assessment

When available, 3D images give us more information than a 2D assessment. Three-dimensional images can show the mitral apparatus from the LA or from the LV. The view of the MV from the LA is called the “surgeon’s vision” or “en face view” (Fig. 2) and it has a proven value in the description of leaflet prolapse, other defects of mitral leaflets or the rupture of the chordae tendineae.⁶ This is especially useful in TEE.

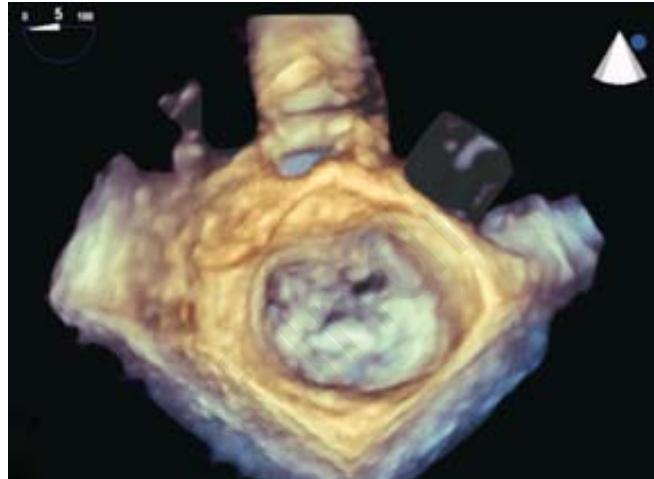

FIG. 2: Surgeon’s vision or *en face* view using three-dimensional transesophageal echocardiogram.

There are three basic modes of acquiring 3D images: Real-time 3D, 3D zoom, and full volume acquisition. Each of them has a different sector width, frame rate, and spatial resolution.

- **Real-time 3D:** Uses a narrow sector for a simple image. It is useful for an initial quick approach
- **Three-dimensional zoom:** We can see the entire MV in one heartbeat. Very useful in case of atrial fibrillation, supraventricular extrasystole or frequent ventricular extrasystole, or artifact electrocardiogram (ECG)
- **Full volume acquisition:** This technique acquires several volumes in several beats: Improves temporal and spatial resolution. The higher the number of heartbeats acquired, the higher the resolution, but the quantity of artifacts produced in the image increases. It is usually combined with color Doppler technique.

Morphological description of the MV, preferably performed by TEE, can also provide information that predicts unsuccessful MV repair (Box 1).

Quantification of the Mitral Regurgitation

The quantification of MR is based on different qualitative, semiquantitative and quantitative parameters. Despite the number of different methods that can be found in the literature, no unique method is good enough to study by itself the MR, so actual recommendations integrate different methods that will be explained below.

Color Doppler

Jet area by color Doppler: It is the most widespread method. It assumes that the greater the severity of the MR, the greater the area of the jet and its extension in the LA. The main limitation of this method is that the relationship between the MR jet and its severity can present significant variability since it also depends on technical and hemodynamic factors, especially on functional MR.

BOX 1**Predictors of unsuccessful mitral valve repair****Mitral valve deformation:**

- Coaptation length ≥ 1 cm
- Tenting area¹ $> 2.5-3 \text{ cm}^2$
- Central or posterior-medial significant regurgitant jet
- Extensae calcification
- More than or equals to 3 compromised MV segments, especially if anterior leaflet is compromised
- Mitral valve tissue lacking (uncommon in secondary MR, common in rheumatic MR or infective endocarditis)

Damaged left ventricle:

- Distance between papillary muscles > 20 mm
- Distance between posterior papillary muscle and MV annulus > 40 mm
- Lateral akinesia or hypokinesia

Remodeled left ventricle:

- LVEDD > 65 mm
- LVESD > 51 mm or LVESV > 140 mL
- Sphericity index > 0.7
- Annular dilation > 50 mm

Up to 50% MR recurrence after repair if:

- Diastolic annulus length ≥ 37 mm
- Tenting area¹ $\geq 1.6 \text{ cm}^2$
- Severe MR with central or multiple jet
- Coaptation length ≥ 1 cm
- LVEDD ≥ 65 mm or LVESD ≥ 51 mm
- Lateral akinesia

1, Tenting area (area between annulus plane and leaflets when coapting).

LVEDD, left ventricular end-diastolic diameter; LVESD, left ventricular end-systolic diameter; LVESV, left ventricular end-systolic volume; MR, mitral regurgitation; MV, mitral valve.

This method alone is not recommended to assess the severity of MR, but it could help us to screen it. A central jet, with an area smaller than 4 cm^2 or smaller than the 10% of LA area without associated valve anomalies, is highly suggestive of mild MR. A central jet that reaches the LA roof and pulmonary veins suggests significant MR, and a large, eccentric jet that adheres and travels around the atrial wall toward the atrial roof (Coanda effect) suggests it in the same way.⁷

Measurement of the Width of the “Vena Contracta”

The vena contracta (VC) is the narrowest segment and the fastest regurgitant flow at the level of the regurgitant orifice or immediately above it. Its width reflects the area of the regurgitant orifice thus it can be used to quantify severity.

For VC measurement, we used the parasternal long-axis and apical four-chambers views, obtaining clear vision of the regurgitant jet through the MV. The measurement of the VC in the apical two-chambers view, parallel to the coaptation line, could overestimate its severity. If possible, zooming in on the flow can help us to identify the frame where the width

of the jet is smaller. The cut-offs to identify a mild MR would be those less than 0.3 cm. Those greater than 0.7 cm suggest a severe MR. Intermediate values require other quantification methods to determine severity.

The measurement of the VC assumes that the regurgitant orifice of the MR is circular. When this situation happens, it presents a good correlation with regurgitant orifice area. The problem arises when MR orifice is not circular. In these cases, the measurement of VC may underestimate the MR severity. This limitation can be solved using 3D ECG, which has been shown to be more accurate when finding a measurement completely perpendicular to the MR jet.

Another limitation appears in the cases in which the MR includes several jets, which in this case are not additive, so we should look for another measurement method. Finally, the measurement is made only on one frame, disregarding the rest of the ventricular systole period, which can cause the measurement not to be performed on the narrowest segment of the regurgitant flow.

With the ECG in two dimensions we can only approximate the width of the contracted vein, there being no such limitation within 3D ECG, which does not assume the premise of a circular regurgitant orifice. It can be used to calculate the true area of the VC.

The “surgeon’s vision” or “en face view” provided by 3D ECG allows us to calculate the area of the VC measuring it by planimetry. It is considered that a VC area greater than 0.41 cm^2 indicates a severe MR with an 82% of sensitivity and a 97% of specificity.⁸ Moreover, using 3D TTE planimetry can obtain the area of the anatomical regurgitant orifice (ARO) with high precision.

The main limitation of 3D ECG is its low spatial resolution, so in the case of a small orifice, or in the case of several small orifices, the measurement could be mistaken. Another important limitation is the time and experience necessary for its performance, which limits its diffusion together with its high interobserver variability for the selection of the measurement frame.

Proximal Isovolumetric Surface Area Method

The proximal isovelocity surface area (PISA) method is based on the hemodynamic principle by which all fluid passing through an orifice undergoes an acceleration, creating hemispheres of increasing velocity and decreasing area.^{9,10} With the use of color Doppler technique, this convergence zone can be identified and its radius (r) measured. This measurement allows the calculation of the effective regurgitant orifice (ERO).

The recommended view for the visualization of the hemispheres of velocity is the apical four-chambers view, nevertheless the parasternal short and long views are frequently useful in case of prolapse of the anterior mitral leaflet. In the selected view for the measurement it is recommended to enlarge the MV and use the color Doppler, reducing the Nyquist limit [aliasing velocity (AV)] to values between 15 and 40 cm/s for the best visualization of the hemisphere, which constitutes the PISA. The PISA r is measured in mesosystolic phase from

the MV plane to the point at which the color changes. To complete the calculation, the maximum jet velocity (V_{max}) of the MR must also be obtained. The ERO is calculated as follows:

$$ERO = 2\pi r^2 \times aV/V_{max}$$

ERO, effective regurgitant orifice (cm^2); r , PISA radius (cm); AV, aliasing velocity (cm/s); V_{max} , maximum MR jet velocity (cm/s).

The cut-offs for functional MR vary respect primary MR. An ERO smaller than 0.1 cm^2 would correspond to a mild MR, from 0.1 to 0.14 cm^2 to a mild-to-moderate MR, 0.15 – 0.19 cm^2 to a moderate-to-severe MR and it would be catalogued as severe MR for an ERO above 0.2 cm^2 .

A simple approximation, derived from this formula, would be just to measure the r with an AV of 40 cm/s . The functional MR would be severe if the radius is greater than 0.5 cm and mild if it is less than 0.2 cm . In addition, the presence of hemispheres of velocity at AV greater than 50 cm/s indicate the presence of significant MR.

If the ERO is assumed to be a uniform, fixed hole during systole, the regurgitant volume (RVol) could be calculated by multiplying the ERO by the velocity-time integral (VTI) of the MR jet:

$$RVol = ERO \times VTI$$

RVol, regurgitant volume (mL); ERO, effective regurgitant orifice (cm^2); VTI, velocity-time integral (cm).

The cut-offs for severity in the RVol are greater than or equals to 30 mL .

The PISA method has proved to be one of the most accurate for quantifying MR severity and it is widespread in numerous cardiac imaging units, but it has several limitations. One of its limitations is to assume that the ERO is circular and the PISA is a hemisphere. Several studies have shown that in most cases this is not the case, and that in addition, correcting by changing the hemisphere for a hemiellipse translates significant differences in the calculation of the ERO.¹¹ This is especially relevant in functional MR where the PISA is ellipsoidal because there are two MR jets, medial and lateral to the coaptation line of both mitral leaflets. By assuming the spherical shape of the PISA, the degree of MR is significantly underestimated in functional MRs in which the long axis to short axis ratio of the ellipse is greater than 1.5. These findings explain the differences in the cut-offs for quantification.

Another limitation of PISA method consists of the dynamic nature of the MR itself. The PISA r is only measured in the frame in which it is greater, rejecting the rest of the ventricular systole. This fact could overestimate its measurement, equaling holosystolic MR to proto or telesystolic MR.

The quantification by PISA method of the MR using the 3D ECG could mitigate these limitations. On the one hand, with 3D ECG we can identify either spheroidal or ellipsoid PISA, improving calculation of its area; on the other hand, with the new advances in this technique we can achieve a high spatial and temporal resolution that allows us to visualize the entire heart cycle.

Pulsed Doppler Wave: Volumetric Method

This method can be used in addition to those already mentioned to increase the precision of the quantification,

or as an alternative method when the previous ones are not feasible. It consists of calculating the RVol and the regurgitant fraction thereof by means of the difference between the mitral stroke volume (MSV) and the systemic stroke volume (SV).

For the measurement of MSV, we choose the apical four-chambers view, using apical five-chambers view for SV. Here we follow the rule that the flow that passes through an orifice can be estimated by calculating the area of that orifice and multiplying it by the VTI.

$$RVol = MSV - SV$$

$$\text{Mitral regurgitant fraction (MRF)} = (RVol/MSV) \times 100$$

$$MSV = (\text{MV length})^2 \times 0.785 \times \text{VTI}_{\text{mitral filling}}$$

$$SV = (\text{LV outflow tract diameter})^2 \times 0.785 \times \text{VTI}_{\text{LV outflow tract}}$$

Its main strength is that it considers the dynamic component of the MR, unlike PISA method is not a measurement of an isolated frame. If the RVol is greater than or equal to 60 mL or 50% of the SV the MR would be classified as severe, while for values lower than 30 mL or 30% we classify the MR as mild.

It has several important limitations, on the one hand it assumes that the orifice of the MR is circular, on the other it needs a precise VTI tracing. Furthermore, since the formula includes the values of the annular diameter and the outflow tract squared, small errors in these measurements could be magnified. Another important limitation is that it is not an accurate measurement in case of significant aortic valve regurgitation (AoR), due to the variations in flow that this entails.

The measurement of the LV outflow tract and the MA by 3D ECG is more accurate since it does not assume the circular geometry of these elements.

Mitral Filling Assessment: Mitral Velocity-Time Integral/Aortic Velocity-Time Integral Ratio

In the absence of mitral stenosis (MS), the increase in the velocity of mitral protodiastolic filling flow is greater as the severity of MR increases. This can be assessed by pulsed Doppler wave (PW), identifying high filling velocities of the E-wave. In the absence of MS, an E-wave peak velocity greater than 1.5 m/sec suggests severe MR. However, a dominant A-wave practically excludes it.

In addition, mitral VTI/aortic VTI ratio can be assessed to quantify the MR. A ratio greater than 1.4 suggests severe MR, while a smaller than 1 ratio suggests mild MR.

Flow Assessment in Pulmonary Veins

The normal flow in PV shows a higher velocity during ventricular systole than during diastole. As MR severity increases the velocity curve, measured by PW decreases. Moreover, in some cases, reversal flow can be documented. This fact is considered a specific marker of MR severity.

In the case of an eccentric MR jet, it may happen that this flow is reversed only in one PV, therefore the study of the four PV is recommended, especially during a transesophageal study. This evaluation is performed with PW located 1 cm deeper from the entrance of the PV from the LA.

One limitation of this method is that any situation that increases LA pressure can decrease PV flow velocity,

so whenever a muffled wave appears, this increase in LA pressure should be studied by other techniques.

Continuous Doppler Wave

The evaluation of MR by CW can be used as a qualitative marker of severity. A high-density holosystolic signal, with a similar density than the antegrade flow, is suggestive of significant MR. However, a protosystolic flow or a low-density flow suggests a mild MR.

Similarly, continuous Doppler wave (CW) can inform about MR chronicity. A triangular wave is highly suggestive of severe an acute MR, while a rounded wave is consistent with chronic MR.

Therefore, table 1 summarizes the methods of quantification of MR.

Echocardiographic Impact of Mitral Regurgitation

The increase of LA filling and the LV overload that produces chronic MR leads to a dilation and progressive dysfunction of these heart chambers. This LV dilation and dysfunction plays a fundamental role in the management of chronic MR. Three-dimensional ECG allows a more accurate assessment of it, so it should be used if available.

Left atrial dilation is part of the natural history of MR. As MR increases, LA dilates due to volume and pressure overload. We also consider LA volume within the indications for surgery management.

Another measurement that should be done in patients with significant MR is the pulmonary systolic pressure (PSP), which increases due to the increase in retrograde pressure on the LA, and the tricuspid valve annulus, since if it is dilated it may require annuloplasty during mitral repair or replacement.

Stress Transthoracic Echocardiogram

Stress TTE is useful in patients with severe asymptomatic MR, or in those with confusing symptoms, to define their functional capacity. In addition, it can inform about the left ventricular ejection fraction (LVEF), the severity of the MR and the PSP increase during exercise. An increase in PSP greater than 60 mm Hg is an indication for repair or replacement and is associated with a poor prognosis. Moreover, the inability to increase LVEF or the increase in MR measured by PISA method is associated with a poor prognosis.

In the case of functional MR quantified as moderate, an increase in ERO greater than 13 mm^2 during exercise leads to an unfavorable prognosis and it would be an indicator of repair or replacement needs.

MANAGEMENT OF FUNCTIONAL MITRAL REGURGITATION

Natural history and symptomatic course of patients with MR is related to its quantification, its chronicity and subsequent cardiac anatomy abnormalities. Patients with an insidious onset and a steadily progression of MR have a prolonged asymptomatic course due to gradual cardiac remodeling with dilation of LA and LV, which adapt heart function to this situation and a delay the increase of pulmonary pressure. This is similar in cases in which MR is acute and severe. These patients present with an acute pulmonary edema, endangering patient's life.

In functional or secondary MR, the pathology that causes it marks the natural history of the MR. Current approach consists of optimize the medical treatment including cardiac resynchronization therapy if indicated. After achieving an optimized medical treatment, if the patient is still asymptomatic, the recommendation is surgery repair or

TABLE 1: Quantification of functional mitral regurgitation

Parameter	Mild	Moderate	Severe
Qualitative			
Color Doppler jet area	Small, central, does not occupy all the systole	Intermediate	Large amplitude, Coanda effect, reaches LA ceiling
CW Doppler	Intermittent, weak	Dense	Very dense, triangular morphology
Semi quantitative			
Vena contracta	<3 mm	3–6 mm	$\geq 7 \text{ mm}$
Mitral TVI/aortic TVI	<1	1–1.3	≥ 1.4
Mitral filling	Dominant A-wave	Variable	Dominant E-wave ($>1.5 \text{ m/s}$)
PV flow		Systolic flow damped	Systolic flow reversed
Quantitative			
ERO	$<10 \text{ mm}^2$	$10\text{--}20 \text{ mm}^2$	$\geq 20 \text{ mm}^2$
RVol	<15 mL	15–30 mL	$\geq 30 \text{ mL}$
Volumetric method	<30 mL or <30%	Intermediate	$\geq 60 \text{ mL}$ or $\geq 50\%$

CW, continuous Doppler wave; ERO, effective regurgitant orifice; PV, pulmonary veins; RVol, regurgitant volume; TVI, time-velocity integral.

TABLE 2: Surgical repair or replacement in secondary mitral regurgitation¹²

Recommendations	Class	Evidence
Surgery is indicated in patients with severe secondary mitral regurgitation undergoing CABG and LVEF >30%	I	C
Surgery should be considered in symptomatic patients with severe secondary mitral regurgitation, LVEF <30% but with an option for revascularization and evidence of myocardial viability	IIa	C
When revascularization is not indicated, surgery may be considered in patients with severe secondary mitral regurgitation and LVEF <30% who remain symptomatic despite optimal medical management (including CRT if indicated) and have low surgical risk	IIb	C
When revascularization is not indicated and surgical risk is low, a percutaneous edge-to-edge procedure may be considered in patients with severe secondary mitral regurgitation and LVEF <30% who remain symptomatic despite optimal medical management (including CRT if indicated) and who have suitable valve morphology by echocardiography, avoiding futility.	IIb	C
In patients with severe secondary mitral regurgitation and LVEF <30% who remain symptomatic despite optimal medical management (including CRT if indicated) and who have no option for revascularization, the Heart Team may consider a percutaneous edge-to-edge procedure or valve surgery after careful evaluation for a ventricular assist device or heart transplant according to individual patient characteristics.	IIb	C

CABG, cardiac artery bypass grafting; CRT, cardiac resynchronization therapy; LVEF, left ventricular ejection fraction.

TABLE 3: Study of MitraClip® and Not MitraClip® feasible

	MitraClip® feasible	Not MitraClip® feasible
MV area	> 4 cm ²	Significant stenosis
MR Jet	Central	Eccentric or multiple
Calcification	Not calcified or mildly	Severe
Specific measurements	Regurgitant orifice width <15 mm Regurgitant orifice height <10 mm Cohesion depth <11 mm Cohesion length >2 mm	Height >2 mm between the leaflets

MR, mitral regurgitation; MV, mitral valve.

replacement if the LVEF is greater than 30% and the patient is candidate for revascularization. If LVEF is less than 30%, the patient is deeply symptomatic and comorbidity is low, repair or replacement may be considered even if patient is not candidate for surgical revascularization.

Table 2 summarizes the recommendations for surgical repair or replacement based on European Society of Cardiology Clinical Practice Guidelines.¹²

A recent approach in these cases is the use of MitraClip® (Abbott Vascular). This percutaneous technique, similar to Alfieri technique, is an alternative therapy that may be considered in patients in class III or IV of the New York Heart Association (NYHA) functional class classification, with severe MR and favorable anatomy (Table 3) for its implantation, but with a prohibitive surgical risk.

Diastology Demystified

Jagdish C Mohan, Vishwas Mohan, Madhu Shukla

INTRODUCTION

Human beings engage in varying physical activity in daily life; physical exercise capacity is a manifestation of diastolic function. The heart chambers contract, eject, relax, fill, and then contract in a sequential manner (Fig. 1). The phase of relaxation and filling is called diastole (Figs. 2 to 4). Diastole fills the ventricles with adequate blood at very low pressures. There is atrioventricular (AV) coupling which maintains the relationship between peak and nadir of filling. Atrial diastole is during ventricular systole and vice versa. Relaxation aids in filling during early diastole in an active manner while there is passive gradient-dependent filling also in significant part of diastole. The phenomena of relaxation and contraction are interlinked and energy-dependent. Diastole precedes systole because no ejection is possible unless there is filling first. The processes of relaxation and filling constitute diastolic function. Increased resistance to filling is the simplest way of defining diastolic dysfunction. Increased resistance leads to elevated filling pressures. Diastolic dysfunction is the

first manifestation of a disease process and explains the symptoms better. Abnormalities of diastolic function are common to virtually all forms of cardiac disease. Noninvasive evaluation of diastolic ventricular function is based on Doppler echocardiographic visualization of inflow pattern and ventricular tissue stretching, although many more parameters are described.

Left ventricular (LV) diastolic pressure becomes elevated as a compensatory mechanism to maintain cardiac output. Therefore, demonstration of elevated LV filling pressure is an important diagnostic target when using echocardiography (ECG) to evaluate diastolic function. The study of pressure-volume loop during diastole is the ideal way to understand and assess diastolic function. However, there are several surrogate methods and parameters in echo-Doppler techniques which provide reasonable, reliable, and actionable information about diastolic function. In general, diastolic dysfunction may be characterized by enlargement of upstream chamber (atrium), alteration in various phases of diastole, and raised

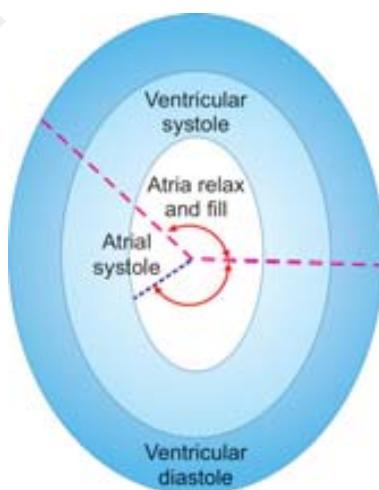

FIG. 1: Temporal components of atrial and ventricular contraction and filling.

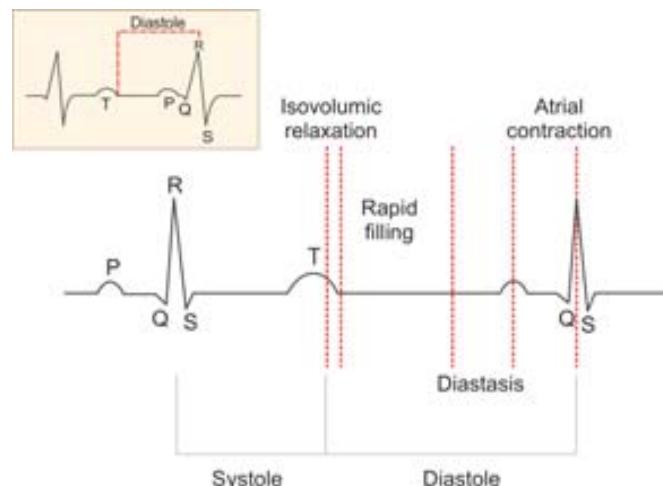

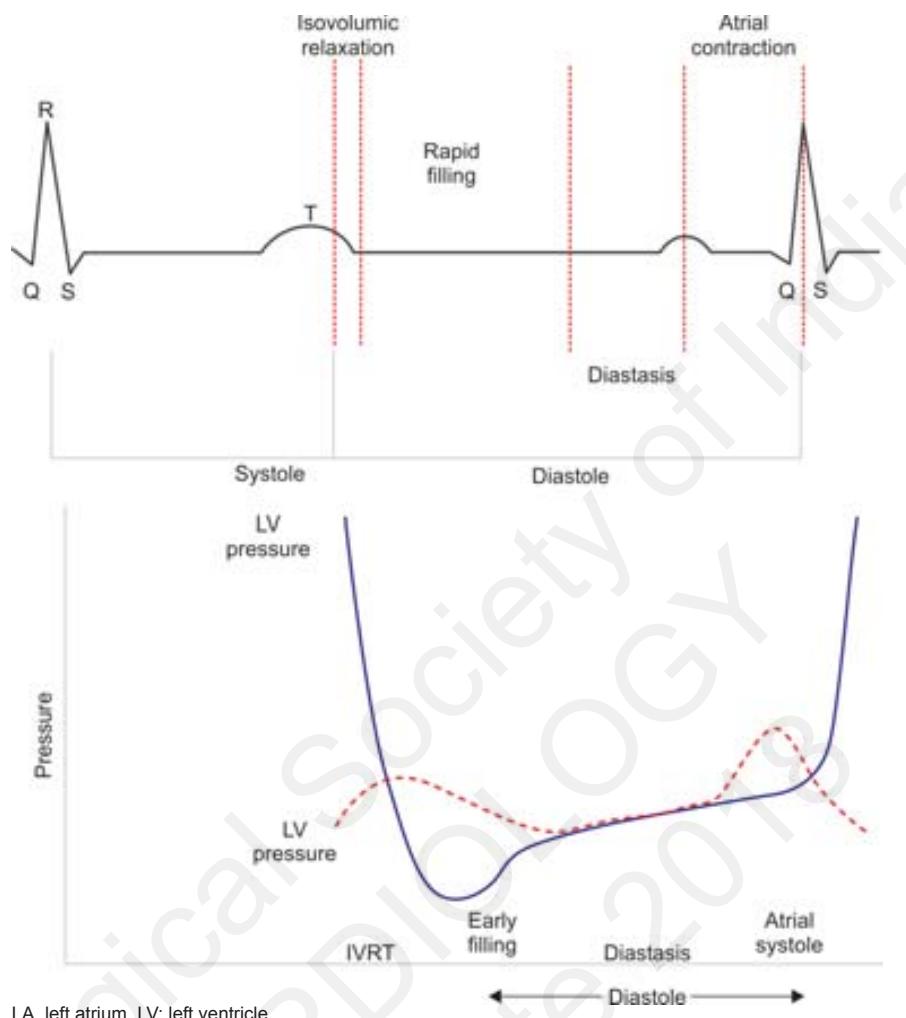

FIG. 2: Relationship of electrocardiogram to four phases of ventricular diastole.

LA, left atrium, LV: left ventricle.

FIG. 3: Relationship of electrocardiogram, phases of diastole, and atrioventricular pressure gradients.

filling pressures. Diastolic dysfunction is dynamic and in early phases, filling pressures are not increased. Assessment of diastolic function in simulated physiological situation like exercise, may provide enhanced information. Diastolic compensatory mechanisms that maintain filling volume are the earliest evidence of dysfunction. Hence, enhanced atrial contraction is the first thing to occur in compensation. There is also evidence of regional diastolic wall motion nonuniformity. Noninvasive surrogates often reported in clinical studies reflect integrative properties of the entire chamber and lack specificity.

PHYSIOLOGY OF DIASTOLE

Form follows function. Diastolic dysfunction is a physiological expression of morphological cardiovascular disease (CVD). The healthy myocardium is an active, nonlinear, non-homogeneous, and anisotropic viscoelastic material. During diastolic lengthening, normal cardiac muscle behaves like a spring. When the spring is more forcefully compressed during systole, diastolic lengthening is higher and vice versa (Fig. 5).

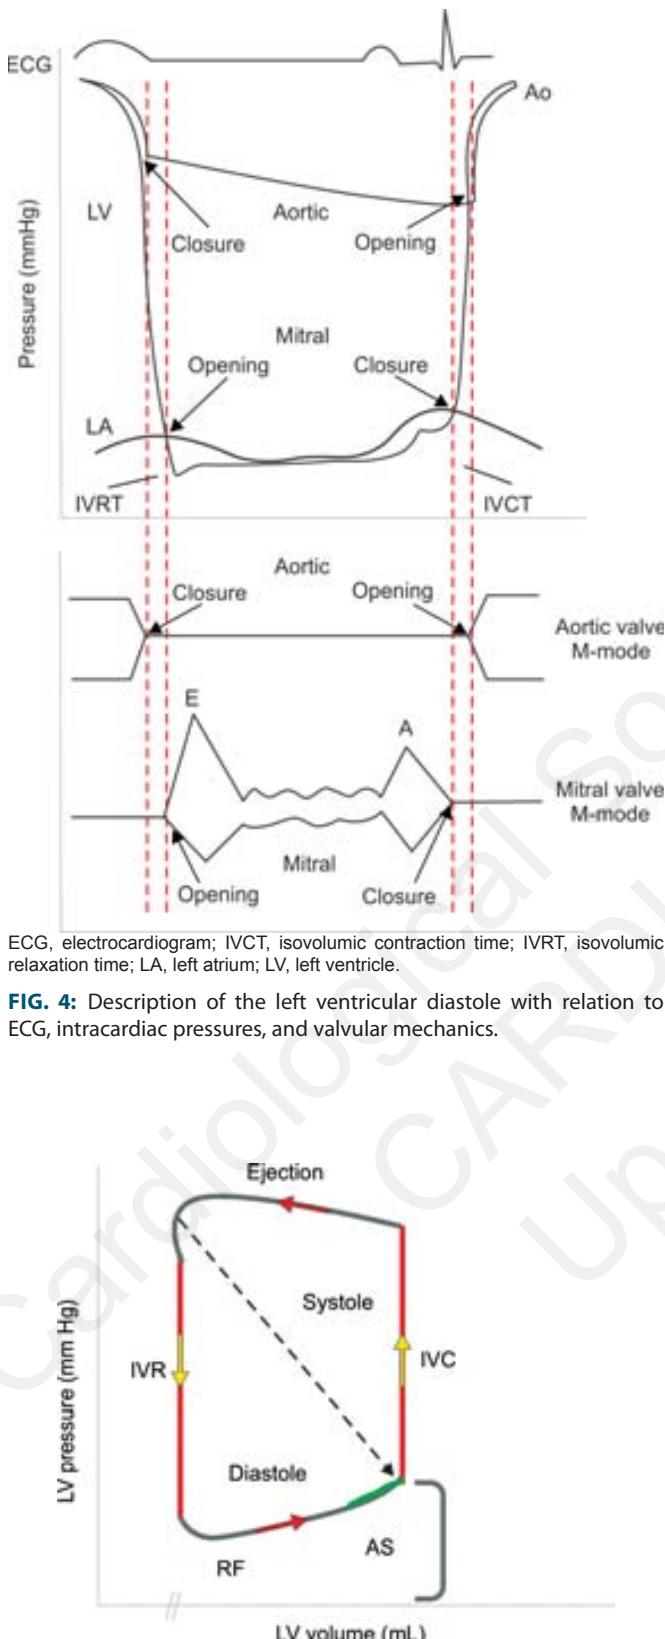

There is a certain degree of systolic elastance (slope between end-systolic pressure and end-systolic volume)

and also a definite diastolic elastance in the ventricles.¹ In several disease states like hypertension, diabetes, and LV hypertrophy as also with aging, systolic elastance remains unaffected or may actually increase and diastolic elastance decreases which can be studied and assessed by echo-Doppler parameters of diastolic function (Figs. 6 and 7). A ratio of mitral E/e' to stroke volume is a good estimate of diastolic elastance and also diastolic function reserve.

On the other hand, when systolic elastance is reduced, diastolic elastance initially increases due to remodeling and diastolic dysfunction denoted by filling pressures, therein, is a manifestation of fluid overload. Most systemic diseases affect the left ventricle primarily and hence, it is pertinent to discuss largely about the LV diastolic function/dysfunction.

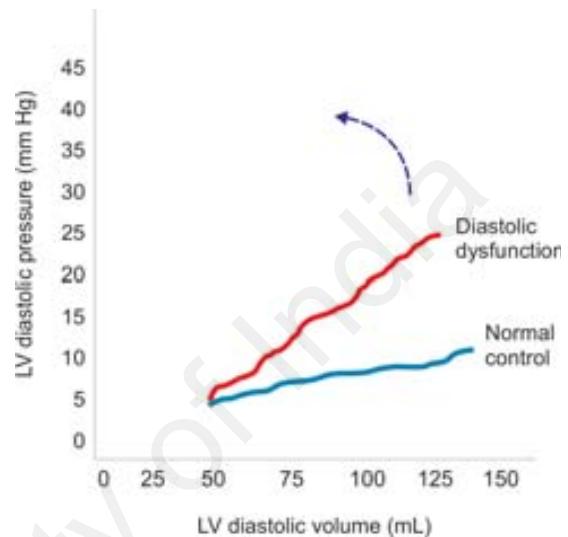

FACTORS CONTRIBUTING TO DIASTOLE

- Decline of the myocardial active state following systole
- Passive effects of expanded extracellular volume
- Rapid changes in atrial and ventricular pressures
- Transmural flow

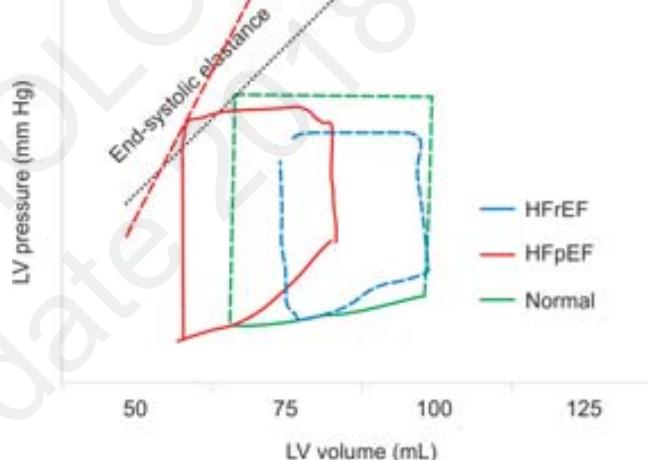

ECG, electrocardiogram; IVCT, isovolumic contraction time; IVRT, isovolumic relaxation time; LA, left atrium; LV, left ventricle.

FIG. 4: Description of the left ventricular diastole with relation to ECG, intracardiac pressures, and valvular mechanics.

LV: left ventricle.

FIG. 6: Diastolic pressure-volume relationship (elastance) of a normal subject (blue color) and that of a subject with diastolic dysfunction (red color).

HFpEF, heart failure with preserved ejection fraction; HFrEF, heart failure with reduced ejection fraction; LV, left ventricle.

FIG. 7: Depiction of pressure-volume loop in pure diastolic heart failure (HFpEF) compared to that of normal control and systolic heart failure (HFrEF).

- Interactions with the right ventricle and pericardium
- Atrial systole.

SIGNIFICANCE OF DIASTOLIC FUNCTION

- Identification of preclinical diseases in probands
- Diagnosis and subtyping of clinical syndrome of heart failure (HF)
- Marker of incremental prognosis in diverse cardiac disorders
- Monitoring therapy and follow-up
- Understanding exercise physiology

AS, atrial systole; IVC, isovolumic contraction; IVR, isovolumic relaxation; LV, left ventricle; RF, rapid filling.

FIG. 5: Left ventricular pressure-volume loop. Note that the diastole is a mirror image of systole.

- Cardiac versus noncardiac dyspnea
- Physiological versus pathological remodeling
- Optimizing devices and drugs response
- Evaluation of intraventricular dyssynchrony
- Study of pericardial diseases.

There is no single definition for diastolic dysfunction. Many features can get altered, and any one change or their combination is typically called diastolic dysfunction, although the pathophysiology and functional significance varies greatly.²⁻⁴ Clinically, the most common manifestation is an elevated mean diastolic pressure and altered filling patterns, but neither of these are specific features of diastolic dysfunction (Fig. 8).

When diastolic dysfunction is detected, it has some morphological, cellular, and proteomic connotations. These are:

- A change in the extracellular matrix of the myocardium, with the formation of excess collagen tissue⁵
- At the cellular level, there is reduced phosphorylation of sarcomeric proteins
- At the proteomic level, an isoform change in important structural macromolecular proteins such as titin.⁶

Diastole starts with closure of the aortic valve and ends with onset of ventricular contraction (Fig. 9). It has an initial period of ventricular relaxation without filling [isovolumic relaxation time (IVRT)] and then three phases of ventricular filling [diastolic filling period (DFP)]. The four phases of diastole are:⁷

1. Isovolumic relaxation (IVR) phase
2. Rapid filling phase
3. Diastasis
4. Late diastolic filling due to atrial contraction.

Diastolic LV function can be assessed in each of the four phases: (1) IVR, (2) rapid filling, (3) slow filling, and (4) atrial contraction by studying the inflow Doppler pattern either in pulmonary veins or at the level of mitral orifice (Fig. 10). These four phases uniquely reflect LV physiology and are invariably accessible to noninvasive evaluation.

In brief, diastolic dysfunction is presumed when there is impaired relaxation (and decreased ventricular suction), poor filling, or loss of atrial contraction.⁷

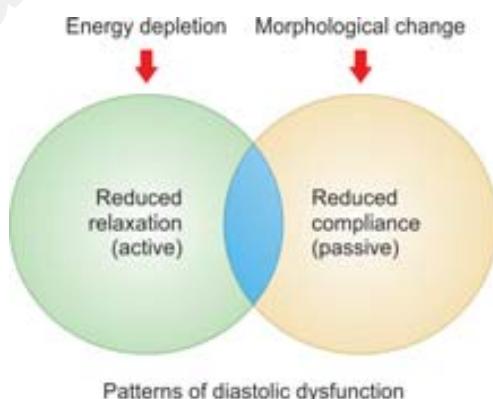

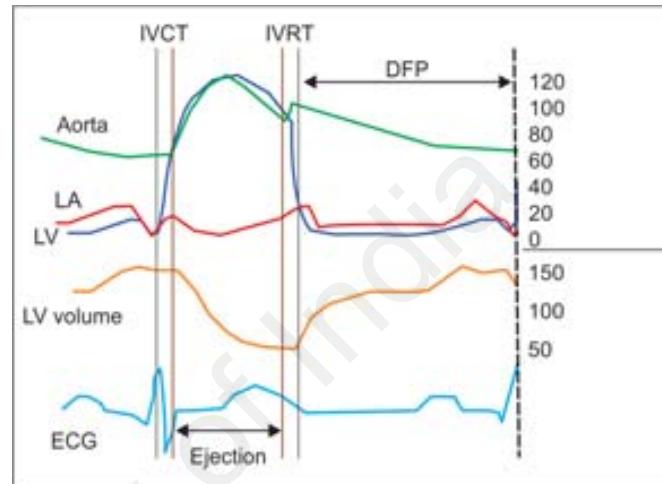

FIG. 8: Diastolic dysfunction in clinical sense is raised diastolic pressures which means reduced compliance or increased diastolic stiffness.

DFP, diastolic filling period; ECG, electrocardiogram; IVCT, isovolumic contraction time; IVRT, isovolumic relaxation time; LA, left atrium; LV, left ventricle.

FIG. 9: Graphic representation of various phases of the cardiac cycle of the left heart.

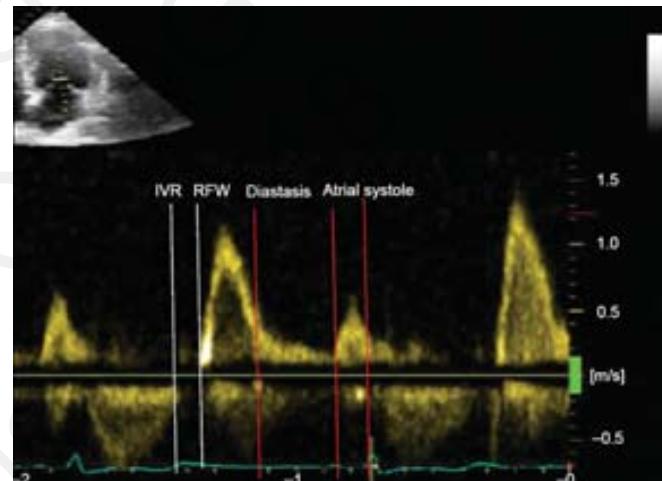

FIG. 10: Doppler interrogation with sample volume placed between the left ventricular outflow and the inflow showing all four phases of diastole: (1) IVR—isovolumic relaxation, (2) RF—rapid filling, (3) diastasis—slow filling, and (4) AC—late filling due to atrial systole.

There are two phases in systole:

1. Isovolumic contraction (IVC) phase
2. Ejection phase (ET).

Combined systolic and diastolic function can be assessed by the ratio of IVR time + IVC time/ejection time. This ratio has been called myocardial performance index.⁸ Although used for prognosis in various diseased states, it has not found practical utility for daily use in most echocardiography laboratories.

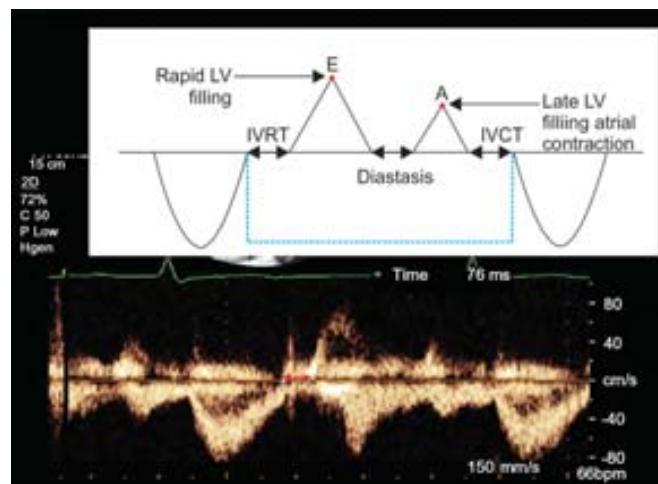

Isovolumic Relaxation Time

Isovolumic relaxation time, which corresponds to the time interval from aortic valve closure to mitral valve opening, is difficult to appreciate from simultaneous LV pressure, aortic pressure, and wedge pressure recordings but is easily measured by pulsed or continuous-wave (CW) Doppler from

the simultaneous display of the end of aortic ejection and the onset of mitral inflow (Fig. 11).

Isovolumic relaxation time has a predictable quantitative relationship to constant of IVR and to left atrial (LA) and aortic pressures.⁸

- Prolonged IVRT indicates impaired myocardial relaxation
- A normal IVRT is about 70 ± 12 ms, and approximately 10 ms longer in people over 40 years
- In abnormal relaxation, IVRT is usually in excess of 110 ms
- With restrictive filling, it is usually under 60 ms

BPM, beats per minute; IVCT, isovolumic contraction time; LV, left ventricular.

FIG. 11: Doppler interrogation between LV outflow and inflow showing measurement of isovolumic relaxation time. At heart rate of 66 BPM, IVRT is 76 ms in this normal subject.

- If IVRT is prolonged (>110 ms), LA pressure is not elevated because the delay in mitral valve opening is related to lower pressure crossover between LV and LA in the setting of delayed relaxation

- It is safe to conclude that LA pressure is elevated if the IVRT is short (<60 ms) in the presence of cardiac disease and normal heart rate range.

Clinical value of IVRT as an index of diastolic LV function is limited because it depends on mitral valve opening pressures and, therefore, is not uniquely related to LV dysfunction.

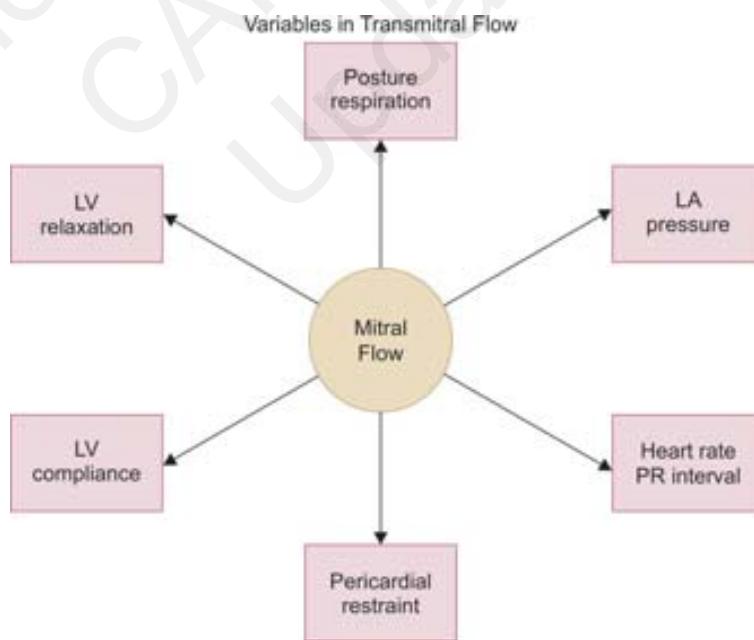

Rapid Filling Phase

In early diastole, chamber wall relaxation unmasks stored elastic strain, allowing the LV to recoil and act as a suction pump by aspirating blood into the ventricle. Normal LV filling occurs rapidly early in diastole caused by a progressive pressure gradient within the ventricle and with a low LA pressure.

Rapid filling phase accounts for 70% of LV filling. It gets shorter in duration with raised filling pressures and is prolonged in subjects with impaired relaxation alone.⁹ When both impaired relaxation and raised LA pressure coexist, it has variable duration like in normal subjects. Rapid filling phase is denoted by early diastolic (E) mitral flow wave and antegrade diastolic (D) flow wave of the pulmonary veins. Variables affecting rapid filling phase are shown in figure 12.

Deceleration Time of Early Filling Wave (Mitral E and Pulmonary D Waves)

Deceleration time (DT) is the duration between the peak of early filling wave and where its linear descending slope reaches zero (Fig. 13). Nonlinear slopes are not measured.

LA, left atrium; LV, left ventricle.

FIG. 12: Variables affecting rapid filling phase in diastole.

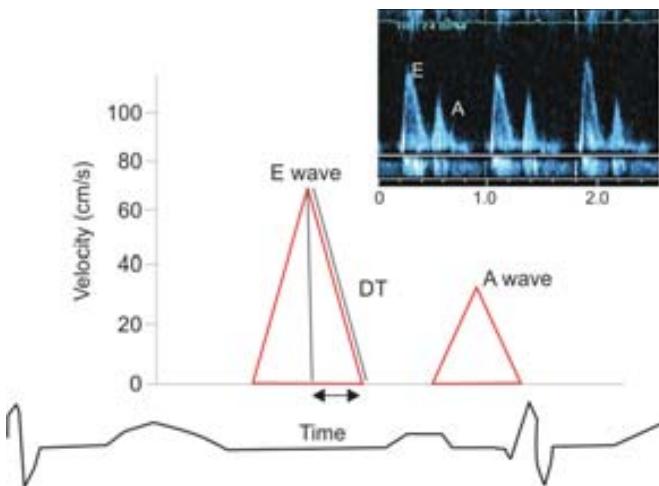

FIG. 13: Graphic display of deceleration time (DT) of mitral early filling wave.

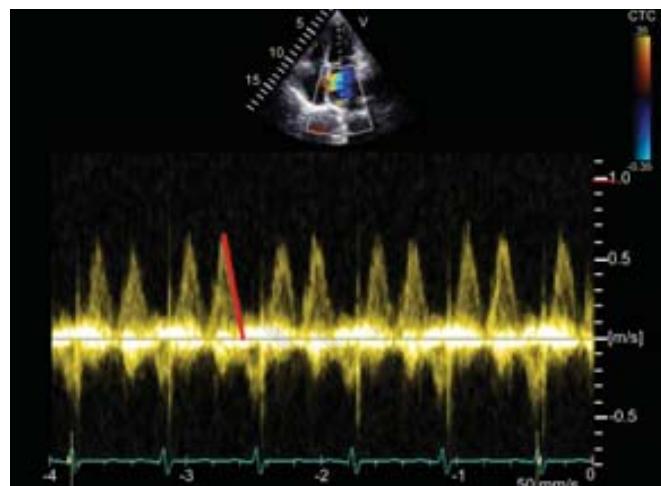

FIG. 15: Right upper pulmonary vein flow in a patient with restrictive cardiomyopathy measuring deceleration time (DT) of D wave.

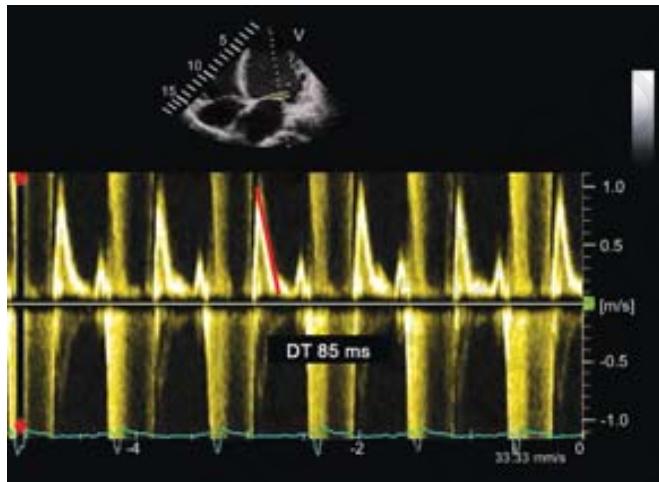

FIG. 14: Restrictive filling pattern with deceleration time (DT) of 85 ms in a 50-year-old male patient with dilated cardiomyopathy.

Conditions associated with increased LV stiffness are associated with a more rapid rate of deceleration of early filling and a shorter time for this deceleration.¹⁰

- It is an index of resistance to early filling with normal values in range of 150–250 ms (up to 200 ms by some). It is shorter in young subjects
- Deceleration time denotes chamber stiffness regardless of heart rate, afterload, and contractility
- Deceleration time of less than 150 ms (range 130–160 ms in some studies) indicates restrictive filling and relatively noncompliant LV beyond the age more than 45 years (Fig. 14)
- Deceleration time more than 200 ms indicates compensatory mechanism is in place to overcome impaired relaxation. Prolonging of DT during therapy after recording a very short DT initially is a positive sign of recovery when heart rates do not change significantly

- There is a close inverse relationship between DT and pulmonary wedge pressure in HF and in subjects more than 45 years of age
- Deceleration time is affected by age as well as pericardial restraint. As myocardial relaxation becomes less active with aging or abnormally delayed due to a disease process, the rate of LV pressure decline during the early diastole is reduced, and it takes a longer time to reach the minimal LV diastolic pressure
- Longer DT indicates impaired diastolic reserve. In this situation with abnormal myocardial relaxation, a reduced DFP and a lack of atrial contraction compromise LV filling further and produce clinically syndrome of effort intolerance.

During the time of early flow deceleration, there is rapid flow into the LA from the pulmonary veins. DT of pulmonary vein diastolic wave has same significance as that of mitral DT (Fig. 15). A pulmonary vein DT of less than 150 ms has much greater specificity for predicting elevated filling pressures and significant diastolic dysfunction.¹¹

Diastasis

During the slow LV filling phase or diastasis, residual effects of LV relaxation and dynamic effects of fast LV inflow have subsided. This phase is used to construct diastolic LV pressure-volume relations from a single cardiac cycle and allows LV stiffness, the slope of the diastolic LV pressure-volume relation, to be derived under static conditions. In subjects with impaired relaxation and longer cardiac cycle, residual effects of LV relaxation may persist and positive filling wave during diastasis (L-wave) may be observed (Figs. 16 and 17). Mitral valve L-waves may be evident in healthy patients with relatively low heart rates.¹²

Importance of L-wave

- The L-wave (between E and A waves) may be seen in relatively bradycardic patients with normal hearts. It is usually less than 20 cm/s in velocity

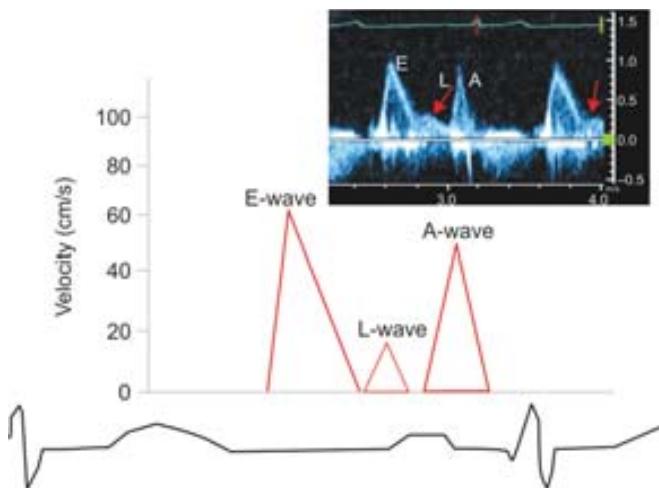

FIG. 16: Pulsed-wave Doppler mitral flow showing positive wave (L-wave) during diastasis.

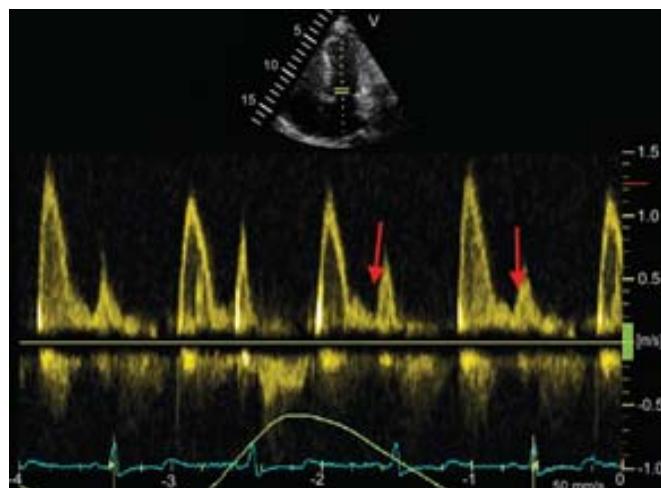

FIG. 18: Transmitral L-wave (red arrows).

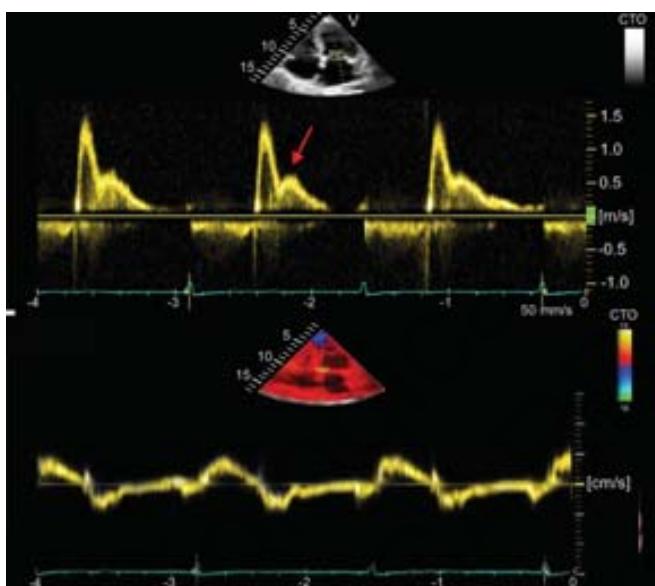

FIG. 17: Pulsed-wave Doppler mitral flow in upper panel showing prominent L-wave (red arrow), no A-wave, and bradycardia.

- A pathologic L-wave typically is found in patients with delayed active relaxation with increased LV stiffness. Its velocity is more than 20 cm/s
- In the echo laboratory, patients who exhibit transmitral L-wave, will often have clinical HF, LV hypertrophy with normal systolic function, or LV systolic dysfunction
- A pathologic L-wave is suggestive of elevated LV preload (pseudonormalization)
- A pathologic L-wave has prognostic value, in that it is predictive of future hospitalizations with HF (Fig. 18).

Occasionally, there can be negative L-wave or mid-diastolic mitral regurgitation due to rapid rise in LV diastolic pressure as a consequence of early filling (Fig. 19). Its exact significance is not clear.

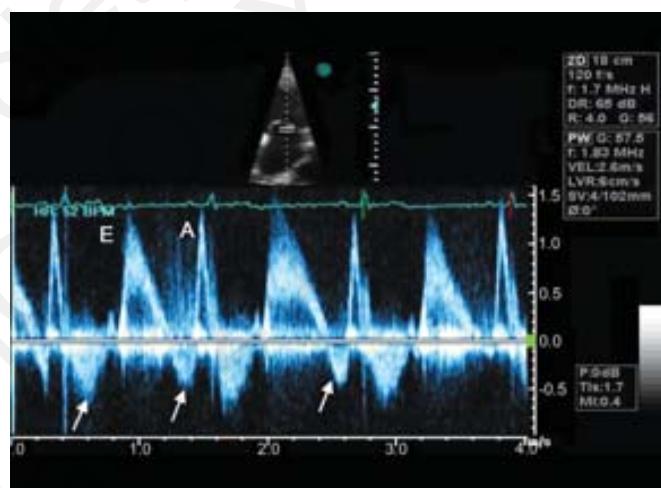

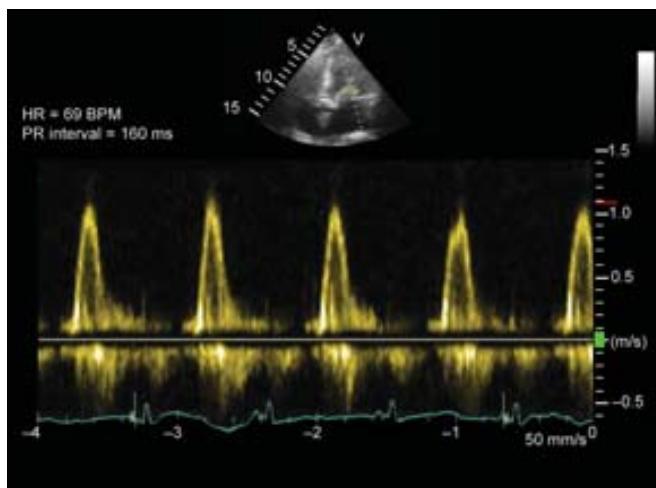

FIG. 19: Mid-diastolic negative L-wave in a patient with left ventricular (LV) diastolic dysfunction.

Atrial Kick or Contribution

Late diastolic filling wave is of short duration and occurs due to atrial contraction just before ventricular systole begins. This accounts for 20–40% of ventricular filling and is absent in atrial fibrillation (AF) and fragmented during atrial flutter. This gets partly or completely obliterated in first-degree heart block and markedly raised ventricular stiffness. Atrial kick is reflected by late diastolic (A) mitral flow wave and atrial flow reversal (Ar) in pulmonary veins. In markedly elevated LV diastolic pressure, atrial contraction may not produce any antegrade flow wave and may be seen to send flow retrogradely in pulmonary veins due to resistance gradient (Fig. 20).

Tissue Motion and Diastolic Function

As transmitral flow commences in diastole, the mitral annulus moves upward the atrium along the long axis. Due to tissue and blood incompressibility, as the annulus rises, the

BPM, beats per minute; HR, heart rate.

FIG. 20: Monophasic mitral flow with normal PR interval and HR of 69 BPM in a 90-year-old subject.

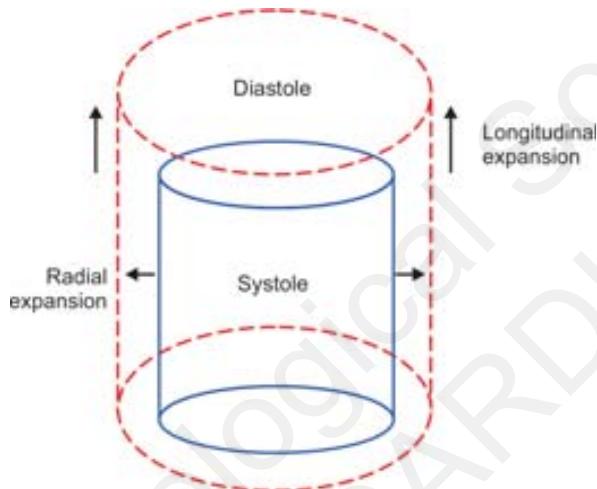

FIG. 21: Graphic display of longitudinal and radial expansion of the left ventricle during diastole (arrows).

wall thins, and the endocardium is simultaneously displaced radially outward toward the epicardium. During filling, the short and long axes change simultaneously (Fig. 21). Hence, rate of longitudinal displacement and radial endocardial displacement are good indicators of diastolic function.¹³ Early diastolic longitudinal excursion rate can be easily obtained from tissue Doppler studies (Fig. 22).

Left ventricular wall motion generates the AV pressure gradient resulting in the early transmural flow (Doppler E-wave) and associated vortex formation.

Substantial residual LV relaxation pressures in mid-diastole present in some patients with stiff LV can result in a positive wave called tissue L' wave (Fig. 23).¹⁴

LEFT ATRIAL VOLUME AND DIASTOLIC FUNCTION/DYSFUNCTION

The measurement of maximum LA volume is an essential component of the comprehensive assessment of LV diastolic

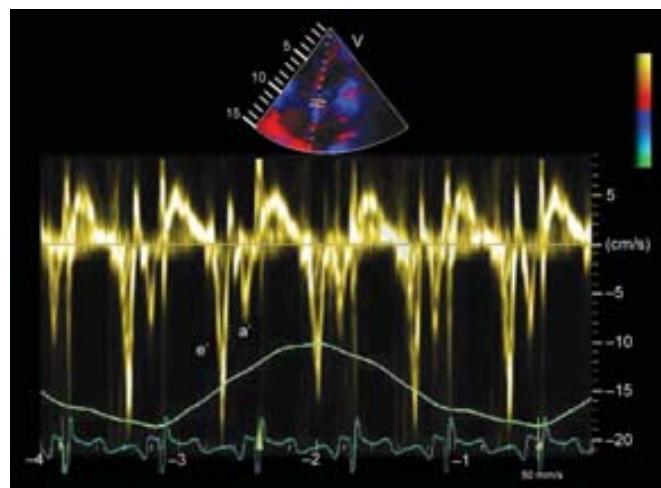

FIG. 22: Biphasic longitudinal expansion of the left ventricle during diastole. e'—early diastolic and a'—late diastolic longitudinal tissue velocity waves.

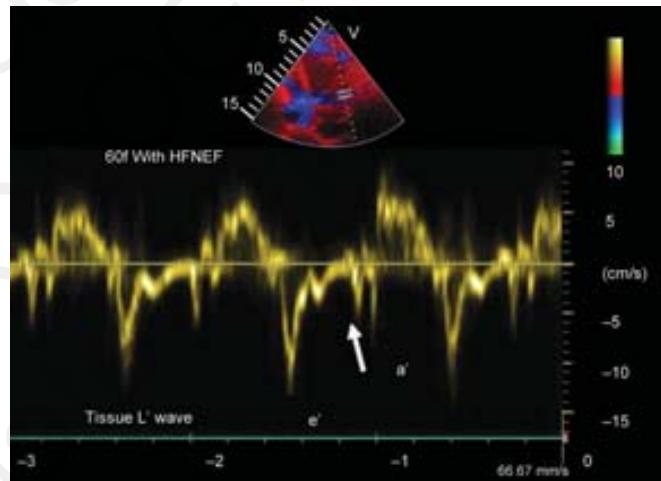

FIG. 23: Tissue L' wave in diastasis (arrow).

function.^{15,16} This is based upon the premise that the form follows the function. Resistance to filling due to diastolic dysfunction causes blood stasis and stretches the chamber. More recently, LA volumes have been obtained by three-dimensional (3D) echocardiography. However, normative data in clinical practice is validated from two-dimensional (2D) echocardiography only.

The LA volume is usually measured by biplane area-length method (Fig. 24). In current guidelines, assessment of diastolic function mandates measurement of LA volume index in every subject. Although, it has limited role in assessing diastolic function or dysfunction in acute situations, it has great relevance in chronic stable CV conditions.¹⁵

- The LA volume can be viewed as a morphologic expression of LV diastolic dysfunction¹⁵
- Left atrial volume is regarded as a barometer of the chronicity of diastolic dysfunction¹⁵
- This simple measure of LA volume provides significant insight into an individual's risk for the development

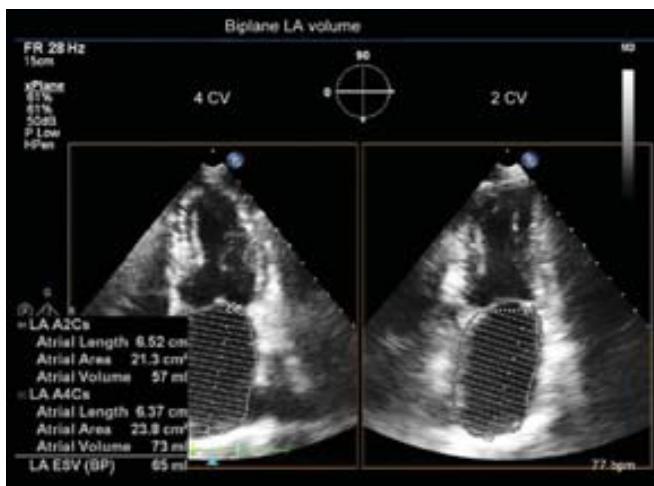

FIG. 24: Estimation of biplane end-systolic left atrial (LA) volume by area-length method.

of adverse CV events including, myocardial infarction, stroke, AF, and HF

- Normal values for LA volume are $22 \pm 6 \text{ mL/m}^2$.¹⁵
- Left atrial volume is graded relative to risk, $28-33 \text{ mL/m}^2$ = mild; $34-39 \text{ mL/m}^2$ = moderate; and more than or equal to 40 mL/m^2 = high or severe.
 - *Normal subjects:* $22 \pm 6 \text{ mL/m}^2$
 - *Mild LA enlargement:* $28-33 \text{ mL/m}^2$
 - *Moderate LA enlargement:* $34-39 \text{ mL/m}^2$.
 - *Severe LA enlargement:* More than or equal to 40 mL/m^2
- Diastolic dysfunction is more likely if the LA volume index exceeds 34 mL/m^2
- However, LA volume can increase in mitral regurgitation, athletes, and in presence of sinus bradycardia without concomitant diastolic dysfunction
- There is a fairly good positive correlation between LA volume index and grade of diastolic dysfunction
- Maximum LA systolic lengthening and its rate have also been found to correlate with diastolic dysfunction (Figs. 25 and 26)

- It is possible to use LA strain during ventricular systole along with LA pressure or its Doppler echocardiographic surrogate (E/e') to calculate LA chamber stiffness.¹⁷ E/e' divided by LA reservoir longitudinal strain is a measure of chamber stiffness
- Left atrial stiffness has good accuracy in identifying patients in diastolic HF
- Change in volume-pressure relationships in left atrium also indicates change in material properties (ischemia, fibrosis, etc.) and physiological or pathological remodeling in the LV.

Factors extrinsic to the LV myocardium may influence the end-diastolic pressure-volume relationship. Changes in intrathoracic pressure (as with spontaneous or assisted ventilation), pericardial constraints, and interventricular interactions may each affect ventricular diastolic pressure (when referenced to atmospheric pressure), which, therefore, influences this relationship. In absence of these, intrinsic diastolic function governs this relationship. Various equations have been derived from mitral flow and tissue expansion rate to predict end-diastolic pressure. E/e' ratio has the strongest relation to pulmonary capillary wedge pressure (PCWP) [$r = 0.86$, $\text{PCWP} = 1.55 + 1.47 (E/E_a)$], irrespective of the pattern and ejection fraction (EF).¹⁸

How to perform a study focusing on diastolic function?

- After estimation of biplane LA volume, one proceeds to interrogate by pulsed-wave (PW) Doppler, four different sites as shown in figure 27
- With the patient supine, apical four-chamber views (4-CVs) using a 2.5-MHz transducer are obtained with the sample volume gated at 1.5–5 mm directed between the tips of the mitral valve leaflets and orthogonal to the mitral valve plane
- Continuous-wave Doppler is used to record aortic outflow and mitral inflow from the apical view for determination of the IVRT using a sweep speed of 100 mm/s
- In apical 4-CV, ostium of the right upper pulmonary vein is interrogated by pulsed-wave Doppler
- M-mode of the color flow propagation velocity across the mitral valve up to 4 cm into the cavity is obtained

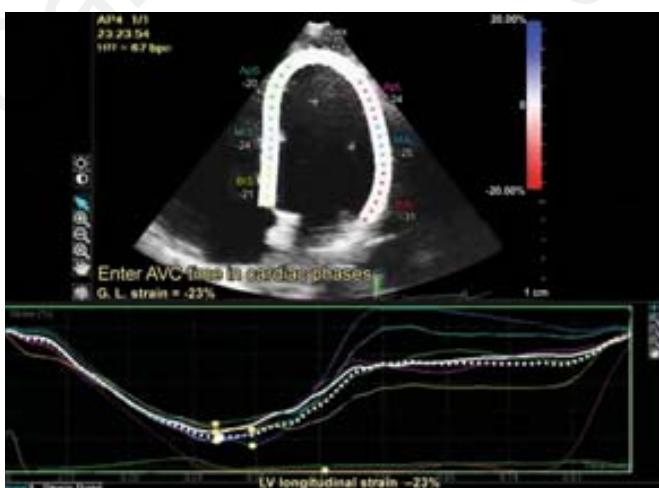

FIG. 25: Left atrial (LA) longitudinal lengthening in a normal subject compared to that of the left ventricular (LV) shortening. Typically, LA lengthening is twice or more of the LV shortening.

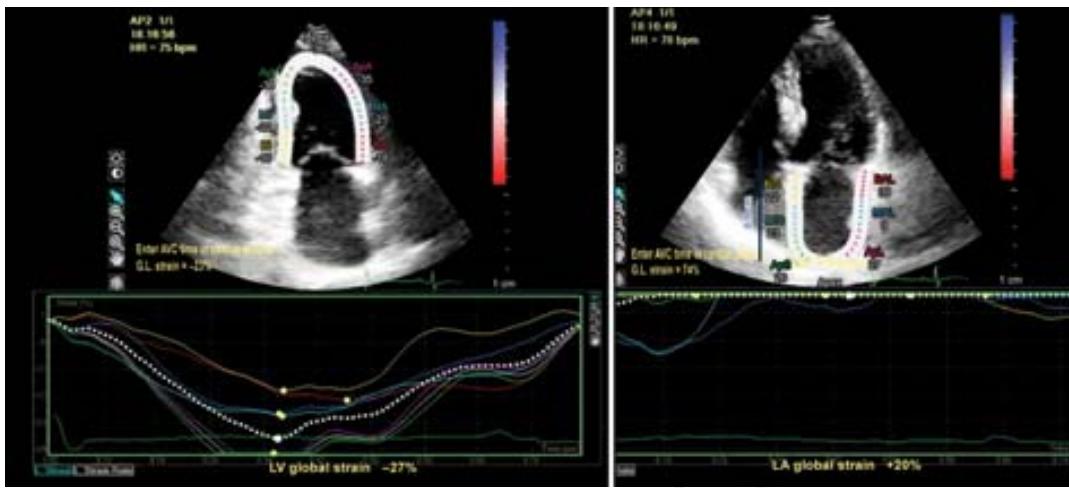

FIG. 26: Significantly reduced left atrial (LA) global strain in presence of diastolic dysfunction.

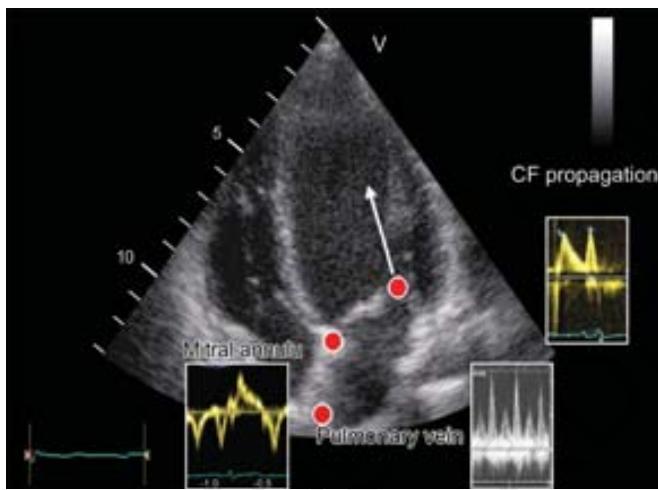

FIG. 27: Sites for assessing diastolic function in an apical four-chamber view (4-CV).

- Doppler tissue imaging (DTI) of the medial and the lateral mitral annulus and M-mode images are also recorded. DTI is performed at a sample size gated at 2.5 mm
- Effect of Valsalva maneuver is also observed for the mitral and pulmonary vein flow
- Sometimes, supine exercise is used to study diastolic function parameters. Postexercise E/A ratio as an independent determinant of severity of exercise-induced dyspnea and impaired exercise tolerance
- Longitudinal strain and untwisting rate of the LV are also recorded by acoustic speckle tracking
- After obtaining all the measurements, the diastolic dysfunction, if present, is graded and occasionally it may be noted as indeterminate if multiparameters give conflicting results and less than 50% parameters are positive for dysfunction.

MITRAL INFLOW VELOCITIES

The mitral inflow velocity profile is initially used to characterize LV filling dynamics (Fig. 28).

- E velocity (E) represents the early mitral inflow velocity and is influenced by the relative pressures between the LA and LV, which, in turn, are dependent on multiple variables including LA pressure, LV compliance, and the rate of LV relaxation¹⁹

- A velocity (A) represents the atrial contractile component of mitral filling and is primarily influenced by LV compliance and LA contractility. It would be absent in AF
- The DT of the E velocity is the interval from peak E to a point of intersection of the deceleration of flow with the baseline and it correlates with time of pressure equalization between the LA and LV. Incomplete or delayed relaxation causes a delay in the transfer of blood from atria to ventricle
- As the early LA and LV filling pressures either move toward or away from equilibrium, so will the DT either shorten or lengthen, respectively
- Diastolic dysfunction can be categorized into three stages based upon transmural filling patterns:²⁻⁴

1. *Grade I:* Impaired relaxation denoted by DT more than 250 ms and E/A velocity ratio less than 0.8 (Figs. 29 and 30). The American Society of Echocardiography (ASE) and European Association of Echocardiography (EAE) guidelines suggest DT more than 200 ms in grade I

Early in the evolution of diastolic dysfunction and the delay in emptying (DT > 250 ms) partially compensated by a more vigorous end-diastolic atria contraction, and, hence, the E/A ratio is reduced (<0.8)

2. *Grade II:* Pseudonormal pattern with DT 150–250 ms and E/A ratio between 0.8 and 1.5. ASE-EAE guidelines put DT in range of 160–200 ms

Pseudonormal pattern needs confirmation by increased LA volume ($>34 \text{ mL/m}^2$) or mitral E wave velocity/annular tissue early diastolic velocity more than 15 (medial) or more than 13 (lateral) or pulmonary vein flow increased duration of atrial flow reversal wave or Valsalva maneuver to unearth impaired relaxation in mitral flow

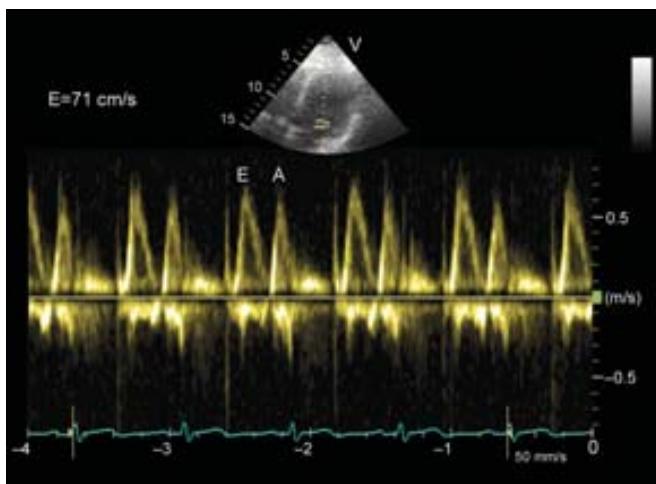

FIG. 28: Biphasic mitral flow with sample volume at the tips of the mitral leaflets.

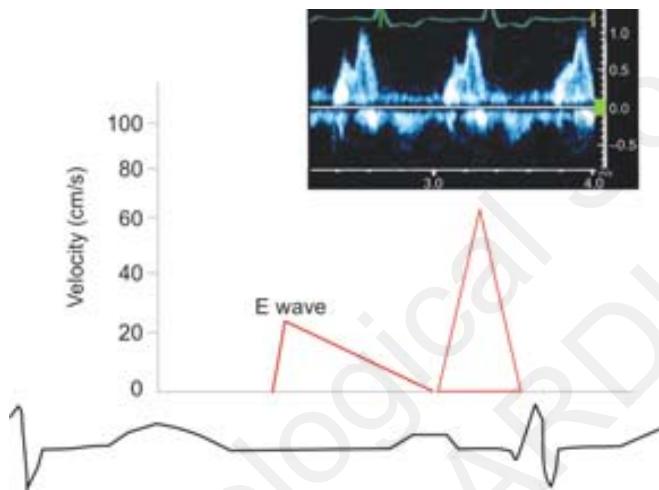

FIG. 29: Grade I diastolic dysfunction in transmural flow with prolonged deceleration time (DT).

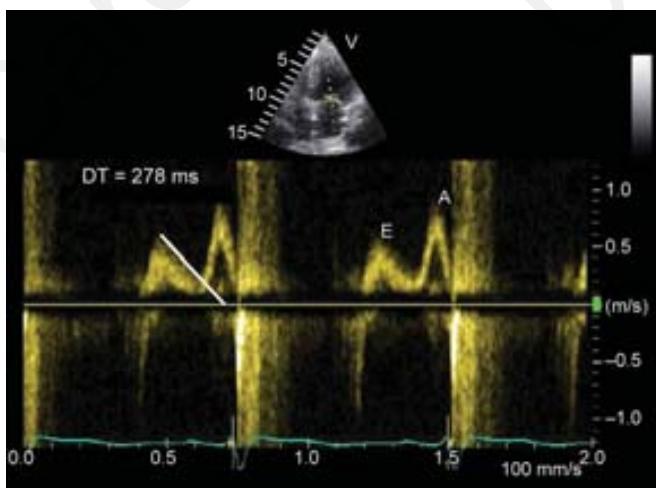

FIG. 30: Grade I diastolic dysfunction denoted by deceleration time (DT) of 278 ms and E/A 0.7.

Presence of L-wave or DT less than 150 ms could also provide clue to pseudonormal pattern if E/A velocity ratio is 0.8–1.5

3. *Grade III:* Restrictive flow or reduced compliance pattern with DT less than 160 ms and E/A ratio more than or equal to 2.0. Others have used DT cutoff limits of less than 150 ms and less than 130 ms as well.

MITRAL INFLOW MEASUREMENTS

Following measurements should be made in each examination:

- Peak early filling velocity (E-wave)
- Late diastolic filling velocity (A-wave)
- E/A ratio
- Deceleration time of early filling velocity
- Isovolumic relaxation time (ms)
- Mitral A-wave duration (obtained at the level of the mitral annulus)
- Diastolic filling time (ms)
- A-wave velocity-time integral (cm)
- Total mitral inflow velocity-time integral (and thus, the atrial filling fraction) with the sample volume at the level of the mitral annulus
- Mid-diastolic flow is an important signal to recognize. Low velocities can occur in normal subjects, but when increased (≥ 20 cm/s), they often represent markedly delayed LV relaxation and elevated filling pressures.

Most confusions arise in so-called pseudonormal pattern wherein one or the other parameter can be discordant (Fig. 31). Help can be obtained from using multiple parameters and any of the other abnormality could be construed as abnormal diastolic function especially if the early diastolic annular tissue velocity is significantly reduced.^{3,4}

Restrictive flow is relatively easy to detect and is unambiguous in adult patients with heart disease (Fig. 32).²⁰ These criteria cannot be used in children and young adults who normally have large E-waves and short DT due to very active suction of the LV.

Although not supported by the ASE, others have used grade IV diastolic dysfunction as the one in which either the restrictive pattern is irreversible²¹ or has monophasic flow pattern with absent A-wave despite sinus rhythm, normal PR interval, and usual heart rates (Fig. 33).

MITRAL INFLOW: ACQUISITION AND FEASIBILITY

- Pulsed-wave Doppler apical 4-CV is performed in order to obtain mitral inflow velocities to assess LV filling
- Color flow imaging can be helpful for optimal alignment of the Doppler beam, especially in the presence of a dilated left ventricle
- Continuous-wave Doppler to assess peak E (early diastolic) and A (late diastolic) velocities should be performed before applying the PW technique to ensure that maximal velocities are obtained
- A 1–3 mm sample volume is then placed between the mitral leaflet tips during diastole to record a crisp velocity profile

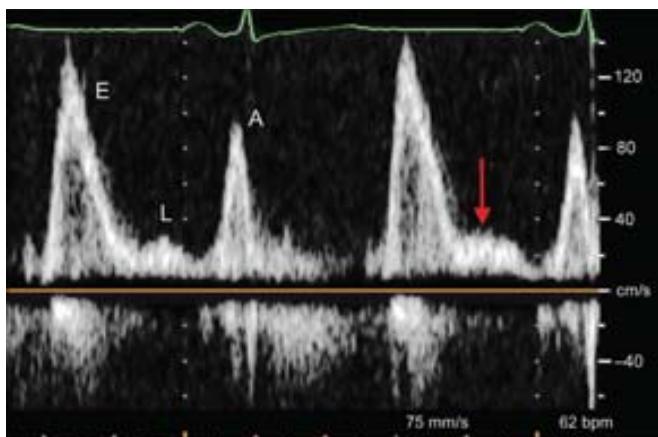

FIG. 31: Pseudonormal or grade II diastolic dysfunction denoted by presence of L-wave (arrow).

Note: E/A ratio of 1.5 and deceleration time (DT) of 180 ms.

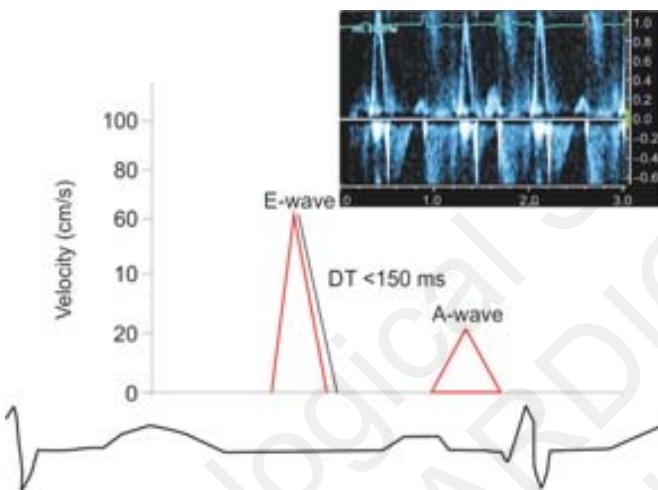

FIG. 32: Restrictive (grade III) flow pattern with short deceleration time (DT) and E/A ratio more than or equal to 2.

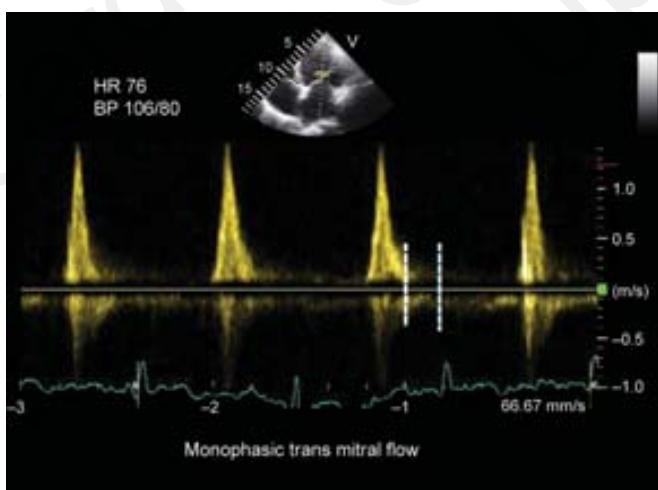

FIG. 33: Monophasic transmитral flow pattern in a patient with advanced diastolic dysfunction and heart failure due to previous anterior wall myocardial infarction.

- Optimizing spectral gain and wall filter settings is important to clearly display the onset and cessation of LV inflow
- Spectral mitral velocity recordings should be initially obtained at sweep speeds of 25–50 mm/s for the evaluation of respiratory variation of flow velocities, as seen in patients with pulmonary or pericardial disease
- If variation is not present, the sweep speed is increased to 100 mm/s, at end-expiration, and averaged over three consecutive cardiac cycles
- The Valsalva maneuver is performed by forceful expiration (about 40 mm Hg) against a closed nose and mouth, producing a complex hemodynamic process involving four phases. It helps to identify pseudonormal mitral inflow and irreversible restrictive flow. A decrease in E/A ratio more than or equal to 0.5 is the criterion (Figs. 34 and 35).

In cardiac patients, a decrease of more than or equal to 50% in the E/A ratio during Valsalva maneuver is highly specific for increased LV filling pressures, but a smaller magnitude of change does not always indicate normal diastolic function.

No change in restrictive flow is an ominous sign.²¹

MITRAL ANNULAR VELOCITIES

Diastolic tissue velocities measured at the mitral annulus show low-velocity deflections during early filling (e') and with atrial contraction (a') with great clarity.^{22,23} These indicate biphasic longitudinal expansion rate of the LV (Fig. 36).

- e' is presumed to correlate closely with LV relaxation indexes and to be relatively preload insensitive
- Similar to mitral E flow, e' appears to be age dependent
- Mitral flow E depends on LA pressure, residual LV relaxation pressure, and age and because e' is presumed to depend only on LV relaxation pressure, dividing E by e' eliminates LV relaxation pressure and age, so the E/ e' ratio becomes a noninvasive estimate of LA pressure (Fig. 37)
- Septal and lateral mitral annular e' velocities differ. Recent guidelines for the detection of diastolic dysfunction recommend use of an E/ e' value that is the average of septal and lateral mitral annular e' and more than or equal to 14 being abnormal
- A value of medial E/ e' more than or equal to 15 is usually proposed as evidence for elevated LV filling pressure and a value of E/ e' less than 10 as evidence for normal LV filling pressure
- There is a wide range of E/ e' values^{10–14} for which additional investigations are required to obtain a LV filling pressure estimate (Fig. 38)
- Technical limitations include angle dependency, signal noise, signal drifting, spatial resolution, sample volume, and tethering artifacts
- e' can be decreased erroneously by mitral annular calcification, surgical rings, or prosthetic valves
- An average of septal and lateral E/ e' more than or equal to 14 is suggestive of elevated filling pressures

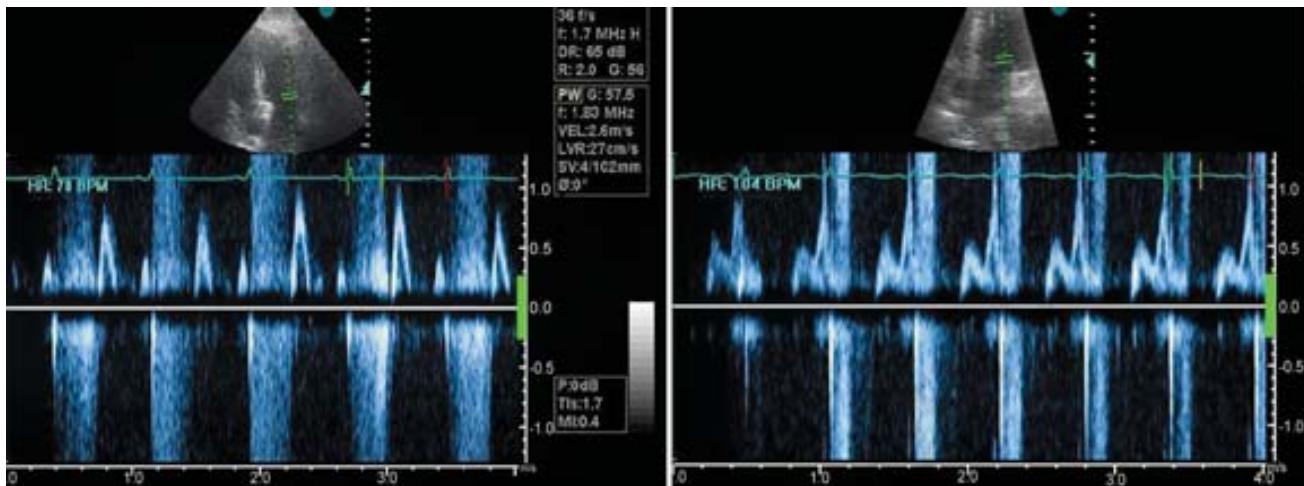

FIG. 34: Valsalva maneuver changing restrictive flow pattern (left panel) to pattern of impaired relaxation (right panel).

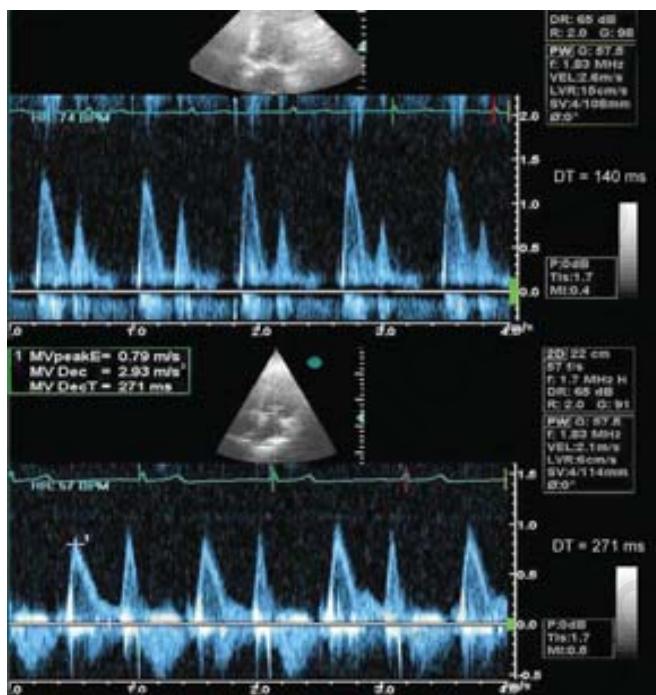

FIG. 35: Effect of Valsalva. Upper panel shows restrictive flow pattern which changes to pseudonormal pattern with an L-wave at the end of Valsalva maneuver.

- A reduced s' velocity is an indirect index of diastolic dysfunction because there is a close correlation between longitudinal systolic function and early diastolic function. However, discordance is quite common
- In healthy young individuals, septal e' is more than or equal to 10 cm/s and lateral e' more than or equal to 15 cm/s at rest. But there are vendor-dependent variations
- e' less than 5 cm/s in cardiac disease is reflection of advanced diastolic dysfunction
- E/e' may not work well in patients with severe mitral regurgitation, intraventricular conduction delay, or pacemaker.

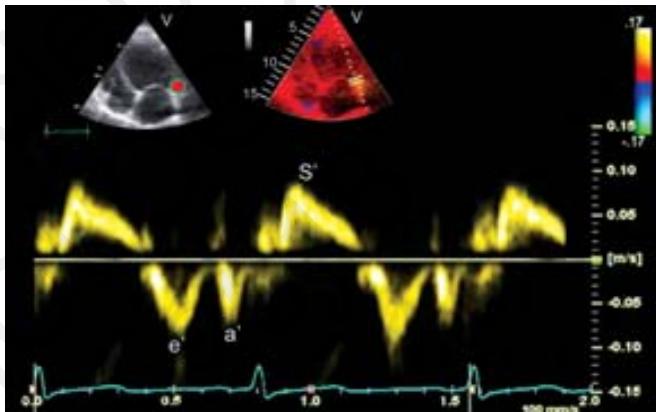

FIG. 36: Annular tissue velocities from lateral edge of the mitral annulus. See text for description.

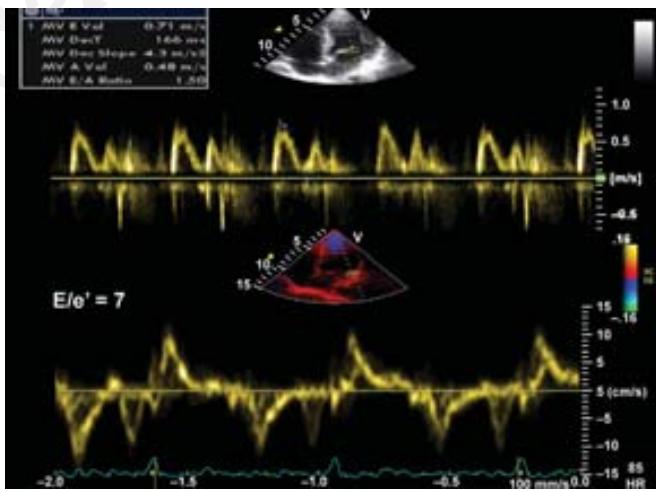

FIG. 37: Upper panel shows mitral inflow pattern and the lower panel depicts annular velocities from the lateral edge of the mitral annulus. An E/e' of 7 indicates normal diastolic function as the e' is 10 cm/s.

How to obtain annular tissue velocities?

- Pulsed-wave DTI is performed in the apical views to acquire mitral annular velocities

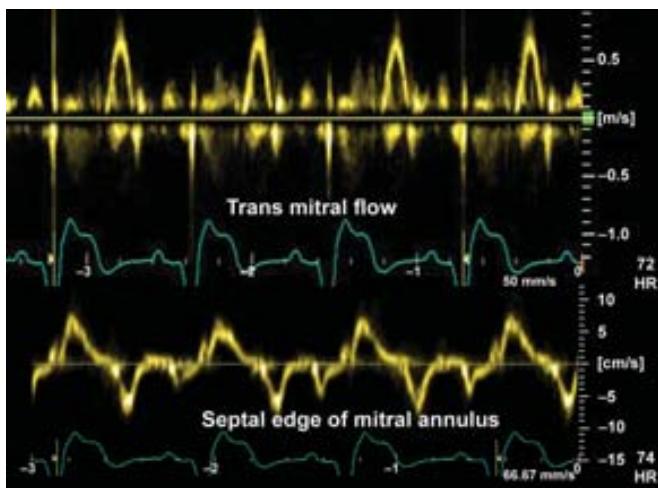

FIG. 38: Upper panel shows restrictive transmитral flow and the lower panel shows annular velocities of septal edge of the mitral annulus. An E/e' ratio of 10 falls in indeterminate zone.

- The sample volume should be positioned at or 1 cm within the septal and lateral insertion sites of the mitral leaflets
- It is recommended that spectral recordings be obtained at a sweep speed of 50–100 mm/s at end-expiration and that measurements should reflect the average of more than or equal to three consecutive cardiac cycles
- Primary measurements include the systolic (s), early (e'), and late (a') diastolic velocities
- For the assessment of global LV diastolic function, it is recommended to acquire and measure tissue Doppler signals at least at the septal and lateral sides of the mitral annulus and their average
- In patients with cardiac disease, e' can be used to correct for the effect of LV relaxation on mitral E velocity, and the E/e' ratio can be applied for the prediction of LV filling pressures
- The E/e' ratio is not accurate as an index of filling pressures in normal subjects or in patients with heavy annular calcification, mitral valve disease, and constrictive pericarditis
- Presence of tissue Doppler wave during diastasis (l') is suggestive of diastolic dysfunction (Fig. 39)
- Higher accuracy of a single-cycle E/e' ratio in predicting mean wedge pressure in patients with AF using a dual Doppler echocardiographic probe has been shown
- Strain rate during IVRT has good correlations with the time constant of LV relaxation and $-dP/dt$ and is not affected by changes in preload. Strain rate can be obtained by tissue velocity imaging.²⁴

PRACTICAL TIPS

- In presence of normal or pseudonormal mitral flow pattern, an E/e' ratio more than or equal to 15 obtained from either edge of the mitral annulus suggests diastolic dysfunction and possibly elevated filling pressures (Fig. 40)
- In long-standing disease, An E/e' ratio may not accurately reflect the magnitude of filling pressures but may be indicative of stiff LV (Fig. 41)

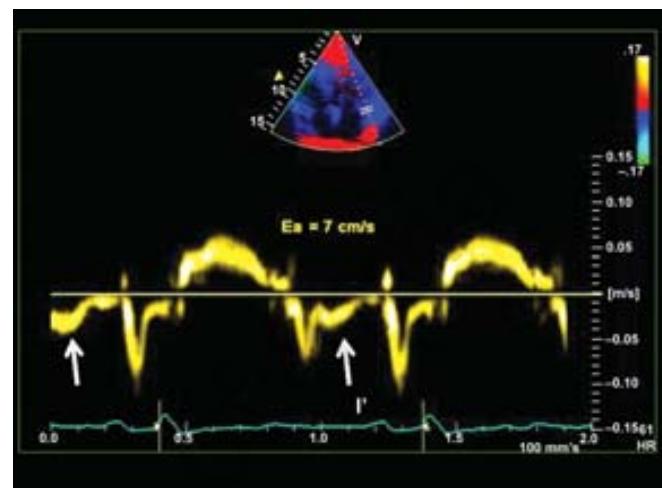

FIG. 39: Lateral edge mitral annular velocities showing l' (arrow). Diastolic dysfunction is also suggested by e' less than a'.

- Greater utility of E/e' lies in patients with systolic dysfunction as compared to those with pure diastolic dysfunction
- In relatively younger patients, this ratio has greater predictive value for filling pressure and symptoms (Fig. 42). However, it is not wise to predict filling pressures from E/e' although one may get into the right ball-park (Fig. 43)
- If E/e' does not clearly indicate presence of diastolic dysfunction, an e'/a' ratio less than 1 can be used along with other data (Fig. 44)
- In elderly people, all normal-appearing mitral flow patterns cannot be regarded as pseudonormal. An E/e' may help define the degree of normalcy (Fig. 45)
- Fusion of mitral E- and A-waves may make E/e' calculation difficult (Fig. 46). Fusion occurs in several conditions listed here:
 - Sinus tachycardia
 - Prolonged PR interval
 - Intraventricular dyssynchrony
 - Advanced diastolic dysfunction.
- In many disease states, postsystolic tissue waves may mask tissue e', making it difficult to estimate E/e' ratio (Fig. 47)
- Annular postsystolic positive waves may convert severe diastolic dysfunction to mild by virtue of changing transmитral flow pattern (Fig. 48)
- An E/e' ratio may not be reliable in presence of AF, sinus bradycardia, and first-degree AV block (Fig. 49)
- Left ventricular diastolic function can be deciphered through the evaluation not only of the relationship of the amplitude of E to e' but also by evaluating the relationship of the timing of the onset of E to the onset of e'. Normally, mitral inflow is initiated with rapid LV relaxation and suction of blood into the LV. When this occurs, the onset of e' will be slightly before or simultaneous with the onset of E.²⁵ If, however, LA pressure is elevated and LV relaxation reduced, E velocity onset may precede the onset of e' (Fig. 50). These timing relationships have been correlated with LV filling pressure.

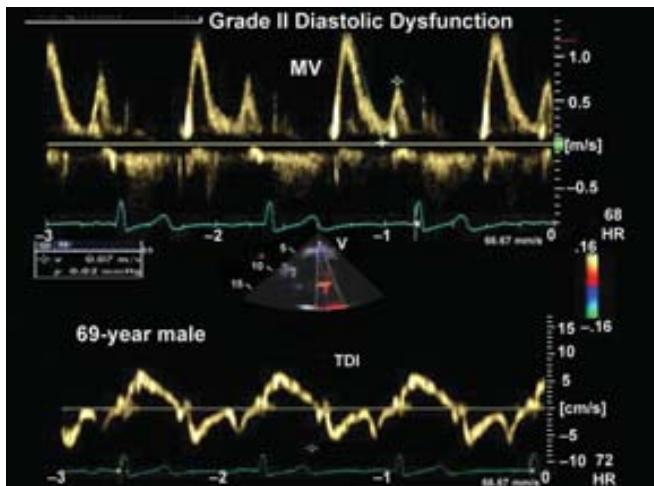

FIG. 40: Upper panel shows mitral E of 130 cm/s and the lower panel shows septal edge e' of 7 cm/s. An E/e' ratio is 19, indicating grade II diastolic dysfunction.

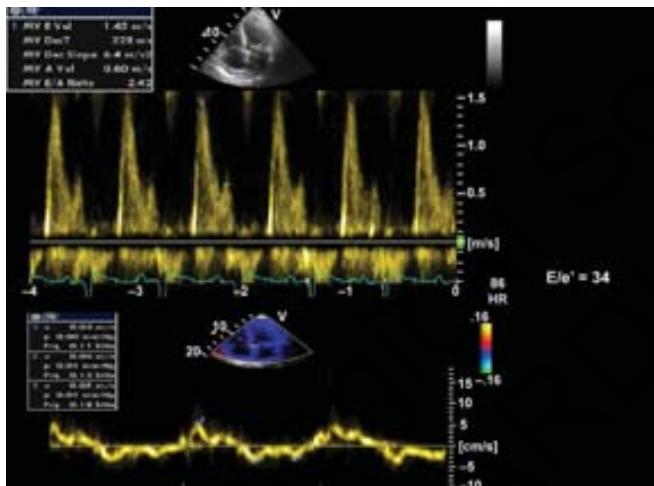

FIG. 41: Upper panel shows transmital flow while the lower panel shows annular velocities at the septal edge in a patient on maintenance hemodialysis. An E/e' ratio of 34 does not necessarily imply very high filling pressures in this otherwise stable patient.

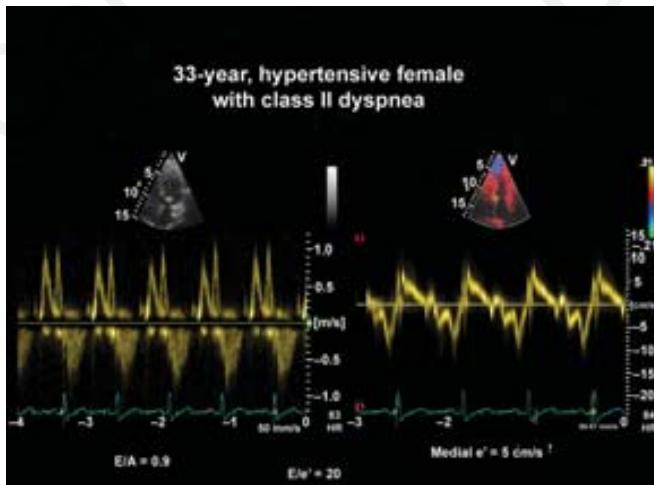

FIG. 42: Left panel shows normal transmital flow while mitral annular velocity at septal margin is 5 cm/s and E/e' ratio of 20 is indicative of elevated filling pressures and most likely cause of dyspnea.

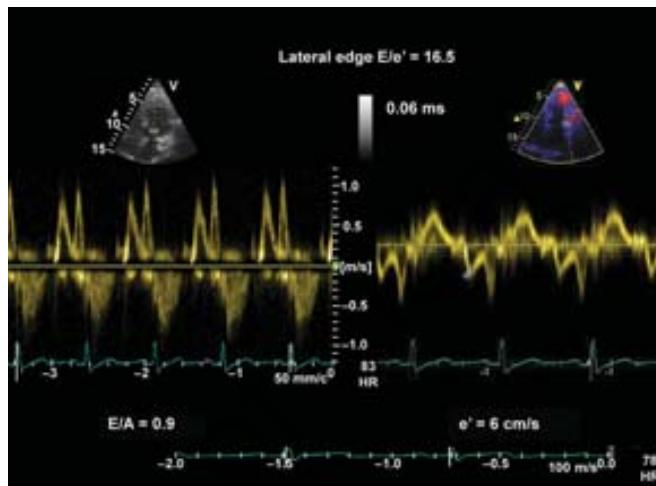

FIG. 43: Same patient as in figure 36. E/e' at lateral margin of the mitral annulus (16.5) is lower than that at the septal margin but is still way above normal. A lateral E/e' more than or equal to 13 is indicating of diastolic dysfunction.

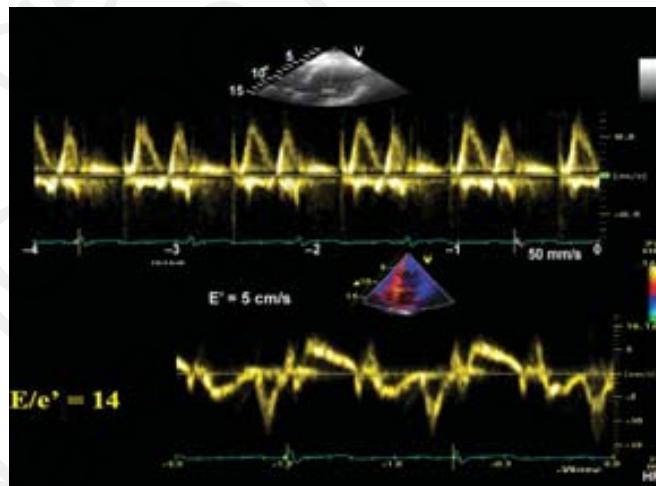

FIG. 44: An indeterminate E/e' ratio from the septal edge is complicated by absolute e' of 5 cm/s and e'/a' ratio less than 1 in suggesting diastolic dysfunction.

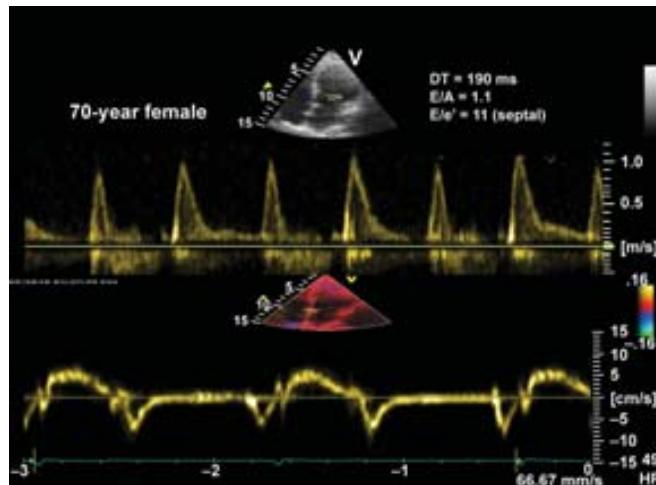

FIG. 45: A 70-year-old healthy woman with normal mitral flow and a septal edge E/e' of 11.

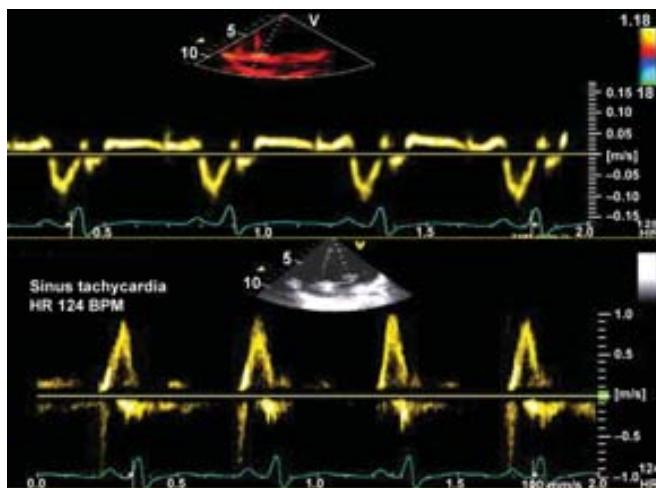

FIG. 46: Imprecision of estimating E/e' ratio due to fusion of mitral E- and A-waves in presence of sinus tachycardia and absence of annular e' wave (upper panel).

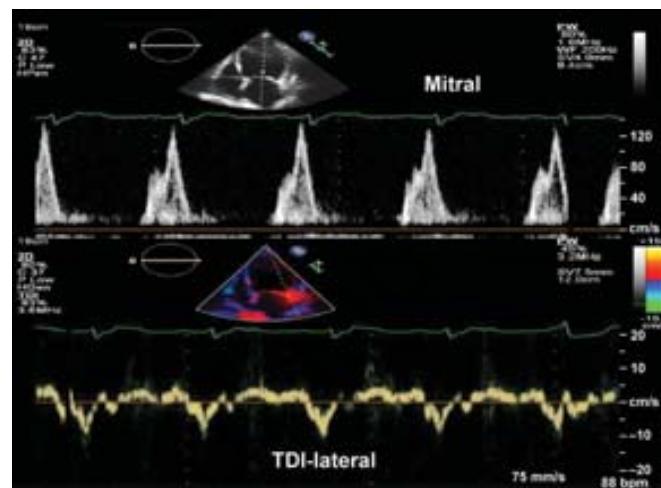

FIG. 48: Impaired relaxation pattern of mitral flow (upper panel) in a patient with advanced heart failure. Postsystolic annular waves extending into mid-diastole (lower panel).

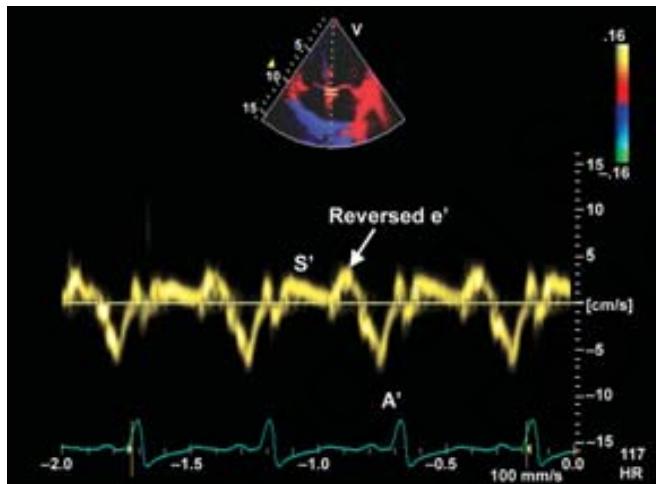

FIG. 47: Postsystolic annular tissue wave masking e'. This could be called reversed e'.

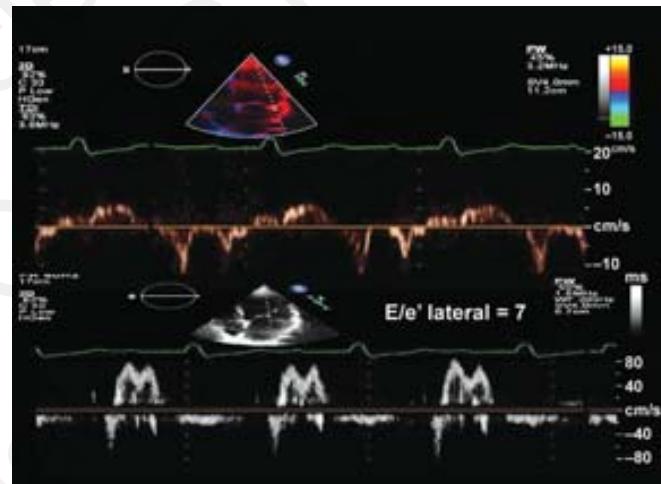

FIG. 49: E/e' ratio of 7 (lateral) in an 84-year-old person with sinus bradycardia, first-degree atrioventricular (AV) block with, and heart failure.

PULMONARY VEIN FLOW AND DIASTOLIC FUNCTION

Pulsed-wave Doppler flow pattern of pulmonary veins shows two over-riding antegrade systolic waves (mostly seen as one, S wave), one antegrade diastolic wave (D), and a retrograde wave during atrial contraction, Ar (Figs. 51 to 53). First S wave is due to atrial relaxation and the second one (S2) due to descent of the mitral annulus during systole.

D wave occurs during opened mitral valve. Ar wave occurs following atrial contraction when blood has option of flowing antegradely into the LV as well as back in pulmonary veins depending upon the relative resistance.²⁶

- The pattern of pulmonary venous flow (systolic vs. diastolic predominance) has been proposed as a predictor of diastolic dysfunction (Figs. 54 and 55). However, diastolic preponderance is invariable in children and young adults
- Ar velocity more than 35 cm/s also indicates raised filling pressures (Fig. 55)

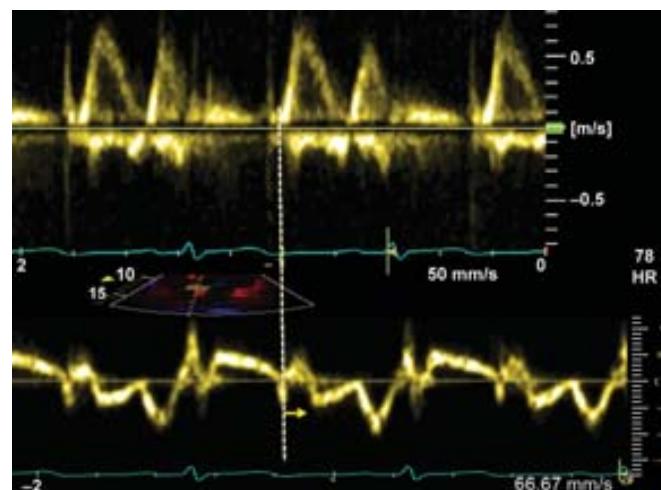

FIG. 50: Mitral E preceding tissue e' in a patient with grade II diastolic dysfunction.

- Comparison of the duration of flow at atrial contraction across the mitral valve (on the mitral inflow velocity curve) and the duration of reversal flow back into the pulmonary veins (on the pulmonary venous velocity curves) has been repeatedly demonstrated to reflect the LV end-diastolic pressure (Fig. 56)
- If the duration of atrial reversal flow in the pulmonary vein exceeds by more than or equal to 30 ms, the duration of flow across the mitral valve, raised LV end-diastolic pressure can be diagnosed with high specificity
- The major limitations to the use of the pulmonary venous signals are that these signals are difficult to obtain and interpret. The technical feasibility of obtaining adequate signals is perhaps less than 80% of unselected patients
- Pulmonary vein flow when interpretable, is used to refining the grades of diastolic dysfunction (Figs. 57 to 60).
- Longer duration of mitral atrial flow compare to that of pulmonary vein atrial flow reversal velocity may be found in grade I diastolic dysfunction besides in normal subjects.

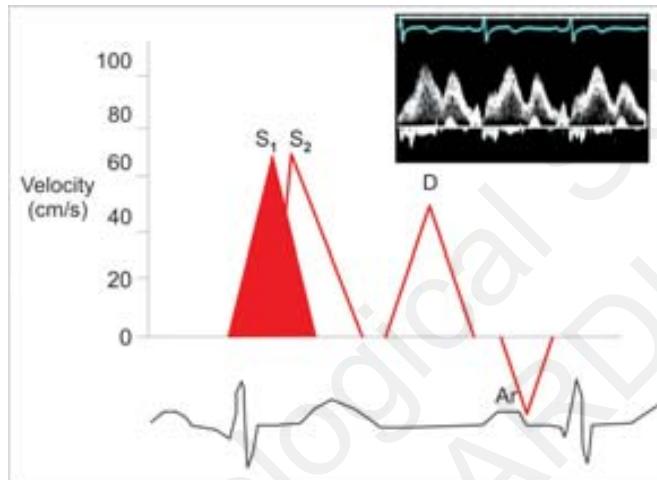

FIG. 51: Pulmonary vein flow pattern in a normal subject. Patients with grade I diastolic dysfunction have similar pattern.

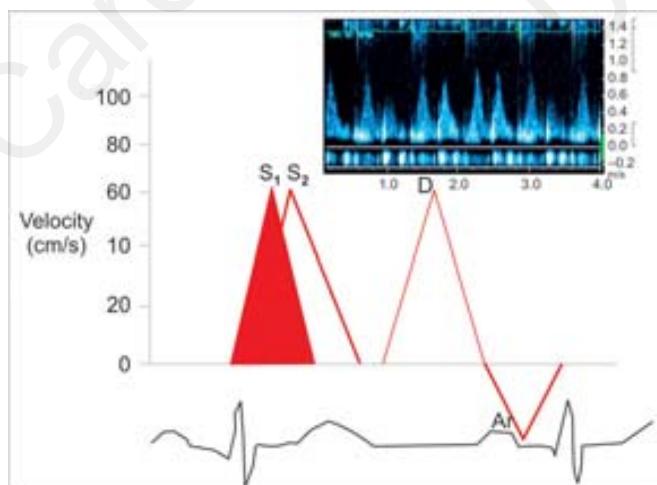

FIG. 52: Equivalent pulmonary systolic and diastolic wave but with prolonged Ar suggestive of diastolic dysfunction.

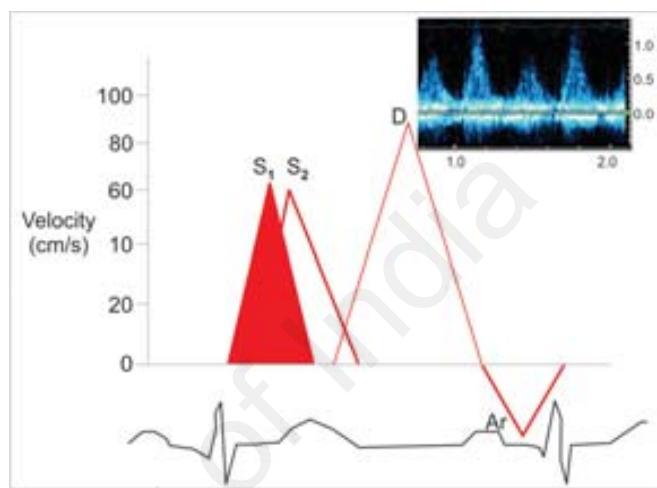

FIG. 53: Graphic representation of pulmonary vein flow in a subject with raised left ventricular (LV) filling pressure. The inset shows the real Doppler spectrum.

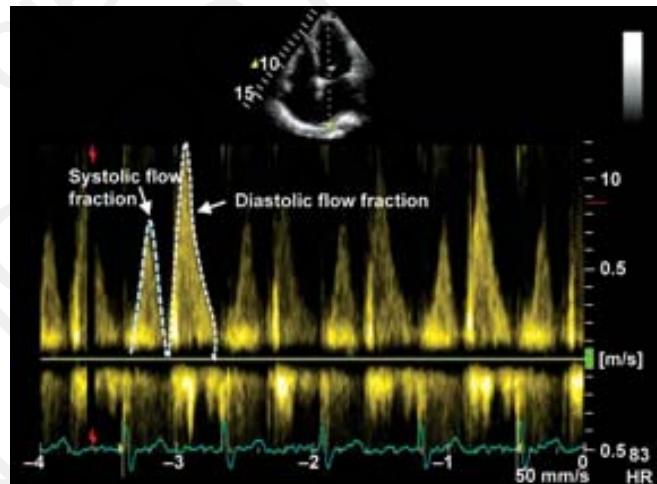

FIG. 54: Right upper pulmonary vein diastolic flow velocity and velocity-time integral is greater than systolic filling fraction in a patient with significant diastolic dysfunction.

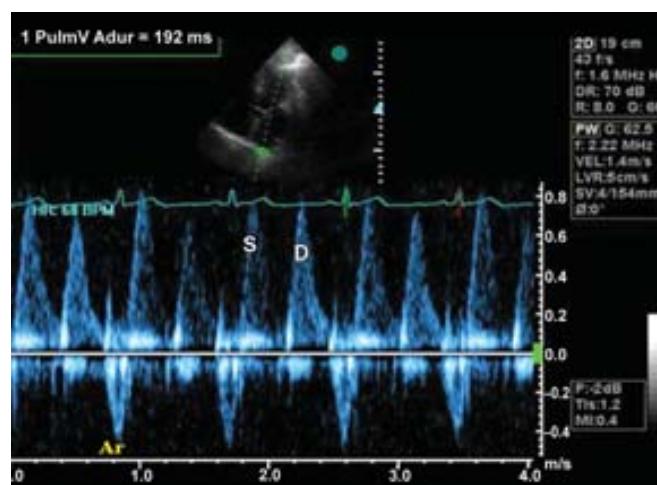

FIG. 55: Right upper pulmonary vein Ar velocity of 50 cm/s indicative of diastolic dysfunction.

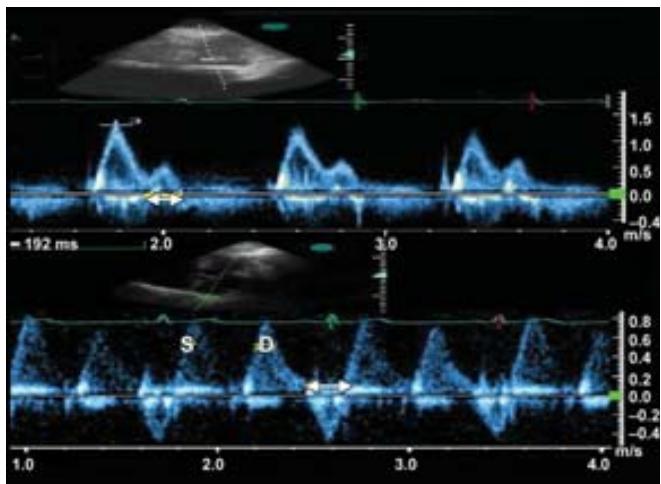

FIG. 56: Ar duration of mitral A more than 30 ms suggestive of elevated end-diastolic pressure.

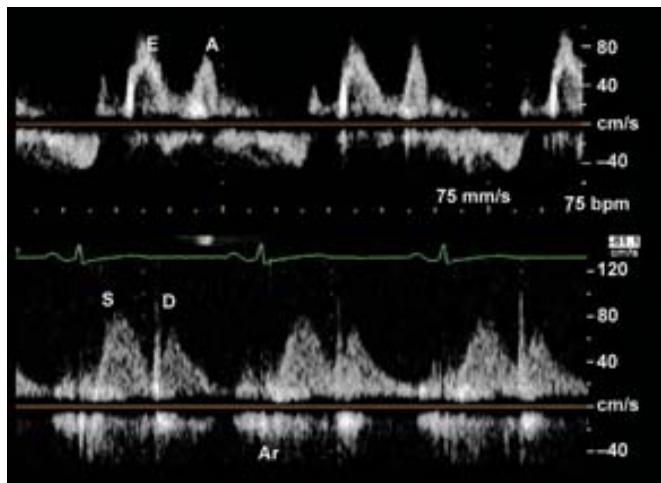

FIG. 57: Upper panel shows mitral flow pattern and the lower panel shows right upper pulmonary flow pattern. In presence of normal-appearing mitral flow, predominant systolic fraction and short Ar indicate that the above pattern is of a normal adult.

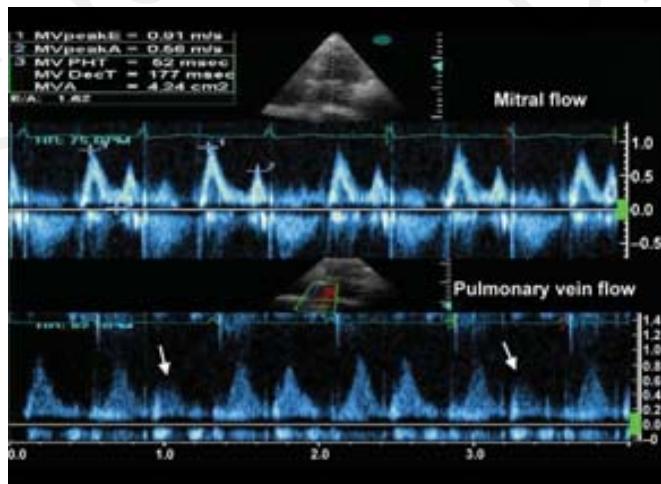

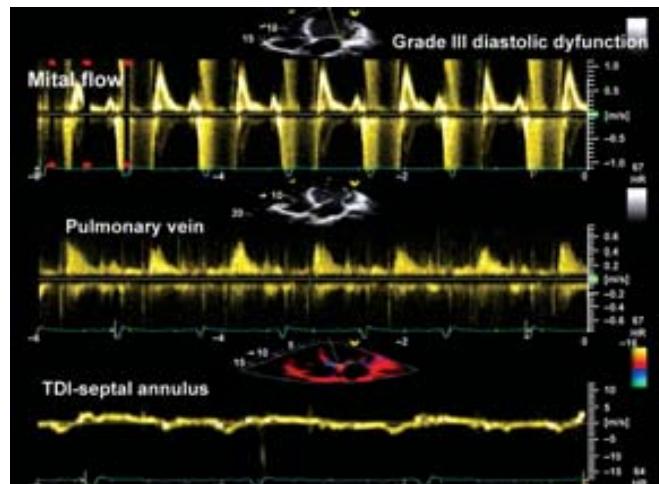

FIG. 58: Equivalent pulmonary venous systolic and diastolic flow fraction (lower panel) but with inspiratory decrease in D-wave (arrow) is suggestive of normal filling pattern.

SHS, systolic heart failure; VT, ventricular tachycardia.

FIG. 59: Upper panel—mitral flow, middle panel—pulmonary flow, and lower panel—septal annular velocities. There is hardly any S-wave in pulmonary vein flow and E/e' of 30 indicating of advanced or grade 3 diastolic dysfunction.

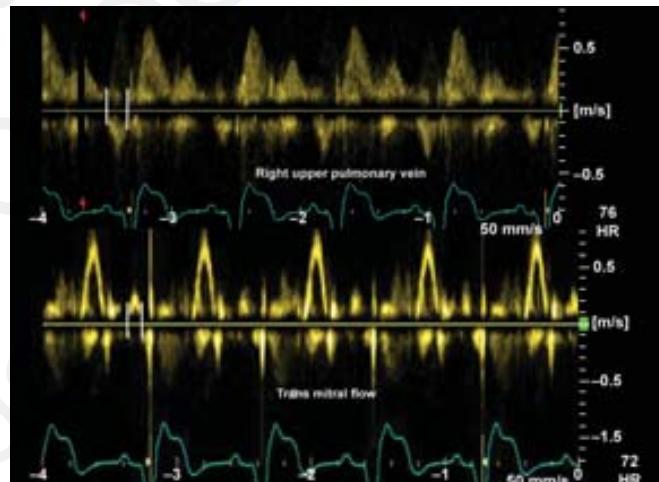

FIG. 60: Upper panel: pulmonary vein flow. Lower panel—transmitral flow. Restrictive transmural flow is negated by normal pulmonary venous flow although Ar is 20 ms longer.

ACQUISITION OF PULMONARY VEIN FLOW SIGNALS

- Color flow imaging is useful for the proper location of the sample volume in the right upper pulmonary vein
- In a majority of the patients, the best Doppler recordings are obtained by angulating the transducer superiorly in such a manner that the aortic valve is visualized
- A 2–3 mm sample volume is placed more than 0.5 cm into the pulmonary vein for optimal recording of the spectral waveforms
- Wall filter settings must be low enough to display the onset and cessation of the atrial reversal (Ar) velocity waveform
- Pulmonary venous flow can be obtained in about 80% of ambulatory patients with an effort though the feasibility is much lower in the intensive care unit setting

- The major technical problem is LA wall motion artifacts, caused by atrial contraction, which interferes with the accurate display of Ar velocity
- Spectral recordings should be obtained at a sweep speed of 50–100 mm/s at end-expiration and measurements include the average of more than or equal to three consecutive cardiac cycles.

PULMONARY VEIN FLOW PARAMETERS

- Measurements of pulmonary venous waveforms include peak systolic (S) velocity, peak anterograde diastolic (D) velocity, the S/D ratio, systolic and diastolic filling fractions, and the peak Ar velocity in late diastole
- Other measurements are the duration of the Ar velocity, the time difference between it and mitral A-wave duration (Ar – A)
- D-wave velocity DT
- There are two systolic velocities (S₁ and S₂), mostly noticeable when there is a prolonged PR interval, because S₁ is related to atrial relaxation. S₂ should be used to compute the ratio of peak systolic to peak diastolic velocity
- S₁ velocity is primarily influenced by changes in LA pressure and LA contraction and relaxation whereas S₂ is related to stroke volume and pulse-wave propagation in the pulmonary arterial tree
- D-wave velocity is influenced by changes in LV filling and compliance and changes in parallel with mitral E velocity
- Pulmonary venous Ar velocity and duration are influenced by LV late diastolic pressures, atrial preload, and LA contractility
- A decrease in LA compliance and an increase in LA pressure decrease the S velocity and increase the D velocity, resulting in an S/D ratio less than 1, systolic filling fraction less than 40%, and shortening of the DT of D velocity, usually less than 150 ms (Fig. 61).
- However, DT of mitral E and pulmonary vein D may not always be concordant as DT of D-wave tends to be nonlinear more often (Fig. 62).

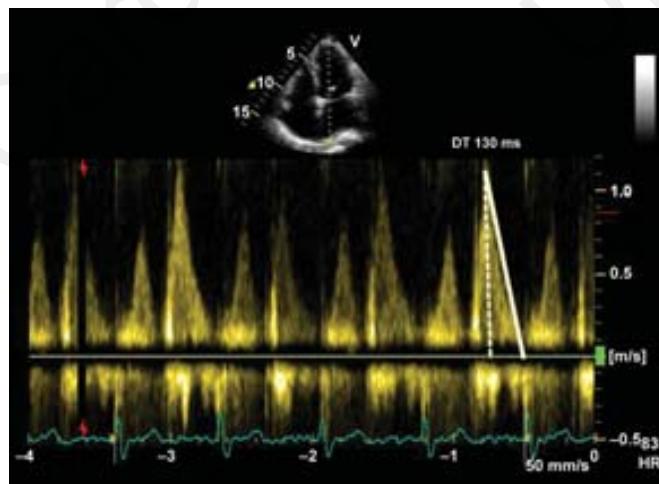

FIG. 61: Pulmonary vein D-wave more than S-wave with deceleration time (DT) of 130 ms indicating elevated left ventricular (LV) filling pressure.

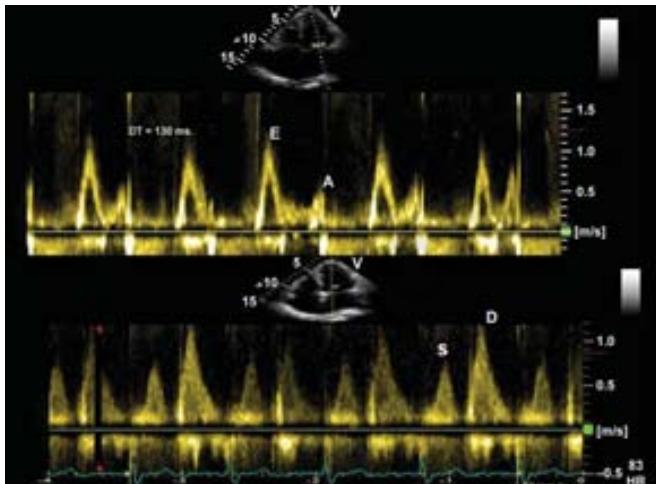

FIG. 62: Upper panel shows short deceleration time (DT) of mitral E while DT of pulmonary vein D is longer (170 ms) and nonlinear.

MITRAL FLOW PROPAGATION BY COLOR M-MODE

Assessment of flow propagation into the left ventricle is another technique that provides better ability to predict filling pressures.^{27–29}

In the normal state, flow rapidly propagates into the LV cavity (Fig. 63). Early-stage relaxation abnormalities show a blunting of flow propagation.

The propagation velocity (V_p) does not show a pseudonormalization and, therefore, can be used in all levels of diastolic dysfunction.

Similar to the tissue Doppler velocities, color M-mode flow propagation has been combined in a ratio with the mitral E velocity to provide an adjusted parameter (E/V_p) with strong correlation to filling pressures and prognosis.

The chief limitations of this tool are lack of consensus on technique and theoretical concerns that this will be invalid in small LV cavities.

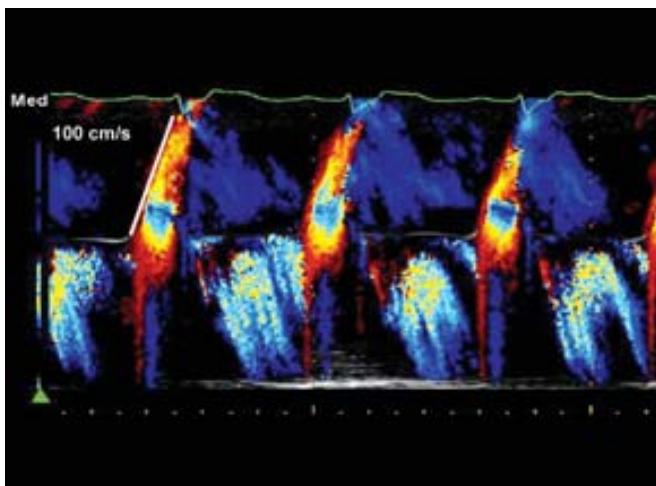

FIG. 63: Mitral flow propagation velocity by M-mode.

Practical Tips

- Acquisition is performed in the apical 4-CV, using color flow imaging
- M-mode scan line is placed through the center of the LV inflow blood column from the mitral valve to the apex, with baseline shift to lower the Nyquist limit so that the central highest velocity jet is blue
- Propagation velocity is measured as the slope of the first aliasing velocity during early filling, measured from the mitral valve plane to 4 cm distally into the LV cavity, or the slope of the transition from no color to color
- Propagation velocity more than 45–50 cm/s is considered normal
- Should other Doppler indices appear inconclusive, an E/Vp ratio more than or equal to 2.5 predicts PCWP more than 15 mm Hg with reasonable accuracy (Figs 64 and 65)
- Patients with normal LV volumes and EFs but elevated filling pressures can have misleadingly normal Vp. Peak velocity of early-diastolic mitral flow Vp has been used as an approximation for ventricular suction.

LONGITUDINAL STRAIN, ROTATION, AND UNTWISTING RATE BY ACOUSTIC SPECKLE TRACKING

- Most patients with diastolic dysfunction have impaired longitudinal strain by acoustic speckle tracking. Impaired longitudinal strain (>15%) is first indication of impaired diastolic function³⁰
- Torsion and circumferential strain are normal in patients with isolated diastolic dysfunction (Fig. 66)
- Assessment of LV torsion has shown that untwisting begins before aortic valve closure and might be an important component of normal diastolic filling²⁹
- Studies in human subjects using indirect indexes derived from right heart catheterization have suggested a relationship between constant of IVR and measures of untwisting
- But the relationship between directly measured diastolic function indexes with micromanometer catheters and

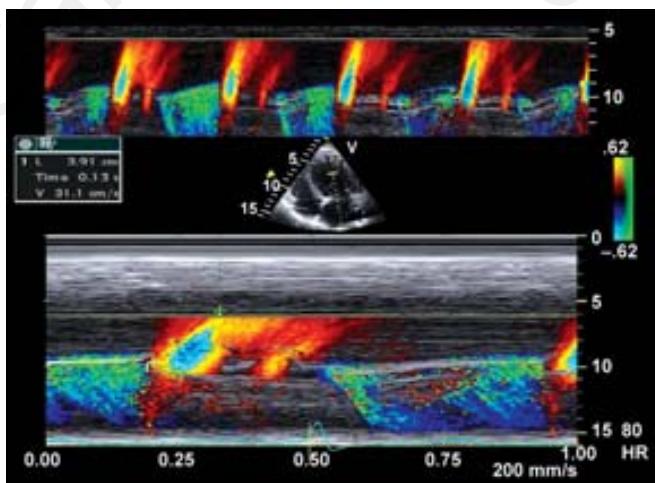

FIG. 64: Propagation velocity (Vp) of 31 cm/s in a patient with heart failure.

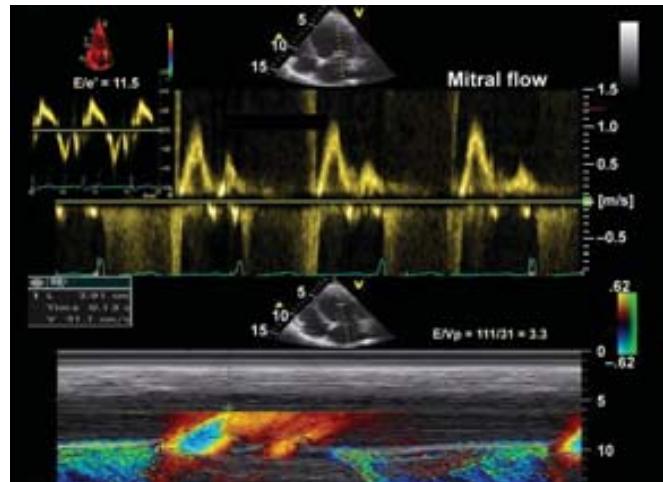

FIG. 65: A 43-year-old female with recurrent pulmonary edema. E/e' of 11.5 (lateral) is inconclusive but E/Vp of 3.3 suggests raised filling pressures.

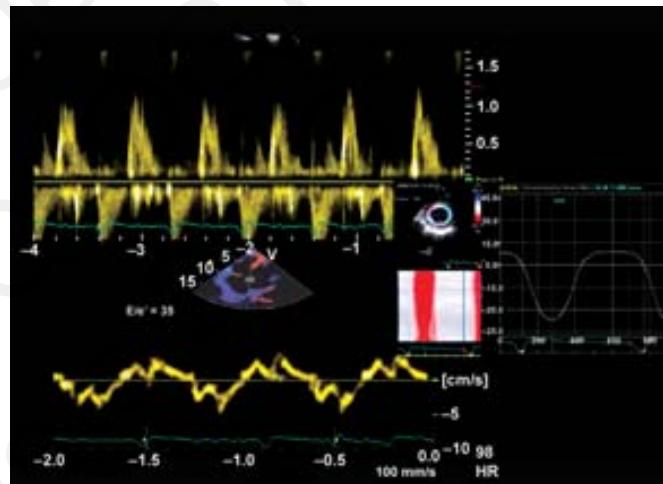

FIG. 66: Normal circumferential strain (right panel) in presence of advanced diastolic dysfunction.

untwisting parameters has not been established in human subjects

- Untwisting parameters are related to invasive indexes of LV relaxation and suction but not to LV stiffness. These data suggest that untwisting is an important component of early diastolic LV filling but not later diastolic events.

DIASTOLIC STRESS TEST

Many patients present with exertional dyspnea but have normal LV filling pressures at rest. In these patients, it is important to evaluate filling pressure with exercise.^{31,32}

Exercise can be performed using a supine bicycle or treadmill protocol. Because most patients have limited functional capacity, the workload starts at 25 W and increases in increments of 25 W every 3 minutes.

We need to record mitral inflow by pulsed Doppler echocardiography at the level of the mitral tips, mitral annular velocities by spectral Doppler echocardiography, and tricuspid regurgitation jet by CW Doppler (Fig. 67).

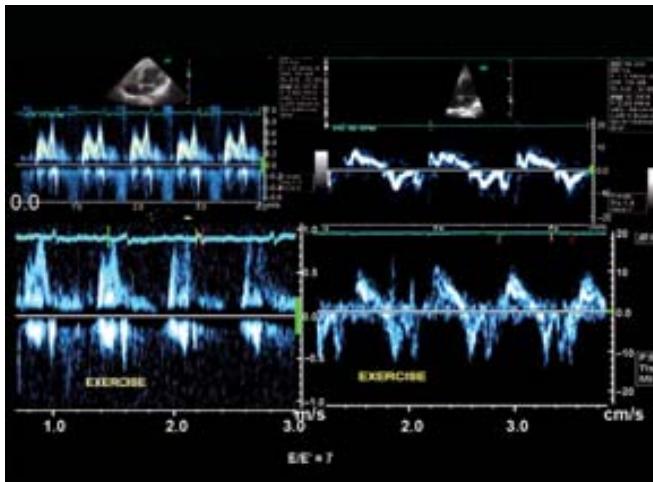

FIG. 67: Diastolic stress test in a normal person. There is proportionate increase in mitral E and e'.

THE NEW GUIDELINES ON DIASTOLIC FUNCTION

The recent guidelines on diastolic function enunciated by the ASE and European Association of Cardiovascular Imaging focus upon four (five) parameters to decide whether diastolic function is normal or abnormal:³³

1. Left atrial volume index ($>34 \text{ mL/m}^2$ being abnormal)
2. Tricuspid regurgitation maximum velocity (abnormal $>2.8 \text{ m/s}$)
3. Average E/e' >14
4. Septal e' ($<7 \text{ cm/s}$ being labeled abnormal)
5. Lateral e' (abnormal if $<10 \text{ cm/s}$).

If less than 50% parameters are abnormal, diastolic function is presumed to be normal. If more than 50% parameters are abnormal, it is considered diastolic dysfunction (Fig. 68). As septal and lateral e' are clubbed as one parameter, then there is possibility of indeterminate diastolic function if only two out of four parameters are present.

Following is the grading of diastolic dysfunction proposed that is given in table 1.

These recommendations have significant advantages, including increased flexibility, with recognition that not all parameters are abnormal in a given case of diastolic dysfunction. These have been validated in some database.^{34,35} Preload dependence, the effects of positive pressure ventilation on mitral inflow velocity, and the angle dependence of tissue Doppler are some of the technical challenges. The relationship between systolic function and myocardial relaxation is such that patients with abnormal systolic function or structural abnormalities must automatically have a degree of impaired diastolic function. Those with normal systolic function need to have impairment of diastolic function detected before subsequent grading of severity, whereas those with abnormal systolic function or structural issues must have impaired relaxation and subsequently can proceed to grading of their diastolic dysfunction.

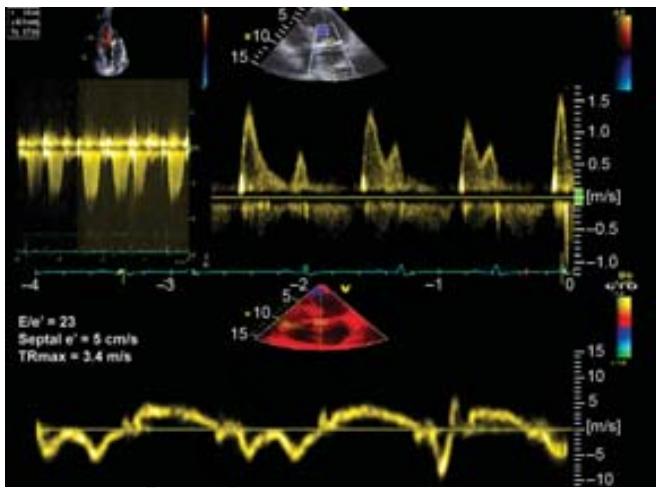

FIG. 68: An 80-year-old male with dyspnea on exertion. Three out of four parameters are abnormal suggesting diastolic dysfunction.

TABLE 1: Grading of diastolic dysfunction

Parameters	Grade 1	Grade 2	Grade 3
Relaxation	Impaired	Impaired	Impaired
Left atrial (LA) pressure	Normal	Elevated	Elevated
Mitral E/A	<0.8	$0.8 - <2.0$	>2.0
E/e'	<10	$10-14$	>14
Trmax (m/s)	<2.8	>2.8	>2.8

CONCLUSION

Doppler echocardiography provides major insights into the pathophysiology of diastolic LV dysfunction. So far, however, no single Doppler echocardiographic index of diastolic LV dysfunction has been shown as a robust criterion for elevated LV filling pressures. A stepwise strategy with sequential use of multiple Doppler echocardiographic indexes reduces diagnostic sensitivity because it frequently leads to an indeterminate outcome. A multiparametric approach with age, LA volume, and clinical situation in mind are the best way of using echocardiography in detection of diastolic dysfunction because it is so complex and dependent upon multitude of variables (Fig. 69). Because of these persistent shortcomings, clinicians should continue to make critical use of current Doppler echocardiographic estimates of LV filling pressures and should not hesitate to implement invasive investigations to confirm their clinical suspicions.^{34,35} Guidelines for assessing diastolic function by echocardiography are continually being updated. There is reasonable agreement in estimating diastolic function grade and LA pressure using current guidelines but accuracy is not guaranteed. Further refinements in the definition of mild and moderate dysfunction may improve agreement. There are a number of limitations to these measurements, including the need for high-quality signals, adequate flow visualization in the apical views, experience in acquisition and analysis, impact of PR interval, and heart rate, etc.

Echocardiographic Assessment of Right Ventricular Function

K Tamilselvan, R Alagesan

INTRODUCTION

Echocardiography is an important tool to evaluate heart chambers. Lack of well-established data coupled with excessive focus on left ventricle (LV) had resulted in lack of interest in detailed right ventricular (RV) echocardiographic study for quite some time. However, for the past two decades, evaluation of RV function is being increasingly recognized, as RV dysfunction is linked to prognosis of many conditions like coronary artery disease, pulmonary hypertension, and congenital heart disease. It is also a very powerful independent predictor of morbidity and mortality in patients with advanced heart failure requiring implanted LV assist devices and heart transplantation.

ANATOMICAL AND PHYSIOLOGICAL BASIS FOR RIGHT VENTRICULAR ECHOCARDIOGRAPHY

Right ventricular differs from LV structurally, as LV has no infundibulum and fewer trabeculation. Ventricular wall thickness and mass is lower in RV in comparison to LV. Orientation of myofibers is different as RV has only two layers, middle layer being absent. Subendocardial fibers orientation is similar in both ventricles but subepicardial fibers course obliquely in LV but circumferentially in RV. Thinner walls and prominent trabeculations due to distinct embryologic origin and hemodynamic environment (high-volume, low-pressure system), makes it difficult to characterize the walls.¹ While LV adapts better to pressure overload states, RV is suited for better adaptation to volume overload state. Both anatomical and physiological differences between the two ventricles play key roles in technical differences observed during echocardiography.

Right ventricular is triangular in the transverse plane and crescentic in the coronal plane and inflow portion of RV is perpendicular to outflow tract so that both segments are not situated in the same plane. This complex geometry prevents

direct imaging of the entire RV in a single view, requiring as many views as possible for accurate assessment.²⁻⁴ In addition to this complex three-dimensional (3D) geometry, accurate RV assessment by echocardiography is often a difficult job for the sonographers due to paucity of well-defined anatomical landmarks.

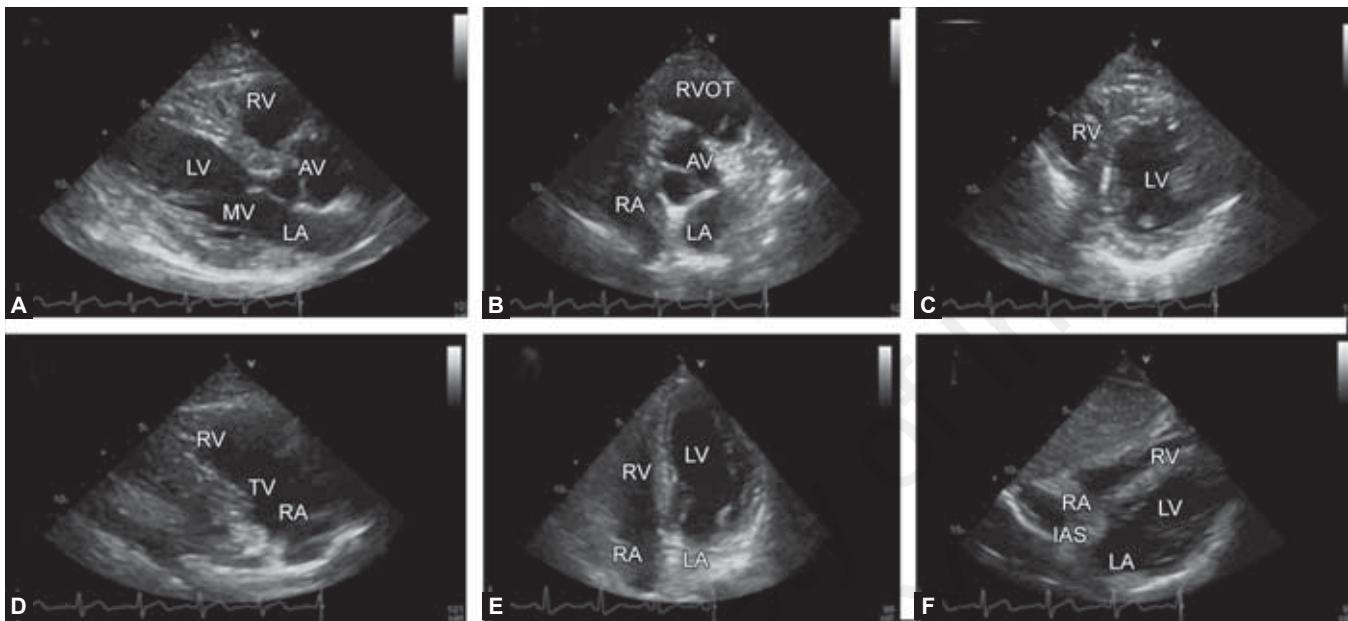

Other factors which interfere in RV assessment include the marked load dependence of RV function indices, complex contraction-relaxation pattern among the different segments of the RV, ill-defined endocardial borders due to markedly trabeculated RV and the unfavorable retrosternal location of the RV, which limits optimal imaging views.

According to the American Society of Echocardiography (ASE) guidelines, a comprehensive 2DE evaluation of the RV needs the six standardized views: parasternal long-axis (PLAX), parasternal RV inflow, parasternal short-axis (PSAX), apical four-chamber (A4C), RV-focused A4C, and subcostal views (Fig. 1). A systematic RV assessment involves evaluation of shape, thickness, area, volume, tissue characterization, and its systolic and diastolic function.

RIGHT VENTRICULAR CHAMBER DIMENSIONS ASSESSMENT

The RV consists of inflow region, RV apex and outflow tract. In the usual A4C view the LV is in the center and RV inflow tract is visualized, and the RV apex is not visualized. From this view the transducer is moved little laterally to visualize the entire RV and this view is called the RV focused A4C view. The inflow tract measurements and fractional area change are measured from this view. In addition, in this view the RV free wall is parallel to the ultrasound beam making it the best view for measuring tricuspid annular plane systolic excursion (TAPSE), tissue Doppler imaging (TDI), and tricuspid regurgitation (TR) velocity.

The diameters measured are RV basal diameter close to the tricuspid annular plane from inner border of RV free wall to the inner border of interventricular septum (IVS), mid-RV

AV, atrioventricular; IAS, interatrial septum; LA, left atrium; LV, left ventricular; MV, mitral valve; RV, right ventricular; RVOT, right ventricular outflow tract; TV, tricuspid valve.

FIG. 1: Views for assessment of right ventricular (RV) function. **A**, Parasternal long-axis view; **B**, Parasternal short-axis view atrioventricular level; **C**, Parasternal short-axis view papillary muscle level; **D**, Parasternal RV inflow tract view; **E**, Apical four-chamber view; **F**, Subcostal four-chamber view.

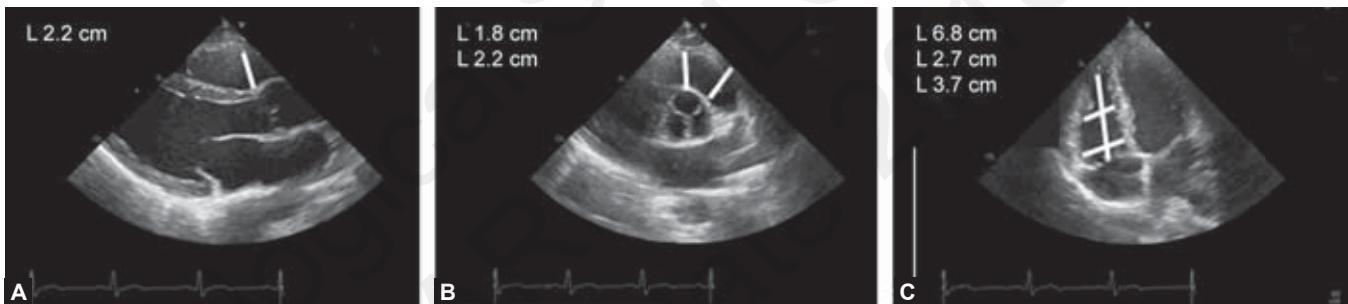

FIG. 2: **A**, Proximal right ventricular (RV) outflow tract; **B**, Proximal and distal RV outflow tract; **C**, RV inflow tract major and minor axis.

diameter at the middle of RV at the level of papillary muscles and RV long-axis diameter from the tricuspid annulus to the RV apex. The diameters of proximal right ventricular outflow tract (RVOT) can be measured in PLAX view from anterior RV wall to septal-aortic junction. In PSAX view, distal RVOT at the level of pulmonary annulus can be measured (Fig. 2). All these measurements are taken at end diastole without oblique cuts.

While RV linear diameters are measured in end diastole, area measurements should be measured in end diastole and end systole. While trabeculations and papillary muscles are included in RV volume measurement, they should be ignored during RV thickness measurement. Normal reference values are summarized in table 1.

RIGHT VENTRICULAR ANTERIOR WALL THICKNESS ASSESSMENT

Guidelines recommend that RV thickness should be measured in the subcostal four-chamber view at the level

of the chordae tendineae usually opposite to the tip of the anterior tricuspid valve (TV) leaflet when fully open, at end diastole during apnea, avoiding echo dense epicardial fat and trabecula. Subcostal four-chamber view does not have the problem of near field artifacts.

ASSESSMENT OF RIGHT VENTRICULAR HEMODYNAMICS

Evaluation of right ventricle hemodynamic data involves both afterload and preload assessment which include measurement of systolic pulmonary artery pressure (SPAP), mean pulmonary artery pressure (MPAP), diastolic pulmonary artery pressure (DPAP), pulmonary vascular resistance (PVR), and assessment of filling profiles. Both volume loading and pressure loading effects on right ventricle can be assessed by looking at the IVS. In pressure overload the IVS is flat during systole and diastole making the ventricle D shaped whereas the IVS is flat only during diastole in volume overload. Right atrial pressure is estimated from measuring

the size of the IVC during inspiration and expiration and calculating percentage change in IVC dimension during respiration. When the respiration is shallow the patient is asked to sniff and the change in IVC dimension is assessed (Table 2). Other secondary indices include restrictive filling pattern, $e/e' > 6$ and systolic filling fraction $>55\%$ in hepatic venous flow Doppler spectrum.

Estimation of systolic and diastolic and MPAP is derived from peak TR and pulmonary regurgitation velocities (Table 3).

Estimation of PVR adds prognostic information on

top of the diagnostic information gained from MPAP. Various methods had been suggested to estimate PVR noninvasively, especially by echocardiography. Peak TR velocity/RVOT velocity time integral (VTI) >38 provided a specificity of 100% for a PVR of >8 Wood units. In children, the ratio isovolumetric relaxation time (IVRT) to RV ejection time (RVET) correlated well with PVR, with IVRT/ET <0.3 being 97% specific for a PVR <3 Wood units. PVR calculated by cardiac catheterization is far superior than echocardiographic estimation of PVR.

TABLE 1: Normal values for right ventricular chamber dimensions and volumes

Linear dimensions	Normal range (mm)	
RV basal diameter	25–41	
RV mid diameter	19–35	
RV longitudinal diameter	59–83	
RVOT PLAX diameter	20–30	
RVOT distal diameter	17–27	
RV wall thickness	1–5	
Volumetric data	Normal range(area in cm^2/m^2 , volume in mL/m^2)	
	Men	Women
RV end-diastolic area indexed to BSA*	5–12.6	4.5–11.5
RV end-systolic area indexed to BSA	2.0–7.4	1.6–6.4
RV end-diastolic volume indexed to BSA	35–87	32–74
RV end-systolic volume indexed to BSA	10–44	8–36

*Indicates body surface area.

PLAX, parasternal long-axis; RV, right ventricular; RVOT, right ventricular outflow tract.

TABLE 2: Estimation of right atrial pressure

Parameters	Estimated RA pressure
IVC diameter <2.1 cm that collapses $>50\%$ with a sniff	RA pressure of 3 mm Hg (range, 0–5 mm Hg)
IVC diameter >2.1 cm that collapses $<50\%$ with a sniff	RA pressure 15 mm Hg (range, 10–20 mm Hg)
IVC size and IVC collapse does not fit into the above categories	RA pressure 8 mm Hg (range, 10–15 mm Hg)

IVC, inferior vena cava; RA, right atrial.

TABLE 3: Estimation of hemodynamic indices by echo*

Parameters	Formula
Systolic pulmonary artery pressure	$4 (\text{TR Vmax})^2 + \text{right atrial pressure}$
Systolic pulmonary artery pressure in ventricular septal defect (VSD)	$\text{SBP} - 4\text{VSD Vmax}^2$
Systolic pulmonary artery pressure in patent ductus arteriosus (PDA)	$\text{SBP} - 4\text{PDA Vmax}^2$
Diastolic pulmonary artery pressure	$4 (\text{end-diastolic pulmonary regurgitation velocity})^2 + \text{RA pressure}$
Mean pulmonary artery pressure	$4 (\text{early peak pulmonary regurgitation velocity})^2 + \text{RA pressure}$
Mean pulmonary artery pressure	$79 - (0.45 \times \text{pulmonary acceleration time})$
Pulmonary vascular resistance	$\text{IVRT to RV ET ratio}$
	$\text{TR Vmax/VTI } [(RVOT) \times 10] + 0.16$

*In the absence of RVOT obstruction. RA pressure to be calculated as per guidelines

ET, ejection time; IVRT, isovolumetric relaxation time; RA, right atrial; RVOT, right ventricular outflow tract; SBP, systolic blood pressure; TR, tricuspid regurgitation; VTI, velocity time integral.

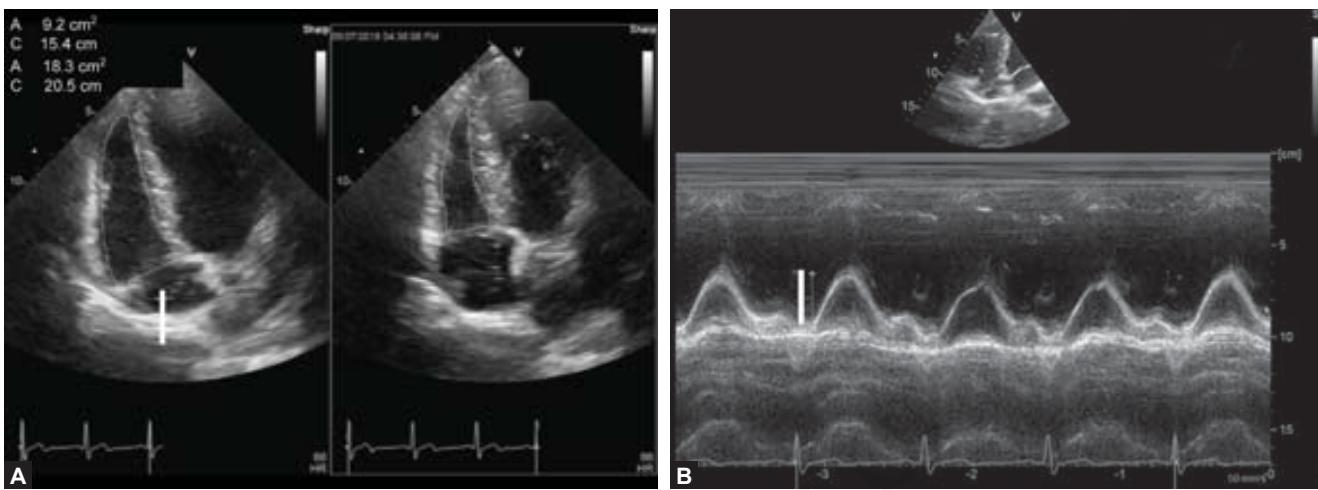

FIG. 3: A, Fractional area change measurement; B, Tricuspid annular planar systolic excursion.

ASSESSMENT OF RIGHT VENTRICULAR SYSTOLIC FUNCTION

Right Ventricular Fractional Area Change

Right ventricular fractional area change was calculated by doing planimetry involving endocardial borders from end-diastolic to end-systolic frames in RV focused A4C view (Fig. 3A). Among other parameters of RV systolic indices, RVFAC correlates well with RV ejection fraction (RVEF) measured by cardiovascular magnetic resonance (CMR).⁵ Though it is not an accurate estimate of RVEF and global RV function, it serves as an independent predictor for mortality after heart failure, MI, and pulmonary embolism. The normal value is 40–56% abnormal cutoff point to predict RV dysfunction, is less than 35% (Table 4).

TABLE 4: Normal values for parameters of right ventricular function

Parameters	Cutoff values for abnormality	
	Cutoff	Range
RV fractional area change (%)	<35%	49 ± 7
TAPSE (mm)	<17	24 ± 3.5
Pulse Doppler MPI	>0.41	0.26 ± 0.085
Tissue Doppler MPI	>0.54	0.38 ± 0.08
Pulse Doppler S'(cm/s)	<9.5	14.1 ± 2.3
Color Doppler S'(cm/s)	<6	9.7 ± 1.85
E-wave deceleration time (m/s)	<119 or >242	180 ± 31
E/A	<0.8 or >2.0	1.4 ± 0.43
e'/a'	0.52	1.18 ± 0.33
e'	<7.8	14 ± 3.1
E/e'	>6.0	4.0 ± 1.0
RV free wall 2D strain (%)	>-20	-29 ± 4.5
3D EF	<44%	58 ± 6.5

EF, ejection fraction; MPI, myocardial performance index; RV, right ventricular; TAPSE, tricuspid annular planar systolic excursion.

Source: Adapted from ASE guidelines 2015

Tricuspid Annular Planar Systolic Excursion

Tricuspid annular planar systolic excursion is the distance travelled by anterior tricuspid annulus from end-diastole to end-systole. It is measured by recording the M-mode by placing the cursor through the anterior tricuspid annulus as parallel as possible to the RV free wall using the zoom with low gain setting at a sweep speed of 75–100 mm/s during apnea (Fig. 3B). The amplitude of movement from end diastole to peak systole is measured in mm TAPSE is angle and load dependent.⁶ It has reasonable correlation with ejection fraction (EF) measured by radionuclide angiography and CMR. Guideline recommends the use of less than 17 mm of TAPSE as abnormal. TAPSE is dependent on the longitudinal contraction of RV and so reflects only partially the status of global RV function, nevertheless TAPSE is an easily obtainable measurement with prognostic value for routine clinical use.⁷

RIGHT VENTRICULAR MYOCARDIAL PERFORMANCE INDEX

The right ventricular myocardial performance index (RVMPI) is load independent unlike majority of other RV systolic function indices, therefore found to be useful in many clinical settings especially volume loading conditions.

Tricuspid valve inflow and pulmonary valve (PV) outflow Doppler tracings are acquired in RV modified A4C view and PSAX view, with low wall filters and 75–100 mm/s sweep speed.⁸ Time duration from the end of A-wave to onset of next E-wave from the tricuspid inflow Doppler tracing that is TV closure to opening time. RVET from the pulmonary Doppler tracing are measured. Isovolumic time is calculated by subtracting the RVET from TV A-wave to E-wave time duration (Fig. 4). And this isovolumetric time is divided by the RVET to get the RVMPI.⁹ Whenever TR jet is holosystolic, the TV A to E time duration can be replaced by measuring the duration of TR jet. Normal reference value for RVMPI is 0.18–0.35 and cutoff value of more than 0.44 indicates RV dysfunction.

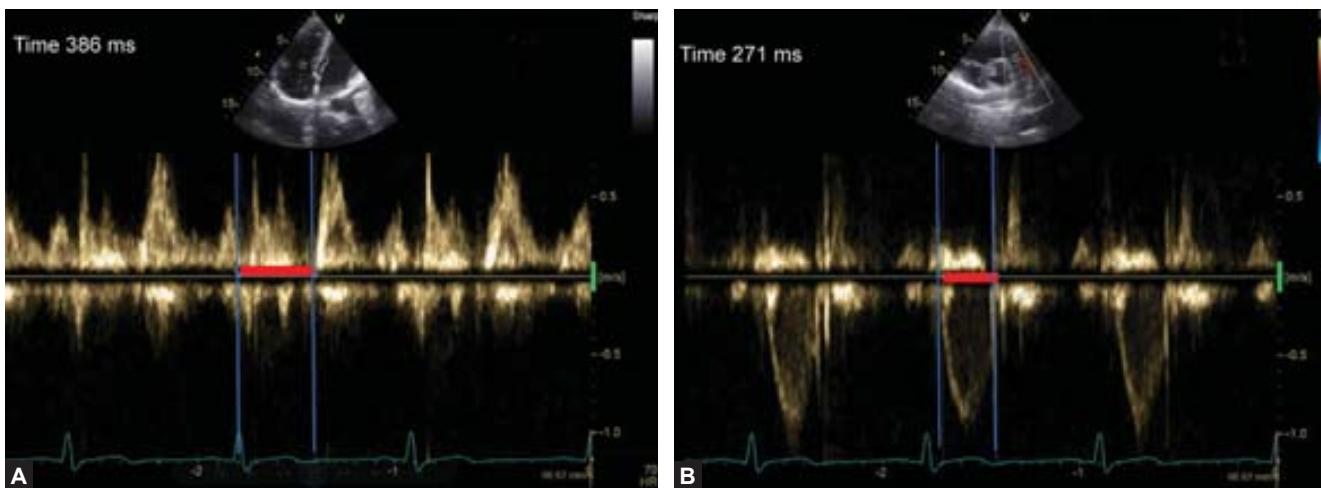

FIG. 4: A, Tricuspid valve closure to opening time; B, Pulmonary ejection time.

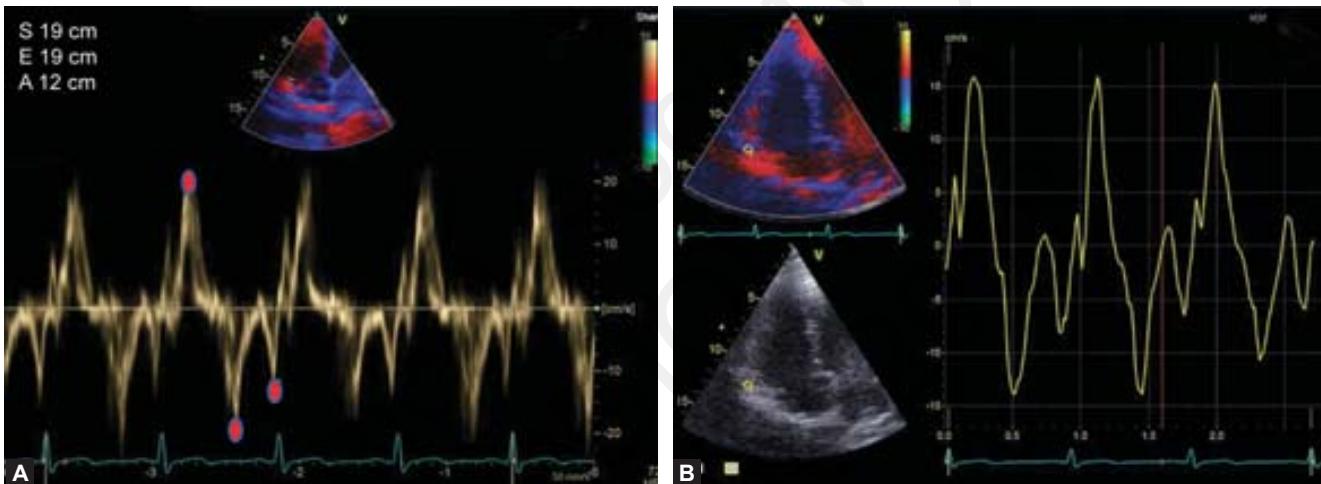

FIG. 5: A, Pulsed tissue Doppler from anterior tricuspid annulus; B, Tricuspid tissue Doppler velocity from color two-dimensional tissue Doppler.

To avoid the variation in RR interval affecting the RVMPI, it can be calculated from pulsed tissue Doppler velocity from anterior tricuspid annulus. The normal value is 0.34–0.46 with a cutoff value of more than 0.54. The RVMPI cannot be relied upon when the right atrial pressure is elevated.

TISSUE DOPPLER IMAGING OF RIGHT VENTRICULAR

Pulsed tissue Doppler velocity of tricuspid annulus is obtained by keeping the Doppler sampling volume over anterior tricuspid annulus. Proper placement of sampling volume, aligning the cursor parallel to the movement of TV annulus, increasing the frame rate by narrowing the sector, and recording during apnea will aid in getting a good tracing. The peak systolic velocity S' , early diastolic velocity E' and atrial systolic velocity A' can be measured (Fig. 5). The normal S' velocity is 12–16 cm/s and the cutoff value is less than 9.5 cm/s for RV dysfunction. The RVMPI also can be calculated from the tricuspid annulus velocity.

The tissue Doppler velocity from tricuspid annulus can be measured offline from two-dimensional (2D) color tissue Doppler recording. The velocities are lower, the normal S' velocity is 8–10.5 cm/s and abnormal cutoff point to predict RV dysfunction, is <6 cm/s by color tissue Doppler imaging and <9.5 cm/s by pulsed TDI (Table 4).¹⁰

Right ventricular structural and functional changes can reduce the peak systolic and diastolic tissue velocities. S' correlated well with mildly reduced RVEF (<50%) but less with markedly reduced RVEF (<30%) by CMR.¹¹

RIGHT VENTRICULAR STRAIN IMAGING

Strain and strain rate imaging are the newer and useful markers to assess RV systolic function. Strain imaging can be performed either with Doppler (TDI) or speckled tracking imaging (STI) method. Measurement of RV strain needs optimal visualization of right ventricle. Higher frame rates (above 50–100 frames/s for STI and 100–150 frames/s for TDI) achieved by narrowing the sector size and decreasing the

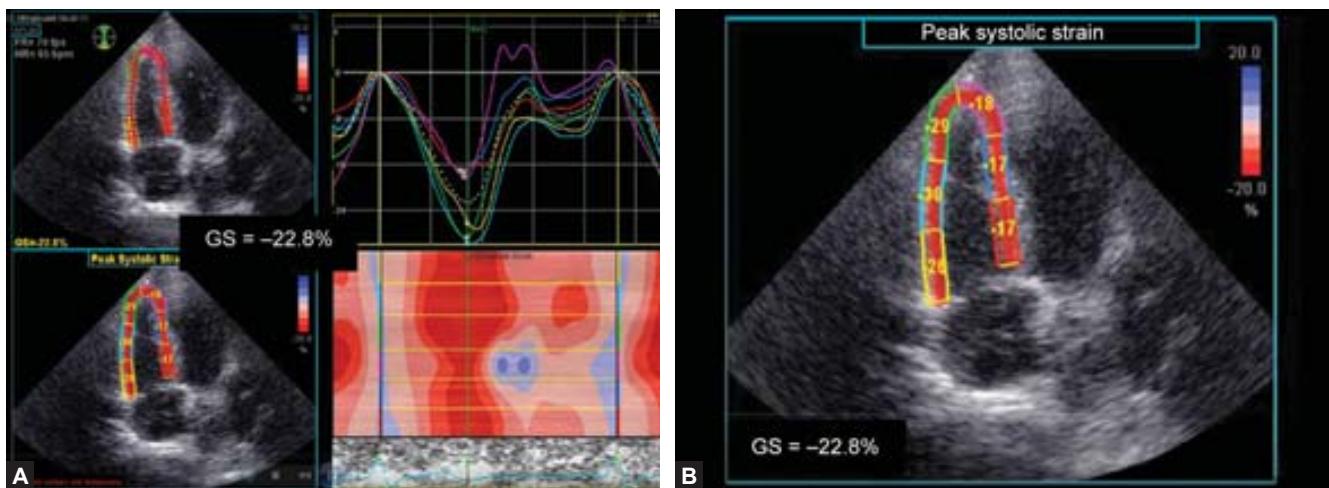

FIG. 6: Speckle tracking derived right ventricular strain. Average of the strain of three segments of free wall.

depth, images are acquired in the RV focused A4C view. Onset of QRS to PV opening is either fed manually or automated. The anterior tricuspid annulus, septal tricuspid annulus and RV apex are marked, the region of interest is reduced to fit the RV wall, the alignment with RV endocardium is checked and the process button is clicked. Peak velocity measured at the end of the T-wave, most often correlates with the peak longitudinal strain. Utilizing six segment methods on the RV-focused A4C view with high frame rates, RV free wall longitudinal strain was computed by averaging segmental peak values. Some authors prefer that the strain from IVS are discarded and only the three values from RV free wall are taken. Averaging the three gives the peak systolic RV strain (Fig. 6).

When compared to tissue Doppler strain imaging, 2D STI has low temporal resolution and dependency on image quality. In addition to the paucity of normative data and insufficient clinical validation, inter-vendor variability, the loss of speckles due to excessive motion of RV lateral wall, and the non-availability of uniform reporting of test parameters are the major limitations of 2D RV speckled tracking. 3D speckled tracking has the potential to overcome the limitations of 2D speckled tracking. However, need for separate software for RV and lower spatial resolution limits its clinical use.

The 2015 ASE/EACVI guidelines state normal values of RV free wall strain, as $-29.0 \pm 4.5\%$ and the cutoff for RV dysfunction is less than -20% (the value in less negative values mean more dysfunction).¹² The RV strain varies from vendor to vendor and has not been standardized.

Right ventricular free wall longitudinal strain showed better correlation with CMR derived RVEF than other systolic function indices.¹³ In patients with pulmonary arterial hypertension it was found that RV longitudinal strain and strain rate correlate well with invasive hemodynamic data and 6-minute walk distance. Moreover, significant gain in RVLS was noted when there was fall in MPAP and PVR after therapy. Kjaergaard J et al. reported the prognostic value of RV strain by Doppler tissue echocardiography in pulmonary

embolism.¹⁴ Rajagopalan et al. showed that TDI strain imaging derived RV dyssynchrony, correlated with SPAP and RV function in heart failure.¹⁵

Three-dimensional echocardiography of right ventricle: Three-dimensional echocardiography (3DE) mitigates the inherent limitations of 2D echocardiography (2DE) in the assessment of RV volumes and function. Live 3DE or multiple beats ECG gated 3DE are used to acquire the right ventricle images. A focused examination or a complete full volume set data are the strategies used depending upon clinical need. Complete 3D transthoracic echocardiogram (3DTTE) examination involves the parasternal, apical, and subcostal views. A complete full volume data collection can be postprocessed and displayed by four methods. They are (1) volume rendering, (2) surface rendering, (3) wireframe, and (4) 2D tomographic slicing.

A full-volume data set consists of standard 2D images in multiple cut planes of the RV sagittal, four-chamber, and coronal views (Fig. 7). These are useful in RV volume calculations and segmental wall motion assessment. Volume rendering provides a 3D visualization of structural abnormalities within the right ventricle like thrombi, masses and septal defects. Surface rendering is useful for measurement of RV volume and EF.

Using the apical long axis of the LV, multiple cuts at various levels of RV can be acquired. The basal, middle, and apical parts of RV are evaluated by these cuts. Anatomical details of right ventricle are evaluated in three axial planes, the A4C view (for RV free wall, septum and apex), the coronal view (for the RV inflow and outflow,) and the RV inflow view (for the right atrium and TV).

A dedicated software guides in identifying the center of the TV and RV apex, and then in dividing the RV into systolic and diastolic planes. Next, RV endocardial borders are traced in the coronal, sagittal, and transverse planes, performing analysis of wall motion during all phases of cardiac cycle. While the apical portion of moderator band is excluded, trabeculations are included in the endocardial border

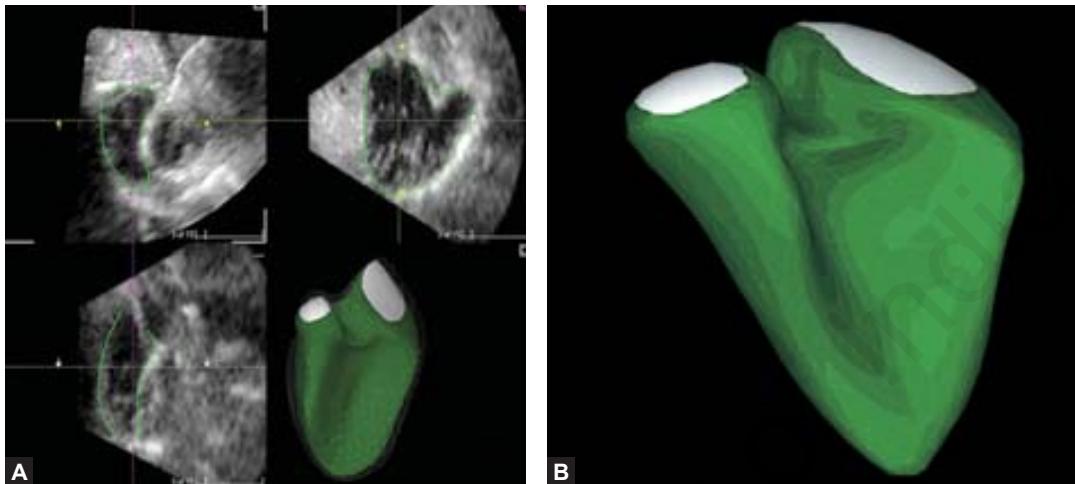

FIG. 7: Three-dimensional reconstruction of right ventricular (RV) inflow tract, RV apex and RV outflow tract from full volume data set.

tracing RV end-diastolic volume, end-systolic volume, stroke volume, and EF are derived. RVOT volume is added by this 3D volumetric method unlike the traditional 2D echo which omits it. This adds accuracy to the 3D volumetric data.^{6,16} The method of disks and volumetric semiautomated border detection approach are used to quantify RV geometry and functions.¹⁷

A good 2DE image quality is must for a better 3DE image quality. Though varying heart rates and breath holding difficulties are some of the limitations, 3DE RV evaluation is increasingly utilized in clinical conditions like congenital heart disease and heart failure. A cutoff value less than 44% of RV EF derived by 3DE indicates RV dysfunction.

ASSESSMENT OF RIGHT VENTRICULAR DIASTOLIC FUNCTION

For right ventricle, pressure and volume are not linearly related. Therefore, correlations between RV filling profiles and chamber dimensions are not well established. RV end-diastolic or right atrial pressures serves as an indirect marker of diastolic properties. Though mean right atrial pressure is calculated in many ways by echocardiography, the tricuspid annular E/e' ratio is useful to estimate right atrial pressure.¹⁸ ASE guidelines suggested grading of RV diastolic dysfunction based on transtricuspid flow velocity and early diastolic tricuspid annulus tissue velocity.

- Grade 1 dysfunction or impaired relaxation (tricuspid E/A ratio <0.8)
- Grade 2 dysfunction (tricuspid E/A ratio of 0.8–2.1) with tricuspid E/e' ratio >6 and
- Grade 3 dysfunction or restrictive filling (tricuspid E/A ratio >2.1 with a deceleration time <120 ms).

Though diastolic function grading of right ventricle lacks clinical data, the role of diastolic dysfunction as a prognostic factor and its importance in diagnosing early RV systolic dysfunction has been validated in clinical studies.

RIGHT VENTRICULAR WALL MOTION ASSESSMENT

Regional wall motion can be assessed by visualizing all the four segments which include anterior, inferior, and lateral walls, with infundibulum as separate entity. Apical four-chamber views allow the visualization of the lateral wall. Other useful views include parasternal RV inflow views for anterior and inferior walls and parasternal short axis view for infundibulum.

In RV myocardial infarction, the wall motion abnormality depends on the culprit vessel. Lateral and inferior wall hypokinesia is seen in proximal right coronary artery disease while isolated anterior wall hypokinesia seen in left anterior descending coronary artery involvement and isolated inferior wall hypokinesia seen in the posterior descending artery.

Regional mid- basal RV free wall hypokinesis with normal contraction of the apical segment (McConnell sign) can be sometimes seen in RV myocardial infarction, it is also very useful in pulmonary embolism. Regional RV akinesia or frank aneurysm in the “triangle of dysplasia” formed by the RV apex, the inferior wall below TV, and infundibulum is specific for arrhythmogenic RV dysplasia.¹

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Evaluation of RV by transesophageal echocardiography (TEE) is less rewarding due to fewer additional information when compared to TTE. However, TEE can be useful in patients with acute pulmonary embolism, during cardiac surgery, patients with poor TTE windows, and in intensive care units.

CONCLUSION

Echocardiography is a very useful tool in RV functional assessment. Traditional methods are less accurate, leading to

the evolving applications of RV echocardiography like speckle tracking and 3DE. Even though the surrogate parameters like fractional area change, TAPSE, RVMPI, and tissue Doppler have issues like angle and load dependency they have been documented to be useful in number of clinical studies. Speckle tracking echocardiography is angle independent, hence it is useful to assess the longitudinal contraction and intraventricular synchrony. For assessment of RV volumes and EF, 3DE is superior.

Right ventricular loading conditions impact heavily on its size, geometry and function. High load dependency of most of the echo parameters is a huge handicap in routine clinical use. Future research should address this serious issue which is increasingly noticed in device therapy in advanced heart failure. A load independent but easy to perform bedside echocardiographic method to accurately estimate RV function, is need of the hour.

Longitudinal Strain Imaging: Is it a Clinical Tool? An Echocardiographic Appreciation

G Vijayaraghavan, S Sivasankaran

INTRODUCTION

Systolic function of the left ventricle (LV) is assessed by the m-mode echocardiography as end-systolic and end-diastolic diameters from which the ejection fraction is calculated.¹ End-systolic dimension has important diagnostic and prognostic value in subjects with ventricular systolic dysfunction.² Ejection fraction calculated from the m-mode is on a presumption that the LV is globular, which is far from the truth.³ American Society of Echocardiography (ASE) no longer recommends measuring the LV ejection fraction from m-mode and advised all echocardiographers to use the two-dimensional (2D) echo biplane Simpson's method or use three-dimensional (3D) echo for LV ejection fraction calculation.⁴ While assessing the regional myocardial function we assess the wall motion, and the terminologies advocated by the ASE are normal, hypokinetic, akinetic, dyskinetic, aneurysmal, or hyperkinetic. Wall motions are assessed by eye balling and require expertise and are purely subjective. We need a more precise measurement of the systolic parameters of LV function.⁵

DEFINITION

As the LV contracts in systole, it shortens in the longitudinal and circumferential direction (negative strain) and thickens in the radial direction (positive strain).⁶ The change in length or thickness could be measured and expressed as a percentage of its diastolic length or thickness which is called the strain or deformation.⁷ Longitudinal shortening is responsible for 60% of the LV ejection and is the most important component of systolic function. This longitudinal shortening varies from -15% to -30% from base to apex.⁸ The circumference of the LV becomes small with systole. This systolic shortening of circumference of LV is circumferential strain which measures to -20% to -30% of its diastolic circumference. LV contraction causes radial thickening in systole. The thickening is measured as a positive strain of +30% to +60%.⁹ In the short-axis view during LV systole basal segments of the LV rotates in

an overall clockwise direction and apex rotates in a counter-clockwise direction when viewed from apex to base.¹⁰ This squeezing movement of the LV is essential for the systolic ejection and is termed as twist and measures to counter-clockwise movement of about 65° and clockwise movement of about 5° in a normal individual.¹¹ This LV torsion is followed by rapid untwisting, which contributes to ventricular filling because LV torsion is directly related to fiber orientation in the LV wall.

LONGITUDINAL STRAIN

When you place a sample volume at the LV free wall in the apical views and record the tissue Doppler, you can demonstrate the longitudinal strain curve of that segment of the LV muscle.

Strain or deformation represents the systolic shortening of a segment of the myocardium and is expressed as a percentage of the diastolic length. This is like the ejection fraction, where it is expressed as a percentage of the diastolic volume ejected out in systole. Along with the beginning of the QRS complex of the electrocardiogram, the strain curve shows a small positive wave indicating lengthening of the myocardium lasting a few milliseconds and then a gradual negative wave. The negative wave represents the systolic shortening percentage of the myocardium in each segment. The maximal shortening occurs at the end systole or peak systole and is more than 15%.¹² This occurs toward the end of aortic systolic velocity curve at the peak of the T-wave of the electrocardiogram. The shortening percentage or strain increases as you move from base to apex.⁶ From the end systole, the curve gradually goes back to the resting level of 0% at end diastole to begin the next cardiac cycle. After the peak systole, the curve may show a small wave in early diastole called the postsystolic wave. This wave normally is less in magnitude than the peak systolic strain. Normal ranges for these values are now available on publications.¹³

SPECKLE TRACKING FOR STRAIN IMAGING¹⁴

Strain curves were recorded using tissue Doppler echocardiography from various segments of the myocardium.¹⁵ For accurate measurements the incident ultrasound beam should be perpendicular to the myocardium interrogated. When you look at the anatomy of the LV this is not a practical proposition while using the tissue Doppler. Strain analysis of the myocardial segments is done by the new method of speckle tracking.¹⁶ This is a post-processing computer algorithm that uses the routine grayscale digital images. Movement of the speckle patterns in the myocardium is utilized to image the shortening of every segment during the cardiac cycle. Within each regions of interest in the myocardium, the image-processing algorithm automatically subdivides regions into blocks of pixels tracking stable patterns of speckles. Subsequent frames are then automatically analyzed by searching for the new location of the speckle patterns within each of the blocks using correlation criteria and the sum of absolute differences.¹⁷ The location shift of these acoustic markers from frame to frame representing tissue movement provides the spatial and temporal data used to calculate velocity vectors.¹⁸ Temporal alterations in these stable speckle patterns are identified as moving farther apart or closer together and create a series of regional strain vectors and the sum of it as strain curves.¹⁴ The strain measurements are done by different software by various vendors. This paper describes the automatic functional imaging protocol used by GE.¹⁹

LONGITUDINAL STRAIN IMAGING PROTOCOL²⁰

Good-quality strain imaging requires excellent apical views, four-chamber, long-axis and the two-chamber views images

with a good frame rate (Fig. 1).²¹ Reduce the depth of the image and the width of the sector to get good quality image without any drop outs. Increase the frame rate to more than 60 frames per sec (fps). Breath held in expiration, minimizes the motion artifacts. Apical four-chamber, long-axis and two-chamber images are to be archived for three cardiac cycles. Aortic closure marked at the peak of the electrocardiographic T-wave. Start the strain measurement with apical long-axis view and follow the machine instructions. The region of interest is marked by placing the points at the base of the LV near the atrioventricular posterior and anterior annulus and finally, the apex. The LV walls will be highlighted in colors depicting the anterior basal septum, mid-septum and apical septum, inferolateral basal wall, mid basal and apical basal wall. Strain of each segment will be inscribed in each of these segments of the LV. The strain curve will be available for each segment and an anatomical m-mode of these segments from medial base to apex and back to lateral basal wall will also be depicted. This is repeated for six segments of the apical four-chamber view and apical two-chamber views. Once all the three apical images have been interrogated and strain measured by automatic functional imaging technique, the bull's eye picture of 17 segments of the LV with measured longitudinal strain will appear on the screen. You can also get the strain curves of all the 17 segments with the bull's eye and you can highlight any segment with abnormal strain curve to analyze the curve. The color of each segment also represents the strain. Normal strain will be depicted in red and reduction of strain will be seen as light strain and if the segments lengthen instead of shortening, it will be seen as blue.

One can select bull's eye view of postsystolic index or see bull's eye view of the time to peak velocity format, which will demonstrate the timing of the peak strain from the onset of QRS complex. This, along with postsystolic strain index will identify areas where the contraction continued on to

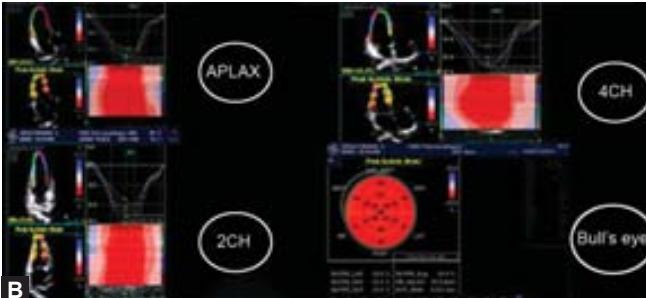

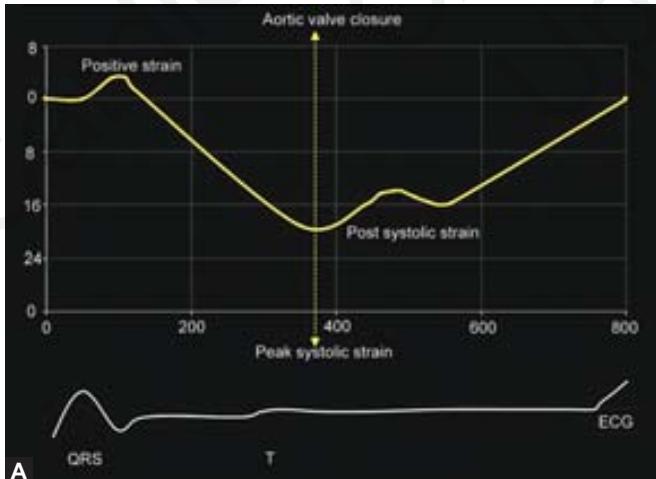

FIG. 1: Strain imaging and Bull's eye map of global myocardial strain. **A**, the myocardial strain of a myocardial segment, correlated with the electrocardiogram. P represents the small positive wave at the beginning of myocardial contraction, and S wave denotes the peak systolic strain, end systole is marked by the closure of the aortic valve. PSS denotes the post systolic wave; **B**, The Bull's eye map of all the 17 segments of the myocardium acquired by the long-axis (APLAX), two-chamber (2CH) and four-chamber (4CH) views at peak systole. Color panels show the curved or anatomical M-mode of the various segments.

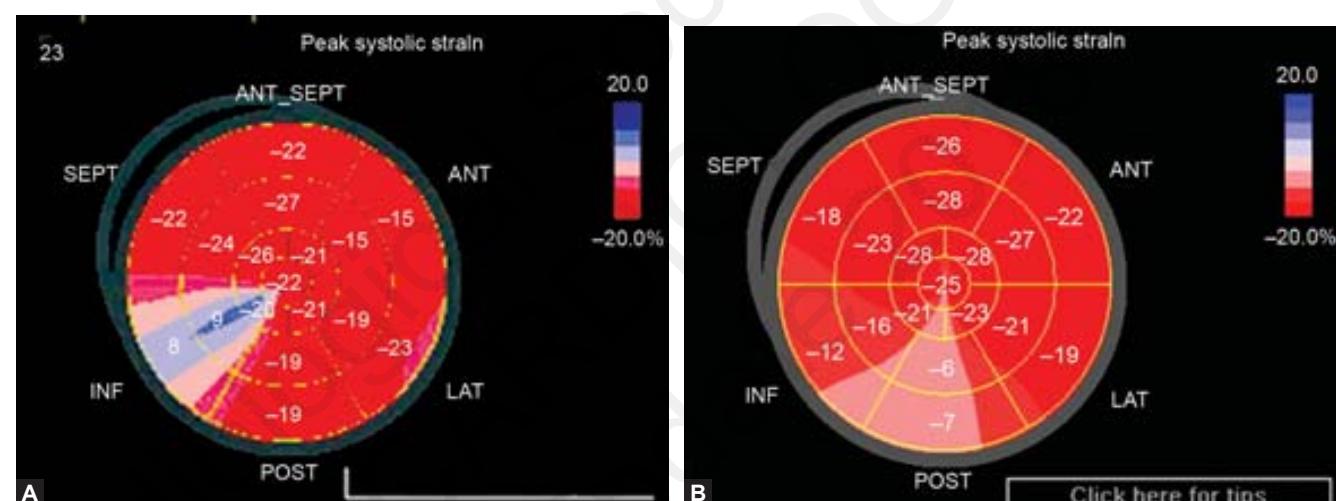

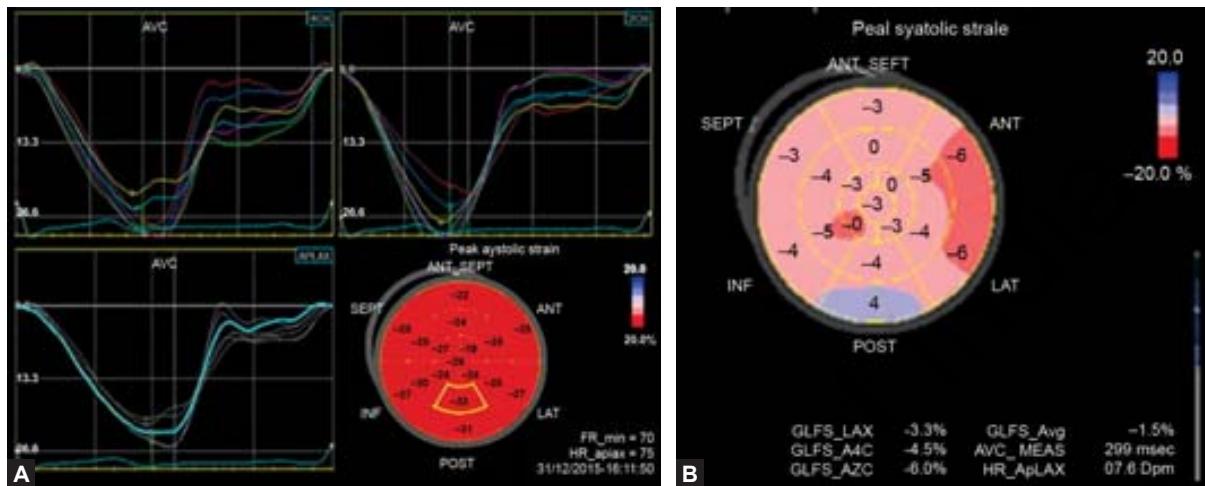

FIG. 3: Bull's eye map of 17-segment global longitudinal strain before **A**, and after **B**, right coronary angioplasty in a subject with coronary artery disease. Note the positive blue strain parameters in the inferior segments which show red (negative/recovering) parameters postangioplasty.

diastole in certain myocardial segments as a pathological phenomenon.

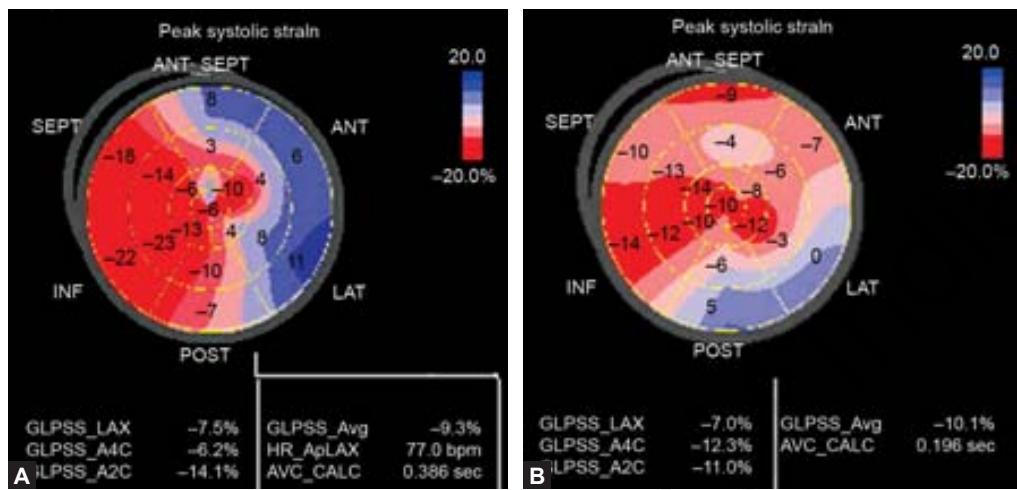

EJECTION FRACTION AND GLOBAL LONGITUDINAL STRAIN

There is wide criticism in the method of assessment of LV function by ejection fraction. M-mode echocardiographic calculation of ejection fraction is not used now and is replaced with 2D Simson's biplane method.⁴ Foreshortening is a major problem for apical imaging and may underestimate ejection fraction. Three-dimensional method is ideal but not universally available in every echo laboratory. It is in this place the global longitudinal strain (GLS) is found to be more

reliable in assessing the prognosis of patients with acute heart failure.²⁰ The strain is labeled as mildly reduced when it is more than -12.5% , moderately reduced when it is between -8.1% and -12.5% and severely when it is less than -8.0% . This assessment of prognosis was found to be statistically more reliable than the use of ejection fraction. Figure 2 represent a patient with dilated cardiomyopathy with markedly reduced GLS of -4.5% , of course with a poor prognosis.

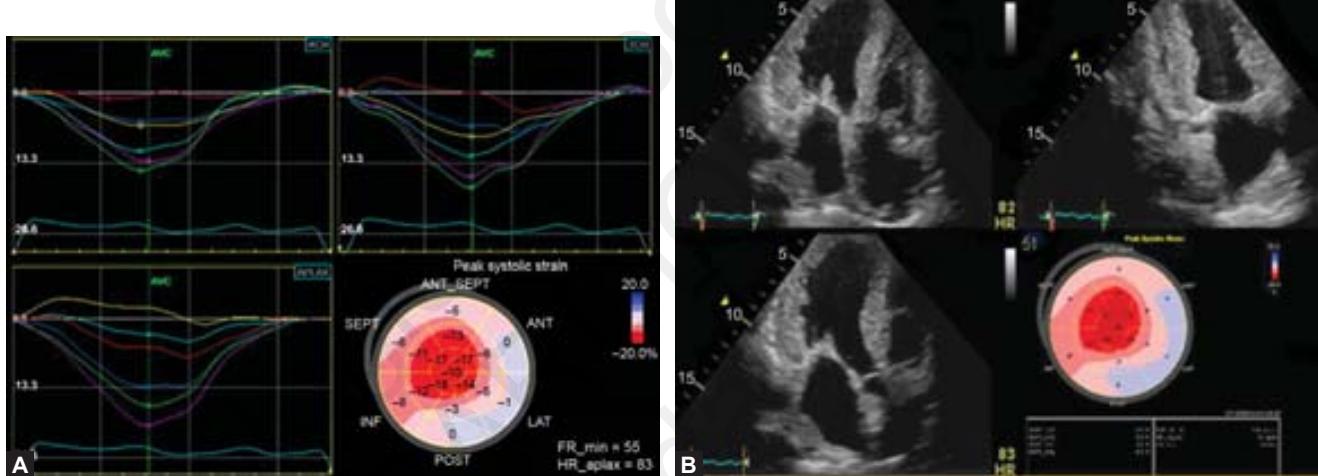

ISCHEMIC HEART DISEASE AND REGIONAL STRAIN²²

Ischemic heart disease produces reduction in strain percentage in the vascular territory involved.²³ An example

ANT, anterior; SEPT, septum; INF, inferior; LAT, lateral; POST, posterior.

FIG. 4: Bull's eye map of global longitudinal strain in coronary artery disease. **A**, in a subject with dominant left anterior descending artery infarction, where there is impaired strain in the anteroseptal anterior and lateral wall with blue regions representing dyskinesia (positive strain); **B**, Global involvement of all myocardial segments with triple vessel disease and ischemic cardiomyopathy.

ANT, anterior; SEPT, septum; INF, inferior; LAT, lateral; POST, posterior.

FIG. 5: Typical cherry red plot of global longitudinal strain bull's eye map in cardiac amyloidosis. **A**, The velocities of the strain curves; **B**, The thickened hyperechogenic myocardium in the respective views.

of inferior wall myocardial infarction before and after angioplasty is given in figure 3. You can appreciate that before angioplasty the strain in the inferior wall segments were positive in the basal and mid segments, which completely disappeared following right coronary angioplasty. However, we can see that basal and mid segments still have low strain even though the systolic lengthening as shown by the blue color is replaced by relatively reduced strain. Global strain rate imaging can be used to assess the infarct size,²⁴ during exercise echocardiography²⁵ and for prognosticating a subject with coronary artery disease.²⁶

Two examples of anterior wall infarction and ischemic cardiomyopathy are given in figures 4 and 5. In figure 4, you can see that the inferior wall strain is normal while that of the anterior septum, anterior wall and lateral wall have reduced strain with the basal and mid segments showing positive

strain. This patient had a dominant left anterior descending artery. The loss of strain has resulted in the global average peak systolic strain which was only -9.3%. Figure 5 were from a patient with triple-vessel disease where the reduction of strain is present in all the territories and the patient was in congestive cardiac failure (ischemic cardiomyopathy).

INFILTRATIVE DISEASES: AMYLOIDOSIS²⁷

The amyloid deposits are predominantly in the basal segments, less so in the mid segments and the apical segments are spared giving the appearance of a cherry on top of the ice-cream on strain imaging. Whether the increase torsional movements at the apex compared to base prevent the interstitial deposition is conjunctural. The strain curves

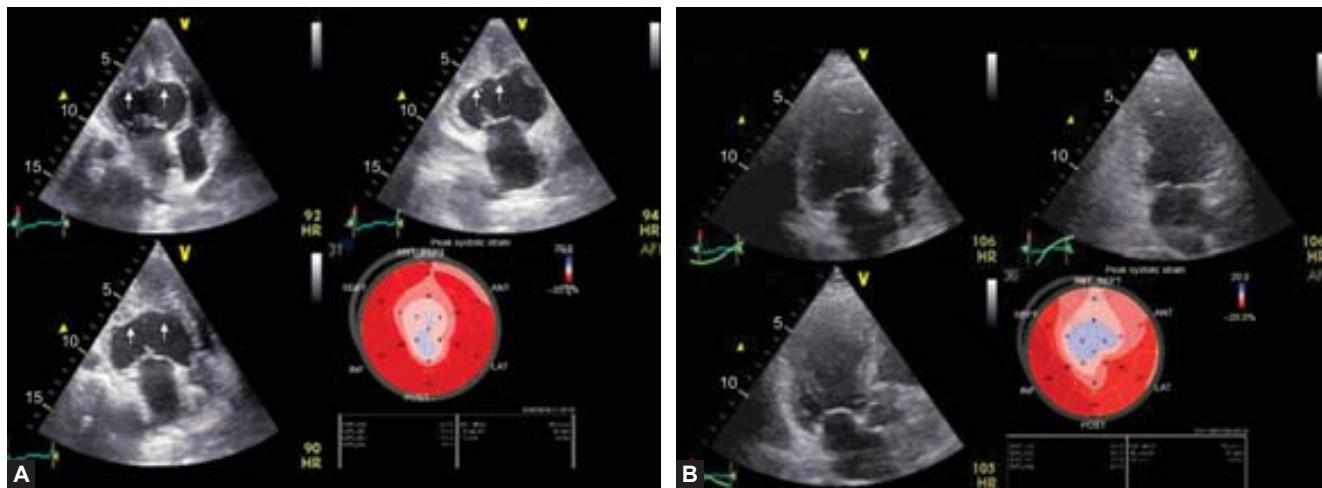

FIG. 6: Global longitudinal strain of the left ventricle represented by bull's eye map in figure A, Left ventricular endomyocardial fibrosis. Short arrows show the thickened calcific endocardium with ventricular apical obliteration. Corresponding myocardial segment shows reduced strain in the bull's eye plot; B, Apical ballooning (Takotsubo) syndrome with good strain rates at the basal segments.

depict the systolic lengthening of the basal lateral and anterior walls. The pathology of amyloidosis can be appreciated from the bright thick ventricular walls. This pattern could be seen in most of the patients with ventricular hypertrophy as the disease progresses to heart failure. Hypertensive heart disease, aortic stenosis, are clear examples.²⁸

LEFT VENTRICULAR ENDOMYOCARDIAL FIBROSIS

The fibrosis and calcification of the LV apex as is seen in the 2D echo is well represented by the reduction of strain in the apical and mid segments.²⁹ Similar picture will be seen temporarily in patients with apical ballooning syndrome where the basal segments of the LV contracts normally and the apical segments balloon out, as figure 6.³⁰ In pictures of strain imaging from a patient with apical ballooning syndrome, as in figure 7, you can appreciate the positive strain in the apical segments and lengthening of segments as is depicted in the strain curves. Some of the segments peak in diastole and this postsystolic strain is classically described for ischemia.

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophied muscles with myofiber disarray have no coordinated contraction and systolic shortening. In fact, it produces disordered contraction and minimal systolic shortening of many segments as shown in the strain curves from a patient, hypertrophy of anterior wall and apical inferior wall (Fig. 8).³¹

It is interesting to note that in apical hypertrophic cardiomyopathy the loss of strain is limited to the apical segments as is shown in figure 9, and the differences in the longitudinal strain helps to differentiate people with physiologic hypertrophy.³² The regions of reduced strain correlates with pathological fibrosis on evaluation with magnetic resonance and hence is useful in prognostication.³³

LEFT BUNDLE BRANCH, CARDIAC FAILURE, AND CARDIAC RESYNCHRONIZATION THERAPY³⁴

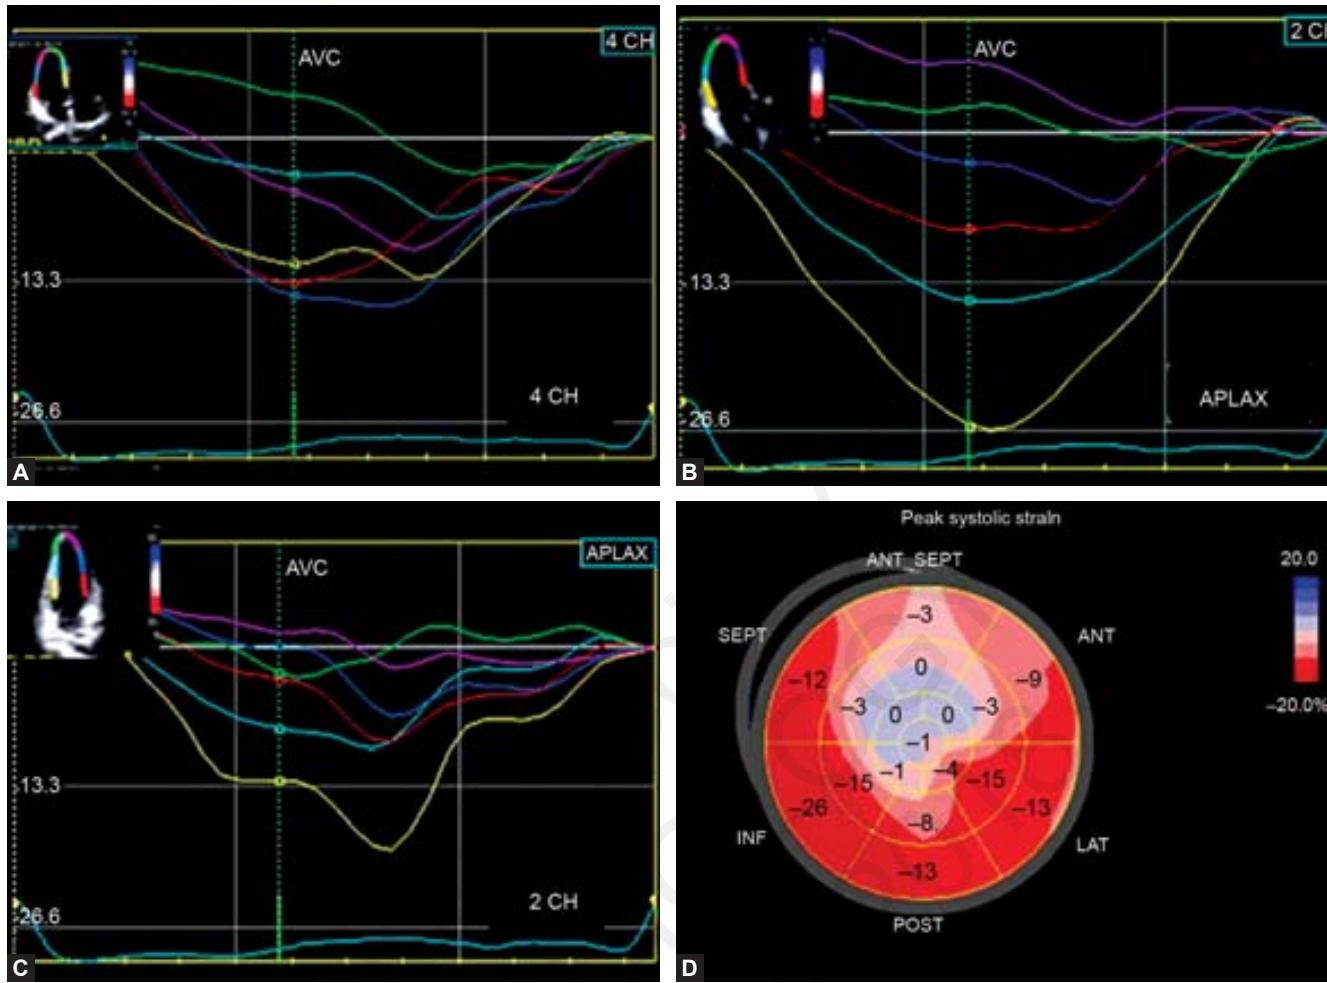

Left bundle branch with lateral walls of the LV contracting in a delayed manner results in loss of myocardial efficiency.³⁵ The segments contracting after the aortic valve closure do not contribute to LV ejection but contractions occurring in early diastole hampers LV filling and adds to afterload dependant dysfunction.³⁶ If cardiac resynchronization therapy can make these segments contract before aortic valve closure, the problem will be solved to a large extent.³⁷ If strain imaging can identify the segments with delayed contraction and place the LV leads over those segments to resynchronize their contractions, one can get significant benefit in patients with cardiac failure and left bundle branch block, which has major prognostic implications.^{38,39} Notice the segments with peak contractions occurring in diastole after the aortic valve closure in a patient with left bundle branch block in figure 10 and the postsystolic index being significantly abnormal over the entire inferior and lateral walls.

MYOCARDITIS

Acute ventricular dysfunction can occur in viral myocarditis as well as in allergic myocardial dysfunction, the Kounis syndrome, and near normal GLS differentiates the latter from acute myocarditis. Similarly, clinical disorders with chronic myocarditis like sarcoidosis can be picked up by strain imaging.⁴⁰ Serial longitudinal studies add additional information on prognosis.⁴¹

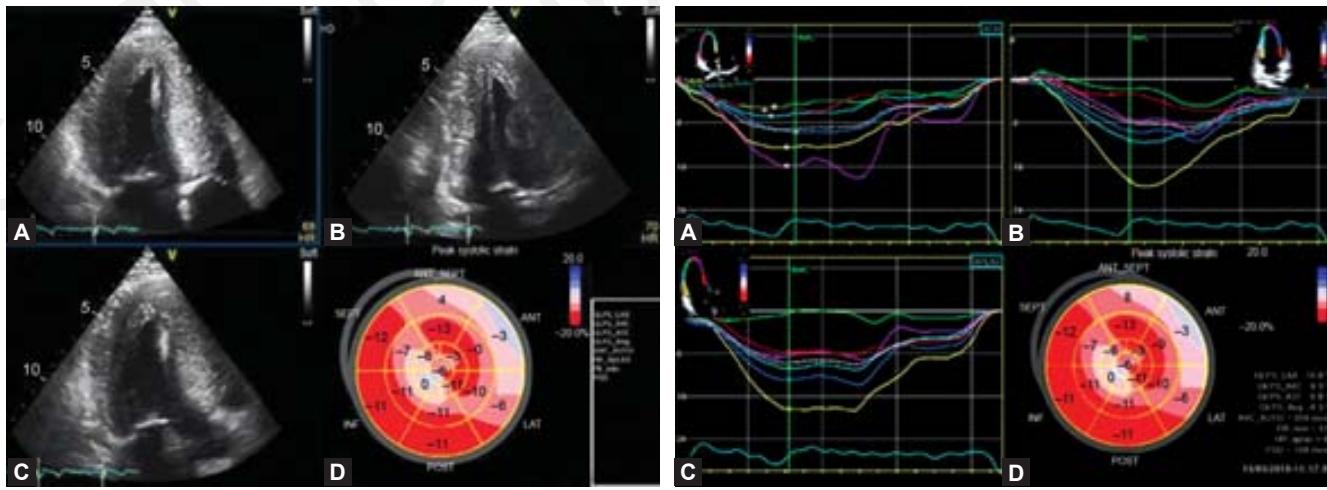

Illustrative Case Study on Myocarditis

Figure 11 depict the GLS images of the LV in a 26-year-old engineer who was admitted following an episode of acute viral fever. His dyspnea was originally being treated by the pulmonologist. Once the high-sensitive troponin T was found to be high, he was transferred to cardiology

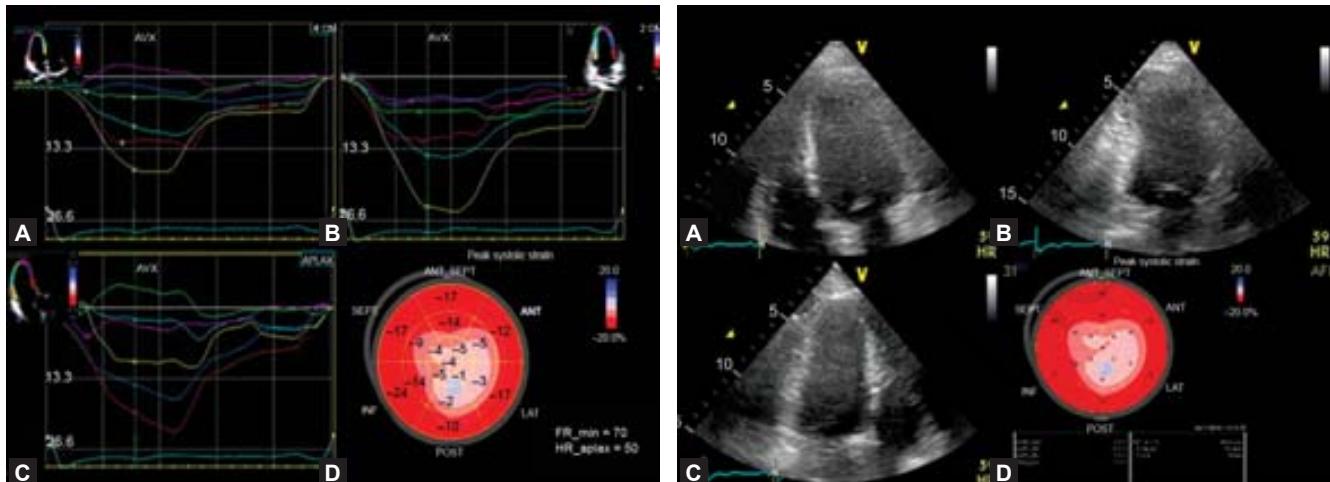

ANT, anterior; SEPT, septum; INF, inferior; LAT, lateral; POST, posterior.

FIG. 7: Global longitudinal strain depicted with the bull's eye plot, typical of apical ballooning syndrome. **A**, Apical four-chamber view; **B**, Apical long-axis view; **C**, Apical two-chamber view; **D**, The bull's eye plot. Note the basal segments shown by red and yellow lines have normal strain pattern whereas the apical segments show lengthening instead of shortening in systole. Moreover, in apical four-chamber and two-chamber views, few segments show significant post systolic strain, beyond aortic valve closure, typical of myocardial ischemia.

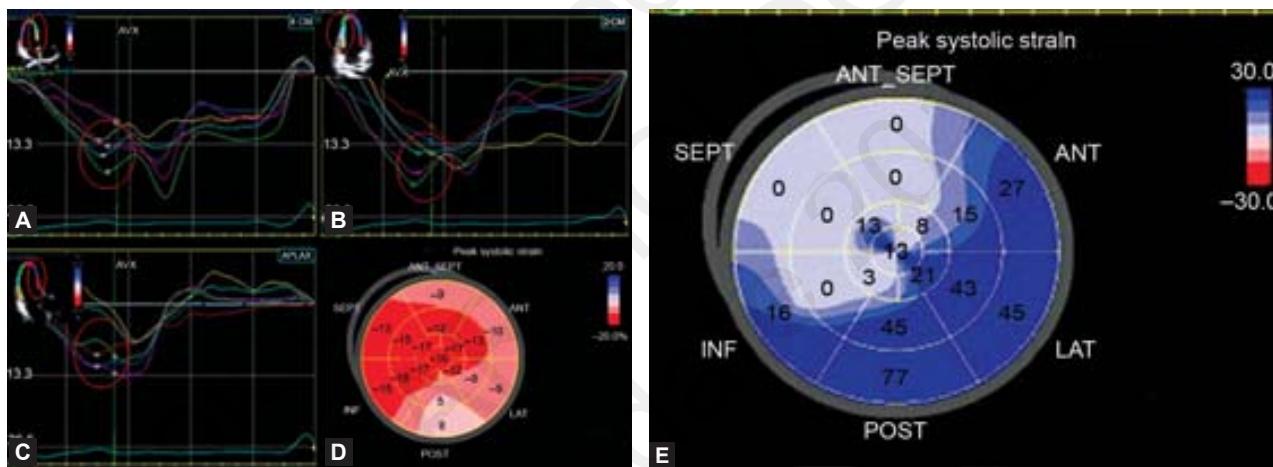

ANT, anterior; SEPT, septum; INF, inferior; LAT, lateral; POST, posterior.

FIG. 8: Global longitudinal strain imaging in hypertrophic cardiomyopathy; left panel shows the two-dimensional images and the right panel the corresponding strain velocities of the various segments. **A**, The four-chamber; **B**, Two-chamber; **C**, The apical long axis; **D**, The bull's eye map. The septal basal and mid segments shown in red and green lines show reduced strain rates consistent with the regional pathology.

ANT, anterior; SEPT, septum; INF, inferior; LAT, lateral; POST, posterior.

FIG. 9: Global longitudinal strain imaging in apical hypertrophic cardiomyopathy; left panel shows the two-dimensional echo images and the right panel, the corresponding strain velocities of the various segments. A, The four-chamber; B, two-chamber; C, The apical long axis; D, The bull's eye map. Note the reduced strain rate along the apical segments, whereas the basal segments have normal pattern.

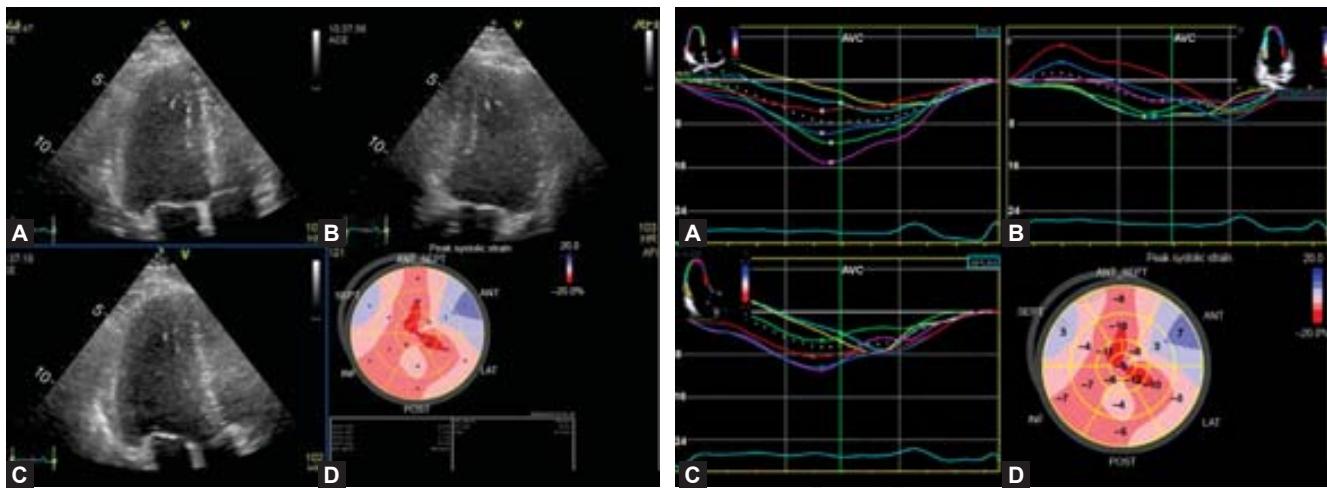

ANT, anterior; SEPT, septum; INF, inferior; LAT, lateral; POST, posterior.

FIG. 10: Global longitudinal strain in a subject with left bundle branch block. The segments contracting earlier are identified by the earlier peaking of strain as shown by the red ovals, which correspond to electrical systole. A, the apical 4-chamber view, shows the septal segments contracting earlier than the lateral; B, Apical 2-chamber view, the inferior segments contract earlier than the anterior wall; C, the long-axis view, the anteroseptal segments are earlier than the inferolateral wall; D, and E, shows the bull's eye map of the peak systolic strain and the post-systolic strain in the same subject.

and subsequently initiated on beta-blockers, angiotensin-converting enzyme inhibitors, and diuretics. His initial strain imaging showed marked reduction of basal and mid-wall strain with many segments showing positive strain. His average GLS was only -6.5% . His edema and dyspnea improved with treatment and he could be discharged on medications. Strain imaging done after 1 month showed remarkable improvement from -6.5% to -10.5% as shown in figure 12.

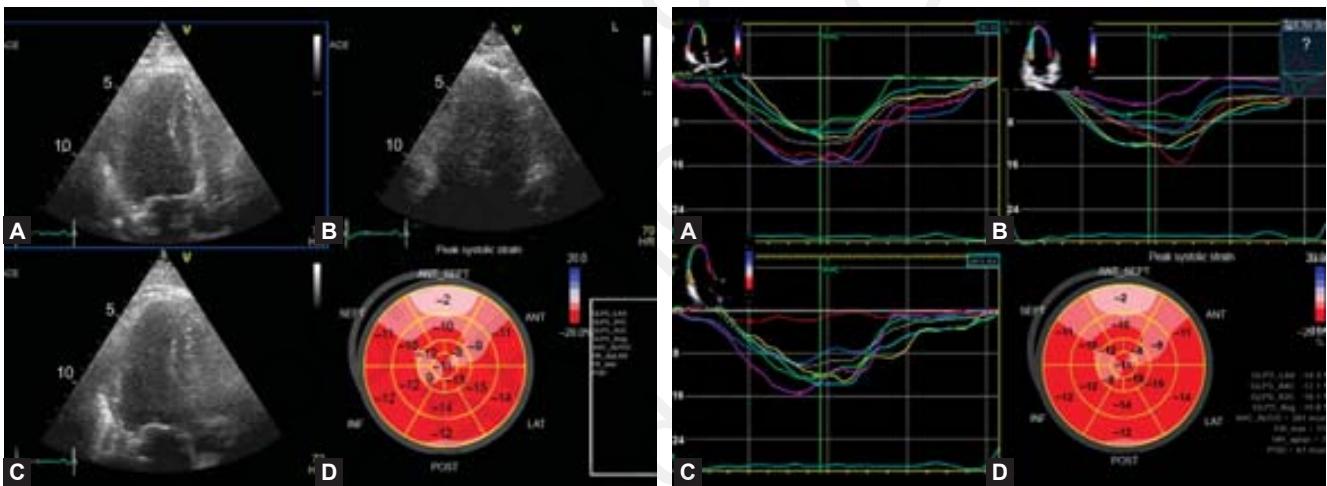

STRAIN IMAGING IN RARE SITUATIONS⁴²

There are many other areas in cardiology where strain imaging has been of great use in evaluating significant pathology before any other investigations could pick up early abnormalities like myocardial ischemia,³³ LV diastolic dysfunction, subclinical myocardial dysfunction before, during and after cancer chemotherapy,^{43,44} fetal echocardiography⁴⁵ and the list will increase as the experience with this new clinical modality increases.⁴⁶ Figure 13

illustrate the utility of GLS imaging in the diagnosis of constrictive pericarditis, compared with circumferential strain imaging.⁴⁷ Circumferential strain imaging cannot image the true apex. In constrictive pericarditis, lateral and peripheral segments are immobilized by the visceral pericardial fibrosis, in a patchy manner, whereas the septum, which is intracardiac maintains its mobility.

LIMITATIONS OF STRAIN IMAGING⁴⁸

We have to overcome many limitations in strain imaging. In-plane deformation or displacement in a 2D sequence of images during speckle tracking, could produce artifacts in short-axis images (but less so in apical views). The 3D

images could overcome this but it has low temporal and spatial resolution.⁴⁹ Ultrasound noise could reduce the frame by frame tracking of local speckle patterns. Acquiring optimized image quality is essential to reduce inter and intra-observer variation.²⁸ Speckle patterns may not be stable due to changes in interrogation angle, between moving tissue and ultrasonic beam. The accumulation of small random errors in detection of speckled pattern along the tracking process leads to inaccurate tracking results. As the technology develops, we may overcome some of these limitations. Two main vendors supplying the equipment for strain imaging are the QLab with cardiac motion quantification (CMQ) software of the Philips IE33 and the EchoPAC 11 of automated function imaging (AFI) from GE. The global average peak strain values

AP, anteroposterior; ANT, anterior; INF, inferior.

FIG. 13: Global strain imaging in constrictive pericarditis. **A**, The circumferential strain imaging where the left ventricular apex cannot be imaged; **B**, The global longitudinal strain imaging. Note that the circumferential strain is more affected than the longitudinal strain and the septal regions are spared. Segmental involvement is patchy and is not restricted to any vascular territory.

may show correlation, but we may find regional variation in strain values from the available vendors.⁶ CMQ is more time-consuming than AFI. There was a comparative study regarding the time needed to complete the measurements using AFI with EchoPAC or CMQ with QLab in 15 subjects.⁵⁰ The time required with EchoPAC compared with QLab was 117 ± 17 s versus 477 ± 43 s, $p < 0.001$.

CONCLUSION

Longitudinal strain has become a clinical tool. Bull's eye pictures on the GLS along with the 2D echo images and the strain curves give important diagnostic information in a host of diseases. In ischemic heart disease the changes may appear before the wall motion and electrocardiogram changes. In congestive cardiac failure, it has important prognostic value. It can detect impending ventricular dysfunction in subjects undergoing chemotherapy with cardiotoxic drugs and help to modulate the dose. With increasing experience and vendors using comparable software of it will soon become a standard imaging format in all echocardiographic laboratories.

Three-Dimensional Echocardiography—Current Indications

Hardeep K Grewal, Ravi R Kasliwal

INTRODUCTION

Echocardiography, since its inception about five decades ago, has evolved to a great extent and has become the most important diagnostic tool in cardiology practice for noninvasive assessment of cardiac structure, function, and hemodynamics. The field of echocardiography has progressed from the earliest M-mode examination to two-dimensional (2D) imaging along with the development of various forms of Doppler and strain imaging. Because this modality is noninvasive, widely available, cost and time efficient and is radiation free, therefore has become the investigation of choice for various cardiac pathologies. However, 2D echocardiography (2DE) has some important limitations. Firstly, for quantification of cardiac chamber size and function, 2DE has to rely on geometric assumptions about the shape of cardiac chambers which can affect the accuracy and reproducibility of various quantitative parameters especially in patients with dilated and aneurysmal ventricles. Secondly, 2DE is a tomographic technique which provides flat views of heart and great vessels; therefore echocardiographer has to take many views and then has to mentally reconstruct the complex cardiac anatomy. These limitations have been overcome by the introduction of 3D echocardiography (3DE). Initially, this technique suffered from limitations like poor image quality as well as labor-intensive and time-consuming offline analysis. But the advancements in the ultrasound and computer processing technology have helped overcome these limitations, enabling online display of 3D images in real time (RT) with accurate, precise, and detailed assessment of cardiac structures from any spatial orientation. Although, considerable improvements are still needed before 3DE can become a truly indispensable part of echocardiographic imaging, there are several clinical conditions in which it offers definite incremental benefit.

In this review, we describe the current indications of 3DE, its incremental value over 2DE, and its limitations.

LEFT VENTRICLE ASSESSMENT

Assessment of left ventricle (LV) function and size is the most essential component of echocardiographic evaluation. There are several parameters for LV assessment like LV volumes, LV mass, LV ejection fraction (LVEF), LV regional wall motion abnormalities (LV RWMA), LV geometry and assessment of regional and global longitudinal strain.

Left Ventricle Volume and Left Ventricle Ejection Fraction

The most common assessments made using echocardiography are the LV size and LVEF calculation, and LV volumes provide estimation of both these parameters. Therefore, accurate assessment of LV volumes is essential during any echocardiographic examination. LV chamber does not have a fixed geometric shape. A healthy heart may resemble an elongated ellipse with a conical apex whereas a diseased heart may have distorted geometry. Traditionally, LV volumes are assessed by M-mode and 2DE-based methods, but all these methods suffer from technical limitations. M-mode-based formulae are based on the assumption that LV is a prolate ellipsoid and therefore, minor LV dimension is cubed to obtain LV volume. However, this assumption does not hold true in distorted ventricles as the linear measurements give information along single plane only and because one dimension is cubed so any error in the measurement also becomes very large. Therefore, the Teichholz and Quinones methods for calculating LV volumes are no longer recommended now.

Currently, recommended 2D method to assess LV volumes and LVEF is biplane method of disks (modified Simpson's method). This method is based on the principle that the total LV volume is calculated from the summation of stack of elliptical disks. In this method, LV volumes are measured by tracing the LV endocardial border from the apical four and apical two chamber views. This method has the

advantage over the linear dimension method that it corrects for shape distortions and is less dependent on geometrical assumptions compared with linear dimension method. But the assumption that the ventricle can be represented by a series of stacked discs with varying diameters does not hold true in ventricles with RWMA and aneurysms. Moreover, foreshortened or off-axis views and endocardial dropout also significantly compromise the accuracy of this method. An alternative method to calculate LV volumes is area-length method especially when apical endocardial borders are not well visualized. This method is based on the assumption that LV is bullet-shaped, which again does not hold true always.

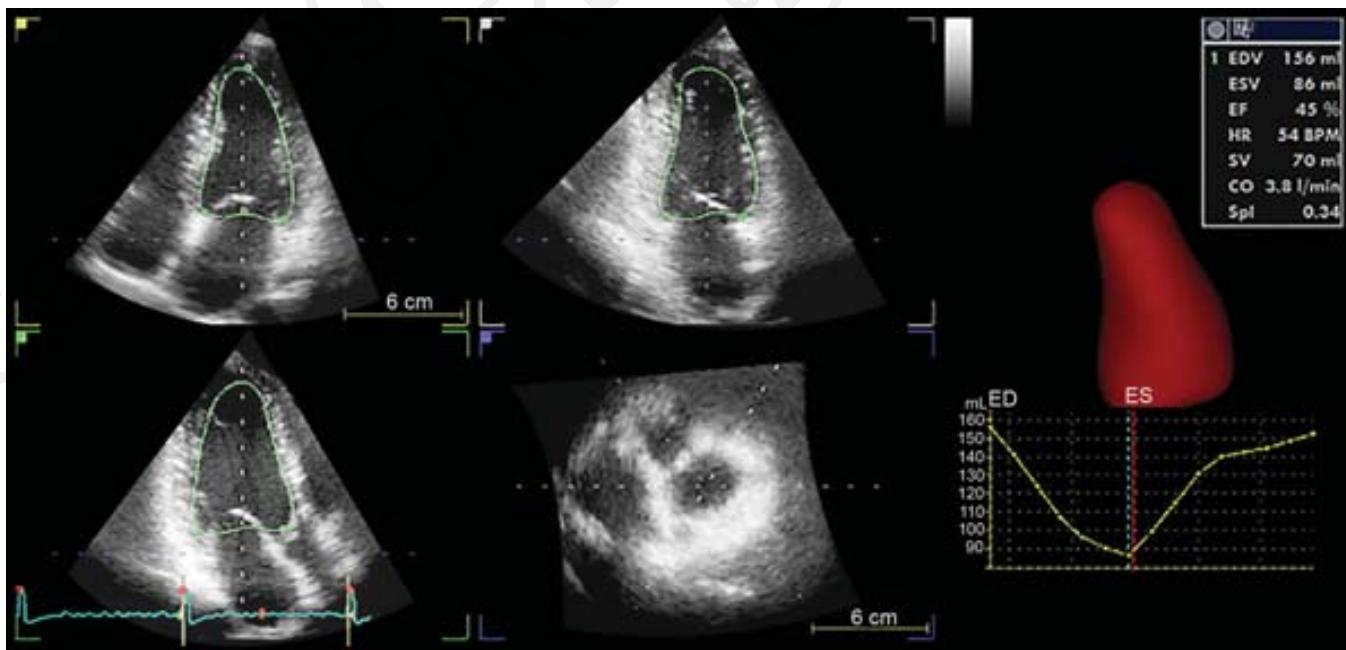

Accurate information about LV size and LVEF is important for any cardiovascular pathology from diagnostic as well as prognostic point of view. Cardiac magnetic resonance (CMR) imaging is the gold standard technique for LV quantification. But it is costly, not widely available, and requires iodinated contrast use. Moreover, CMR cannot be used in patients with implanted pacemakers and defibrillators. Adding third dimension to 2DE can overcome the limitations of both 2DE as well as of CMR imaging.

Three-dimensional echocardiography makes no geometrical assumptions about LV shape and also eliminates problems related to foreshortening and off-axis imaging because the entire LV is included in the acquired pyramidal dataset permitting proper alignment of the LV cavity (Fig. 1). The data thus acquired can be analyzed using computerized automated or semi-automated endocardial surface detection software requiring minimal manual intervention, thereby improving measurement reproducibility. The software creates a cast of LV. Within 3D dataset LV volume is calculated for

each frame and plotted in the form of graph with volume against time, as shown in figure 1. LV volumes (end-diastolic and end-systolic) and EF are automatically derived from this graph and displayed. The calculation of LV volume by 3DE is found to be more accurate and reproducible when compared with conventional 2DE methods because endocardial position is measured at considerably large number of points over LV surface. Studies have shown that 3DE-based LV volumes are larger than 2DE-based values, and corresponding upper limits of the normal range are end-diastolic volumes (EDVs) of 79 mL/m² for men and 71 mL/m² for women and end-systolic volumes (ESVs) of 32 mL/m² for men and 28 mL/m² for women.¹⁻³

High degree of correlation has been found between CMR-derived and 3DE-derived volume measurements.⁴⁻⁸ However, several studies have shown notable underestimation of LV volumes with 3DE when compared with CMR.^{2,5,8-19} Though, there are several potential reasons for such underestimation, the most likely reason seems to be the inability of 3DE to differentiate consistently between the myocardium and the trabeculae.²⁰ To reduce the inter-technique differences, trabeculae in the LV cavity should be included while tracing the endocardium. Another limitation of 3DE is its low temporal resolution. As a result, true end-systolic frame may not be successfully captured in single beat acquisitions. This may result in erroneous ESV calculations and EF measurements.

American Society of Echocardiography (ASE) recommends that in laboratories with experience in 3DE, 3D measurement of LV volumes and LVEF should be done, when feasible depending on the image quality.

EDV, end-diastolic volumes; EF, ejection fraction; ESV, end-systolic volumes; HR, heart rate; SV: systolic volume.

FIG. 1: Estimation of left ventricular (LV) volume and ejection fraction by three-dimensional echocardiography. Single volume dataset is used. LV endocardial contour is defined in both end-diastolic and end-systolic frames and confirmed in different orthogonal planes. The analysis software then generates LV cavity cast and calculates LV volumes and ejection fraction.

Left Ventricle Mass

Left ventricle mass is a well-established prognostic marker which can independently predict adverse cardiovascular events and premature death. Because of the clinical value of LV mass, it is important to have a reliable method of its measurement. Echocardiographically, LV mass is derived from LV volume by multiplying the volume of myocardium by the myocardial density (approximately 1.05 g/mL). Therefore, all limitations of LV volume assessment are applicable to LV mass assessment also. Three-dimensional echocardiography can overcome these limitations as this is the only echocardiographic method that directly measures LV myocardial volume without any geometric assumptions regarding LV shape, therefore it is likely to provide more precise measurements of LV mass (Fig. 2).

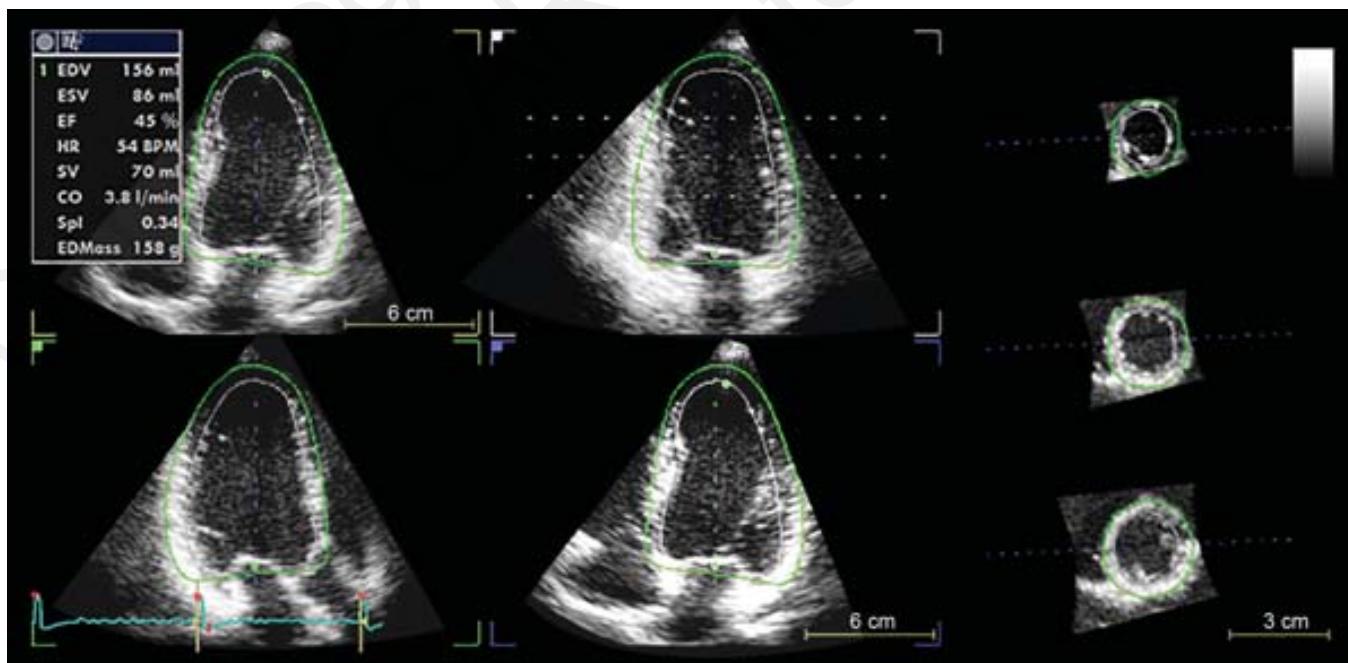

Three-dimensional echocardiography has been found to have better interobserver agreement than 2DE.²¹⁻²³ Studies have shown that LV mass measured by 3DE has better correlation with CMR results.^{4,21-30} Several studies have demonstrated the accuracy of 3DE-based measurement of LV mass, when compared to CMR, and it has been shown that the accuracy is maintained even in diseases with abnormal LV geometry as seen in hypertrophic cardiomyopathy or congenital heart diseases and in the presence of abnormal wall motion abnormalities.^{25,26,31} However, one meta-analysis has suggested that LV mass measurements are more likely to be underestimated in patients with cardiac pathology than in healthy individuals.²⁷

Several studies have validated the precision of 3DE-derived LV mass, however, there have been few studies determining the practicality or prognostic value of 3DE-derived LV mass estimation in large-scale clinical environments.³²

American Society of Echocardiography recommends that 3DE is preferable to 2DE, wherever feasible, for LV mass assessment, particularly in patients with asymmetric or localized hypertrophy or in distorted ventricles. However, 3DE-based LV mass data available so far in normal subjects is not enough to recommend normal reference values.

Left Ventricle Regional Wall Motion Abnormalities

The 17-segment model as suggested by ASE divides the LV into six segments (inferoseptal, anteroseptal, anterior, anterolateral, inferolateral, and inferior) at the basal and mid-ventricular level and into four segments (septal, anterior, lateral, and inferior) at the apex, with apical cap as 17th segment.³³ In 2DE, the LV needs to be scanned through different acoustic windows to image all the LV walls. Whereas in 3DE, all walls of LV can be imaged in a single volume acquisition and the entire LV can also be divided into multiple short-axis slices which can then be rotated and re-oriented at any time after acquisition and can be visualized simultaneously. These advantages, thus, allows comprehensive assessment of LV endocardial motion and myocardial thickening. The LV cast generated can be rotated on computer screen to visualize the regional contractile function of all myocardial segments. Using 3DE, a time-volume curve for each of the LV segments is displayed showing minimum and maximum volumes of that specific segment during the cardiac cycle. Hypokinetic or akinetic segments can be easily recognized by the pattern of the curve. Diseased segments have a flattened curve. This approach has been validated using CMR imaging as the standard.¹⁷

EDV, end-diastolic volumes; EF, ejection fraction; ESV, end-systolic volumes; HR, heart rate; SV, systolic volume.

FIG. 2: Estimation of left ventricular (LV) mass by three-dimensional echocardiography. Both epicardial and endocardial borders are defined, and the software automatically calculates the difference between the two volume measurements to derive LV myocardial volume and mass.

A recent observational prospective study, identified a good agreement between RT-3DE (RT3DE) and conventional 2DE in the assessment of RWMA of most segments and 3DE is found to be noninferior when compared to visual assessment by conventional 2DE. A reasonable correlation ($r = 0.74$) between the extent of delayed gadolinium enhancement by CMR³⁴ and wall motion score index by 3D-transesophageal echocardiography (3D TEE) has been reported in patients with recent myocardial infarction. It has been shown that in patients with suboptimal 3D transthoracic echocardiography (3D TTE) image quality, the use of echocardiographic contrast improves concordance of wall motion assessment with CMR.³⁵ Three-dimensional TTE is also useful in stress echocardiography (SE). Two-dimensional stress echocardiography (2D-SE) has its limitations because several views of the LV have to be acquired within 90 seconds of peak stress to completely visualize all LV segments. Whereas, 3DE requires only a single apical acquisition at peak stress and also avoids foreshortening, which is a frequently encountered problem in 2D-SE. This would be particularly useful in patients with rapid recovery of heart rate post-exercise. Moreover, post-processing analysis allows the assessment of images in large number of planes to ascertain the actual amount of wall motion abnormalities. Several studies have shown the feasibility of exercise and pharmacologic stress testing, with more rapid image acquisition and greater interobserver concordance in wall motion interpretation as compared to 2D TTE.³⁶⁻⁴⁰ Some studies have also demonstrated that the sensitivity of 3D TTE to detect significant coronary artery disease, based on an invasive angiography as the reference standard, is equal to or better than that of 2D TTE.^{36,38} Although some studies have not shown any superiority over 2D TTE.⁴¹

RIGHT VENTRICLE ASSESSMENT

Right ventricle (RV) has a crescent shape which wraps around the LV and can be divided into three different parts—(1) inlet, (2) apical trabecular, and (3) outlet. Because of the complex geometry, all three parts of RV cannot be visualized at the same time in 2DE and has to be imaged through multiple echocardiographic windows for complete assessment. Therefore, the conventional Simpson's method used to assess LV volumes cannot be used for RV volume assessment.

Functional assessment of RV is also difficult as the myocardial fiber orientation is different for RV when compared with LV. The RV has a poorly developed circumferential mid-layer and a longitudinal arrangement of endocardial fibers. Due to this fiber orientation, RV contracts in a peristaltic manner from inflow to outflow area. Furthermore, RV is situated anteriorly in the chest resulting in suboptimal image quality. Because of these reasons the cardiac magnetic resonance imaging (MRI) has become the gold standard as it allows RV quantification (volumes and EF) without any geometric assumptions. However, echocardiography still remains the first line imaging modality as it is widely available and time and cost efficient unlike cardiac MRI.

Two-dimensional echocardiography can assess different RV function parameters which have been found to be useful diagnostically and prognostically. However, all these parameters address RV function in an indirect manner and do not provide precise RVEF and RV volumes.⁴²⁻⁴⁴ Recently, 3DE has gained acceptance for the evaluation of RV volumes and EF. Many studies, though mostly single center studies and studies conducted at centers with high level of expertise, have shown that RV assessment by 3DE is feasible, accurate, and reproducible.^{2,5} A study comparing 2DE and 3DE for RV assessment showed RV volumes are significantly overestimated by 2DE by a factor of 45% and are also less reproducible than 3DE.⁴⁵ In another study of 25 patients,⁴⁶ it was demonstrated that RVEF derived from 3DE was associated with a 39% decrease in interobserver variability when compared 2DE-derived RVEF.

Several studies have shown good correlation between CMR and 3DE-derived RV volumes and EF in various clinical settings.⁴⁷⁻⁵³ In one such study involving healthy individuals as well as patients with congenital heart disease and complex anatomy, RV size and function were assessed by both CMR and 3DE.⁴⁷ Both imaging modalities showed close correlation with each other for RV assessment with correlation coefficients being 0.91 for RVEF, 0.99 for RV EDV and 0.98 for ESV. The utility of 3DE-based assessment has also been demonstrated for guidance of RV endomyocardial biopsies.⁵⁴ However, data assessing the prognostic value of RV volume and RVEF is scarce. A recent study by Nagata et al.⁵⁵ has assessed the correlation between RV function and prognosis in 446 patients and the study demonstrated that RVEF assessed with 3D TTE is independently associated with cardiac outcomes and provides additional prognostic information. This study also provided the 3D RVEF cut off values to stratify prognosis of patients with different cardiac diseases: 35% for cardiac death and 41% for major adverse cardiac events.

Though studies have shown good feasibility but, in these studies, only patients with optimal image quality were included and therefore, it is difficult to extrapolate the data presented in terms of feasibility and reproducibility to everyday clinical practice. Imaging acquisition may also be difficult in patients who have dilated RV. Patients with RV pathology usually have irregular rhythm which may be source of artifacts. We need more studies to test the feasibility and reproducibility of 3DE-derived RV parameters in different clinical settings and patients. New 3D software for RV analysis is under evaluation⁵⁶ to improve accuracy and reproducibility. We hope that with newer developments in the technology RV 3D echo evaluation will become possible in everyday clinical practice.

As per recommendation by 2015 ASE guidelines for chamber quantification,³³ RV size should be routinely evaluated during echocardiography and conventional 2DE using several acoustic windows should be used as the primary approach for this purpose. However, in laboratories with experience in 3DE and when information of RV volumes may be clinically important, 3DE-based RV assessment is recommended.

LEFT ATRIAL ASSESSMENT

Left atrial (LA) size is an important prognostic factor in variety of cardiovascular diseases. Increased LA size is associated with development of atrial fibrillation (AF), stroke, and cardiovascular death.⁵⁷⁻⁵⁹ LA size is also known as glycosylated hemoglobin of LV diastolic dysfunction as it provides information about the duration of LV diastolic dysfunction and is also a determinant of success of therapeutic procedures available for the management of AF.

Most commonly used measure of LA size is LA antero-posterior dimension obtained in parasternal long axis. However, LA volume assessment is superior over LA linear dimension, especially in patients with an enlarged left atrium.⁶⁰⁻⁶³ In 2DE, LA volume is calculated by using the ellipsoidal formula or the modified Simpson method.^{64,65} These formulae are also based on geometric assumptions as in LV assessment. Recent studies have shown superiority of 3DE over 2DE for estimation of LA volumes (Fig. 3).^{66,67}

Recently in a study, RT3DE-derived LA volumes were compared with 64-slice computed tomography (CT) and it was found that LA volumes provided by 3DE are more precise and reproducible as compared to 2DE.⁶⁸ Similarly, in another study, 34 patients undergoing pulmonary vein isolation were enrolled and both echocardiography and CT was done to determine LA maximum and minimum volumes and LA emptying fraction. It was found that 3DE-derived measurements are more robust in terms of intra and interobserver variability⁶⁹ and also had very high degree of correlation with CT. Mor-Avi et al. performed a multicentric study and compared RT3DE LA volume against 2DE biplane volume and CMR in 92 patients.⁷⁰ It was found that

CMR-derived volumes had much better correlation with 3DE for both maximum and minimum LA volumes and the biases were minimal in comparison to 2DE. Additionally, using a threshold of 34 mL/m², overall concordance with CMR was higher for 3DE than 2DE. In a study of 127 patients undergoing radiofrequency catheter ablation of AF, LA volumes with 3DE have also been compared with angiography and electroanatomic mapping.^{68,71,72} The measurements obtained using 3DE were generally smaller than the same obtained using invasive methods. These results suggest that LA volumes assessed by angiography or electro-anatomic mapping should not be used as baseline values for noninvasive follow-up.

Although, several studies have convincingly shown that 3DE provides more accurate LA volumes than biplane 2DE,⁷⁰ it is not yet clear whether there is an additional clinical benefit of 3DE-derived LA volumes. Studies are required to determine whether the incremental precision offered by 3DE for LA size measurement really adds to the clinical decision-making.

Unlike left atrium, there is very limited data for estimation of right atrial (RA) volumes using 3DE. In a study by Keller et al.,⁷³ it was shown that 3DE-derived RA volume measurement is superior to 2DE-based techniques and is also comparable with CMR. A study, involving large number of healthy individuals with a wide age range,⁷⁴ provided the 3DE and 2D-speckle tracking echocardiography (STE) derived normative reference values for RA size and function. It was found that 2DE-derived RA volumes were significantly smaller than those assessed using 3DE. The 3DE-based RA volumes have shown better interobserver reproducibility than that of 2DE RA volumes.

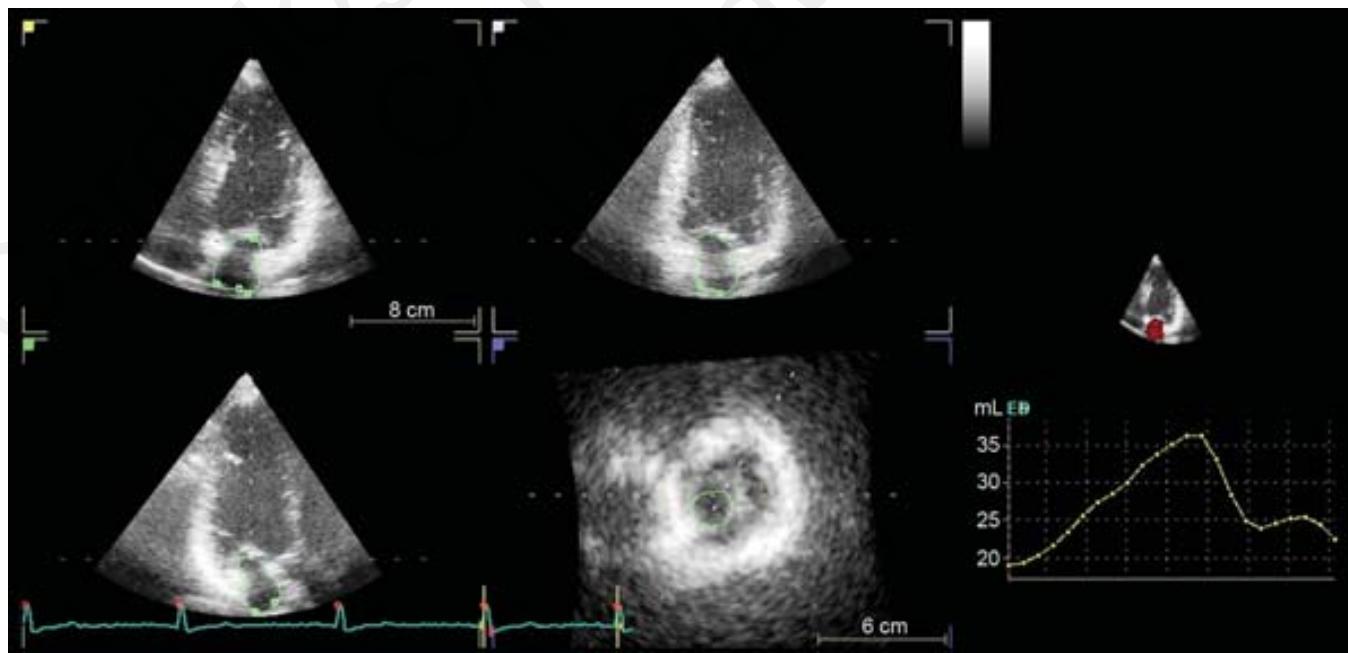

FIG. 3: Use of three-dimensional echocardiography for estimation of left atrial volume. Same principle is used as for left ventricular volume.

THREE-DIMENSIONAL STRAIN OF LEFT VENTRICLE

Two-dimensional speckle tracking strain measurement has been validated as a robust method for quantification of LV systolic function. For 2D strain, multiple views must be obtained to assess all three components of myocardial deformation (longitudinal, radial, and circumferential), but this can affect the strain measurements because of beat-to-beat variability of LV contraction. Moreover, the information collected from limited planes of LV is extrapolated for the whole LV myocardium. In 2D analysis, the out-of-plane motion of speckles due to the rotation and shortening motion of the LV cannot be quantified.⁷⁵

Three-dimensional strain is a new technology aimed for the assessment of LV myocardial deformation and seems promising as it has the capacity to analyze all three components of strain in the same dataset.⁷⁶⁻⁸⁰ Additionally, 3DE also provides area strain which combines the longitudinal and circumferential strain vectors, thus quantifying the deformation of the myocardial segment more comprehensively (Fig. 4). More precise LV torsion values can be obtained by simultaneous measurement of rotation in every short-axis plane and the distance between the planes. It was shown in a study of post-cardiac transplant patients with preserved LVEF that 3D speckle-tracking global longitudinal and circumferential strain, but not 2D strain, is predictive of New York Heart Association functional class.⁸¹ These findings suggest that 3D speckle-tracking strain could be useful in predicting clinical outcomes and in various cardiac and systemic diseases. Two factors which can affect the results of 3D strain are the image quality and temporal resolution. However, we need more multicenter studies to validate this technique over the well-established 2D strain. Therefore,

more data is needed to assess the reliability, feasibility, and reproducibility of this novel technique.

LEFT VENTRICLE DYSSYNCHRONY ANALYSIS

Various echocardiographic techniques have been used to diagnose intraventricular dyssynchrony in order to select patients for cardiac resynchronization therapy (CRT). Most commonly used technique for dyssynchrony evaluation is tissue Doppler method. This method has limitation that it allows simultaneous comparison of only those LV segments which are included in the scan plane which implies that all LV segments cannot be analyzed within the same cardiac cycle. LV dyssynchrony is a 3D process.⁸² In this context, RT3DE can be a promising technique as it allows simultaneous dyssynchrony assessment of all myocardial segments in the same cardiac cycle.⁸³ The 3DE-based LV dyssynchrony assessment can be done by volumetric analysis or by tri-plane tissue synchronization imaging.^{32,84} For volumetric analysis in 3DE, LV cast is divided into ASE defined 16 or 17 segments. Volume of each myocardial segment is then calculated and plotted for each cast. If all the segments of ventricle are contracting synchronously, then each segment is expected to reach its minimum volume at almost the same time during the cardiac cycle. Conversely, in a dyssynchronous LV there will be dispersion in the timing of achievement of minimum volume for each myocardial segment (Fig. 5). Systolic dyssynchrony index (SDI) can be calculated from the degree of dispersion by measuring the standard deviation of the time to achieve minimum volume. SDI can be expressed as a percentage of cardiac cycle enabling comparison between patients who have different heart rates.⁸³ Higher levels of dyssynchrony indicate high degree of dispersion. The

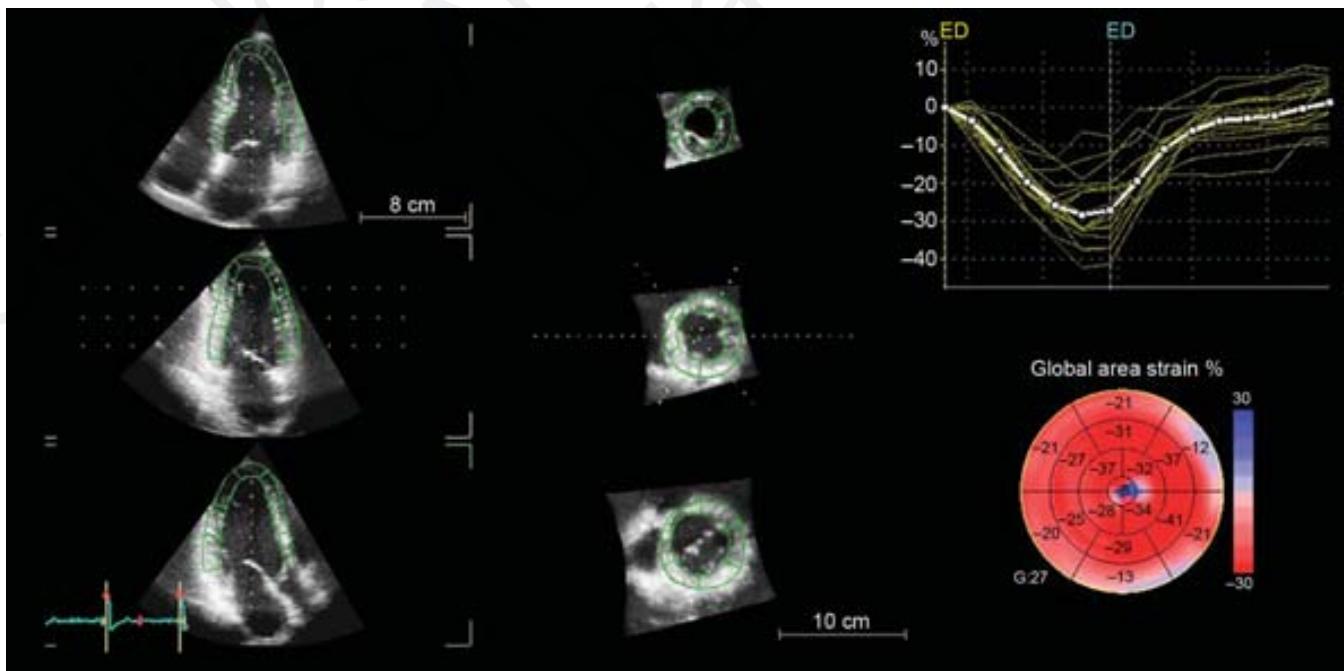

FIG. 4: Three-dimensional speckle-tracking echocardiography. From a single volume dataset, all different components of left ventricular (LV) regional and global strain are derived. Shown in this example is LV global and segmental area strain.

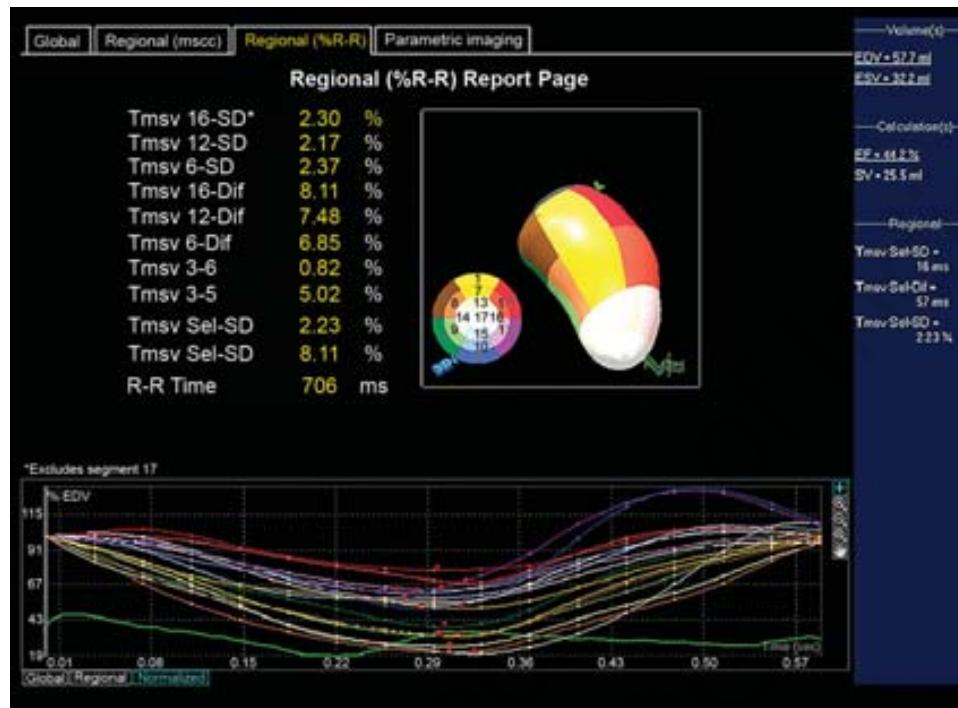

FIG. 5: Left ventricular dyssynchrony analysis by three-dimensional echocardiography. Segmental volume waveforms are created to quantify regional mechanical dispersion.

timing of contraction of different segments of LV can also be displayed in the form of parametric bull's eye. In this method, LV contraction is examined at approximately 700–800 points over the endocardial surface. Different regions of LV are color-coded according to the time of contraction and thus help in identifying the last contracting regions. This approach can be used by electrophysiologists for optimal positioning of LV electrode.

With the introduction of four-dimensional matrix phased-array transducer, triplane imaging is possible and with tissue Doppler imaging all 12-basal and mid-LV segments can be compared simultaneously from the apical window.

Real-time three-dimensional echocardiography seems promising in detecting and quantifying LV intraventricular dyssynchrony and is also useful in predicting patients who will show response to CRT and will show reverse remodeling post CRT.⁸⁵ Studies have demonstrated feasibility of RT3DE in the assessment of intraventricular LV dyssynchrony.⁸⁶ However, inter- and intra-observer reproducibility of the 3D dyssynchrony is hampered by suboptimal image quality⁸⁷ and is less robust than that of tissue Doppler imaging.^{88,89} The inferior temporal resolution of 3DTTE when compared to tissue Doppler imaging is another important limitation.⁹⁰ Though with the introduction of second generation 3DE scanners, the low temporal resolution does not seem to be a major drawback for LV dyssynchrony assessment.² Since, 3DE measures regional volume changes and not regional velocities (as tissue Doppler imaging, which requires a high frame rate), it seems likely that echo systems using a temporal resolution of 20–30 volume/s are adequate to sample the

usual frequency of regional volume curves which is less than 10Hz.⁹¹

Tissue Doppler methods are still considered to be the “gold standard” method for establishing dyssynchrony and it is yet to be ascertained, if 3D-based methods are superior. There is need of more data to know the accuracy, feasibility, and reproducibility of RT3DE based intraventricular dyssynchrony analysis. A reliable, clinically meaningful cut off value for the 3D dyssynchrony index remains to be established.⁹⁰ Larger, multicenter studies are required to evaluate the role of 3DE-based dyssynchrony assessment in the evaluation of patients prior to CRT.

VALVE ASSESSMENT

Three-dimensional echocardiography plays an important role in the diagnosis of valvular heart disease especially for mitral valve (MV) assessment. Image resolution, a factor of concern for transthoracic 3D imaging, has become less of an issue with the introduction of 3D TEE.

Mitral Valve

Among the four heart valves, 3DE, especially RT3D TEE, is most helpful in the diagnosis and management of MV pathologies.

Mitral Regurgitation

There are variety of mechanisms which can result in mitral regurgitation (MR). MV malcoaptation and MR can occur due to dysfunction of LV, papillary muscles, chordae tendineae, mitral annulus (MA), and the MV leaflets. Carpentier's

functional classification describes the mechanism of MV dysfunction based on leaflet motion (normal motion, prolapse or restriction of a leaflet opening or closure). The rationale for treatment depends on the mechanism of MR. Therefore, it is important to identify the type and extent of leaflet motion abnormality. The 3DE provides better overall perspective in the assessment of MV pathology and severity of mitral regurgitation.

Assessment of Mitral Valve Morphology

To assess MV by 2DE, multiple views are required to scan all the segments of the two leaflets and then the operator has to mentally reconstruct the MV image. 3DE can overcome this limitation by providing the *en face* or “surgical” view of MV from the left atrium which cannot be obtained by 2DE. The image can be optimized to bring the entire leaflets and annulus into view (Fig. 6). With the help of established landmarks, the entire coaptation line can be defined from the anterolateral commissure to the posteromedial commissure, passing through the valve segments. This allows accurate assessment of each segment in relation to the MA along with evaluation of segmental prolapse or tenting in relation to the annulus. By using 3D color full volume imaging, additional smaller jets along the coaptation line and commissures can also be detected in addition to the primary jet which can result in residual regurgitation post-repair and may help the surgeon to reassess the sites of the mitral leaflet coaptation requiring attention.

Three-dimensional TEE is found to be superior to 2D TEE and 3D TTE in terms of diagnostic accuracy of localization of leaflet prolapse (96.5, 87, and 90%, respectively; $p < 0.001$)⁹² and other structural defects of MV (Figs. 6 to 8). The 3D TEE is more accurate than 2D TEE at defining the extent of leaflet prolapse when compared against the surgical findings⁹³ (Fig. 6) and superiority is maintained even in complex cases where multiple MV segments are involved.⁹⁴ With the help of 3D TEE it was demonstrated that in MV disease, early systolic changes in MA, i.e., size reduction and deepening of MA, are less marked despite a similar amount of ventricular contraction. This ventricular-annular decoupling plays an

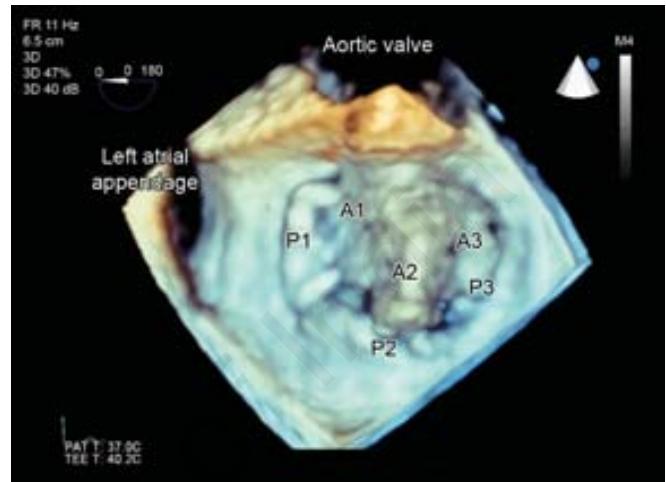

FIG. 6: *En face* view of the mitral valve as visualized from the atrial aspect. As per convention, the aortic valve is on top of the image and the left atrial appendage is towards the left side. All different scallops of anterior and posterior mitral leaflets are clearly visualized. A2 scallop prolapse can also be appreciated.

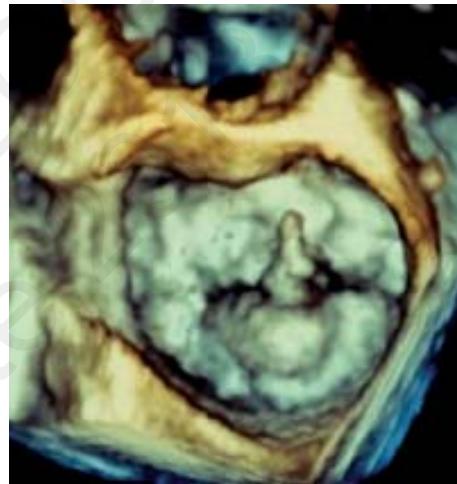

FIG. 7: Flail P2 segment of the posterior mitral leaflet. Ruptured chordae attached to the flail segment is also seen.

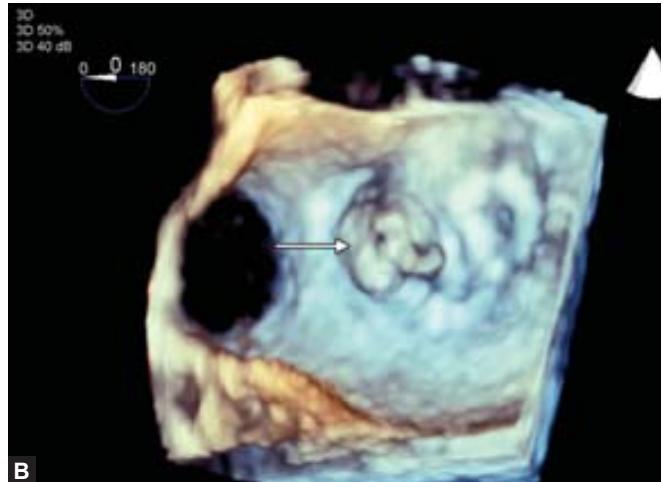

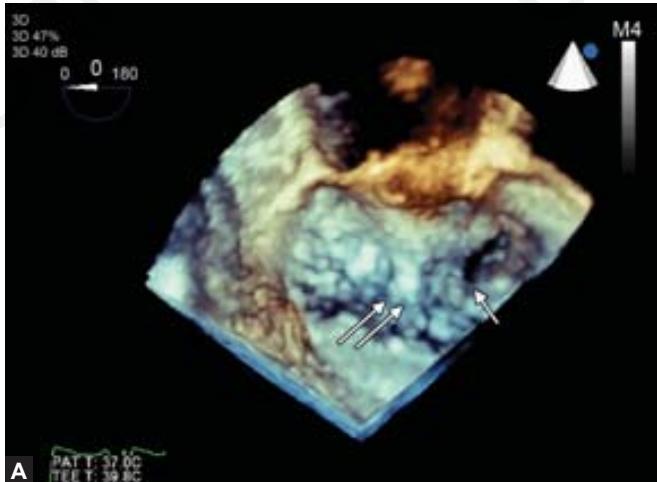

FIG. 8: Two examples highlighting utility of three-dimensional transesophageal echocardiography in the assessment of mitral valve pathologies. **A**, There is perforation in the A3 segment (single arrow) and prolapse of the A2 segment; **B**, A1 P1 segments are flail with perforation in A1 (arrow).

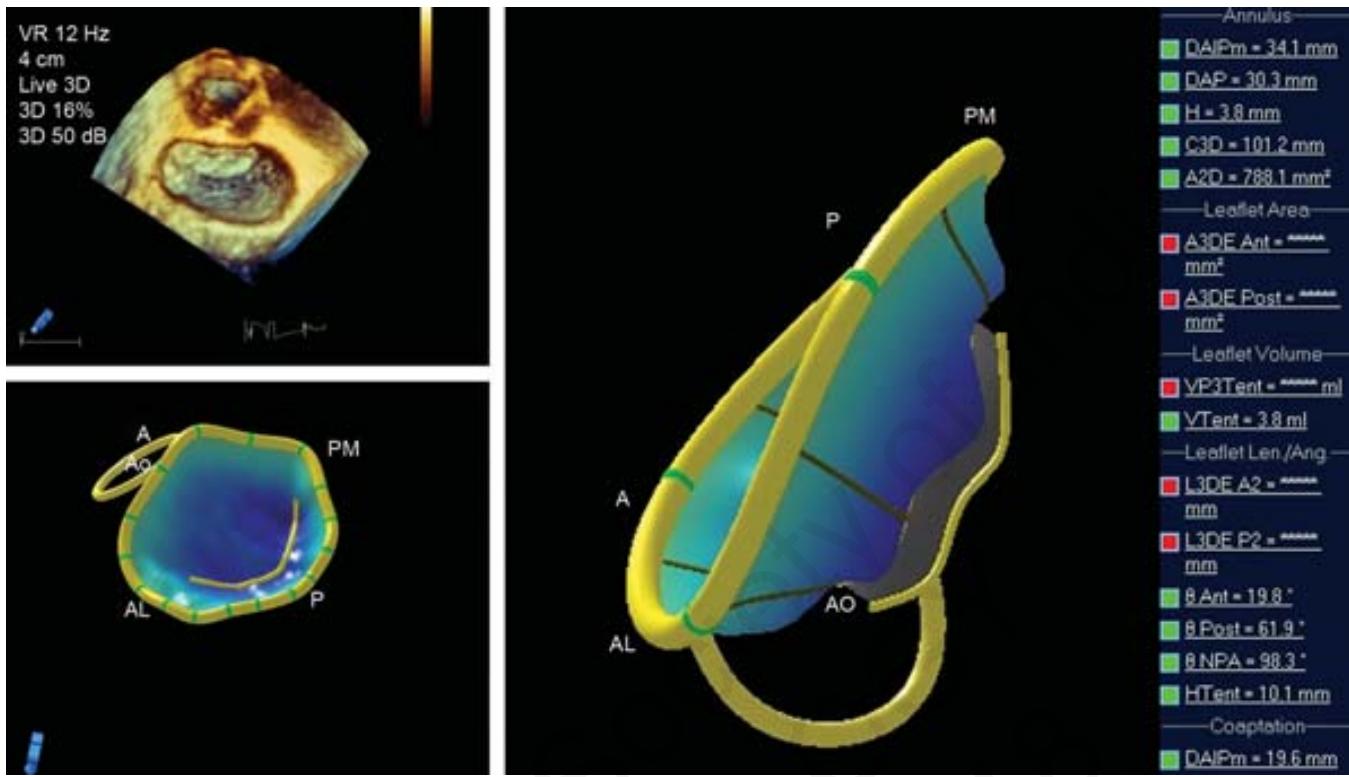

FIG. 9: Mitral valve analysis software for detailed characterization of the mitral apparatus anatomy in patients with functional mitral regurgitation.

important role in causing mitral incompetency. There is MV quantification software which enables comprehensive evaluation with precise measurements of the annulus and leaflets, aortic-mitral angles and papillary muscle position (Fig. 9) and is likely to play an important role in preoperative planning of MV repair in the future. However, there is limited published data on its clinical use.

Assessment of Mitral Regurgitation Severity

Methods used to quantify MR severity are vena contracta (VC) and proximal isovelocity surface area (PISA) assessment. PISA allows the calculation of effective regurgitant orifice area and regurgitant volume.⁹⁵ The conventional PISA method assumes a hemispheric shape of the isovelocity surface, which is usually not the case. Assessment of the severity of MR by 2DE can be challenging, particularly with eccentric jets. Three-dimensional color Doppler enables better assessment of the origin, shape, and size of jets.^{96,97} The novel 3D techniques allow evaluation of the correct shape of proximal flow convergence region resulting in more precise measurement of the VC and PISA (Fig. 10).^{98,99} The 3D-derived data has provided better insight in understanding the shape of the regurgitant orifice.¹⁰⁰ PISA is more spherical in degenerative MV disease and more elongated and elliptical in functional MR and this partly explains the discrepancies in regurgitation severity by 2D PISA methods. Underestimation of MR can be reduced from 49 to 26% with application of hemi-ellipsoid formula.¹⁰¹ The VC area determined by color Doppler 3DE has also been

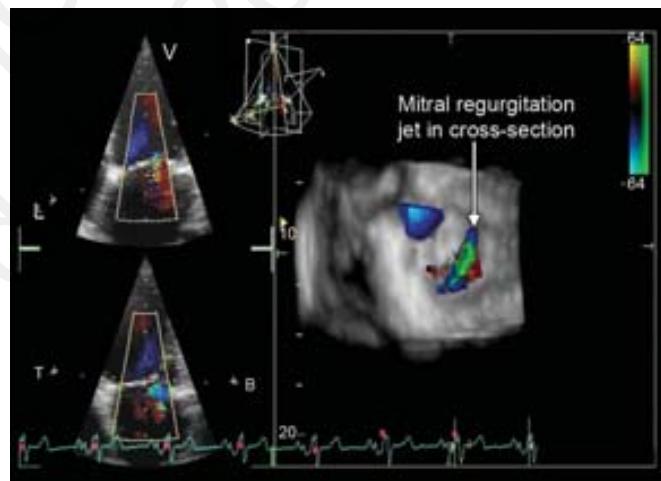

FIG. 10: Use of three-dimensional echocardiography for visualization and quantification of the shape and the size of the mitral regurgitation vena contracta.

found to be useful for quantification of MR.^{99,102-105} Studies have shown that there are variety of VC shapes in functional MR patients.¹⁰³ The idea of 3D VC seems promising as it is free from geometric assumptions. Despite these advances, the routine clinical use is limited as the analysis by these methods is time-consuming. Moreover, factors like image resolution, dependence on multiple cardiac cycles (7–14 cycles) and narrow sector acquisitions increase the chances of artifacts.

Mitral Stenosis

Transthoracic echocardiography is usually sufficient to assess mitral stenosis (MS) severity. TEE is usually done to exclude intracardiac thrombi before a percutaneous or surgical intervention. Quantification of MS severity is usually described in terms of mean transmural gradient and mitral orifice area.¹⁰⁶ The “effective” mitral orifice area can be calculated by Doppler-derived methods like pressure half-time measurement (PHT), continuity equation, and PISA method. However, these methods are influenced by many factors like heart rhythm, tachycardia, nonlinear Doppler velocity curves and associated valvular disease, and are also not reliable in the immediate post-balloon valvuloplasty period. Therefore, direct planimetry is favored to measure the true MV orifice area. This is considered to be the reference method in clinical practice. It has also been shown that this method is more closely related with the anatomic MV area (MVA) when compared with explanted valves.¹⁰⁷ However, obtaining the narrowest mitral orifice opening with 2D planimetry requires considerable experience and may be specifically difficult when the stenotic MV forms a funnel shape and the orifice is placed obliquely. Moreover, there is no definitive anatomical landmark to make sure that the short-axis view used to trace the MV orifice is the narrowest one, which can lead to underestimation of MS severity.¹⁰⁸

Three-dimensional echocardiography can overcome the limitations of 2D MV planimetry as it allows cropping of the 3D data set and defines the true MV anatomic area. Multiplanar 3D imaging can also be used to display the orifice in both the long and the short axis. MVA planimetry by 2DE was compared with MVA by 3D TEE in 87 patients. It was demonstrated that 2D planimetry tends to overestimate MV orifice area when compared with 3D TEE measurements especially in patients with a large left atrium.¹⁰⁹ 3DE-based MVA is more accurate and reproducible with superior interobserver and intraobserver concordance when compared with MVA by 2D planimetry and PHT (Fig. 11).¹⁰⁹⁻¹¹¹

Sugeng et al.¹¹¹ demonstrated that direct 3D planimetry of MV from ventricular aspect is the most accurate method for MVA estimation. Studies have also shown that 3DE derived MVA is highly correlated with those obtained from invasive catheter measurements using Gorlin’s formula¹¹² in both rheumatic and calcific mitral stenosis.^{113,114} Additionally, 3DE is also useful in detailed morphological assessment of mitral valvular and subvalvular apparatus which is particularly important in candidates undergoing balloon mitral valvotomy. Reliable 2D planimetry is difficult when the MV leaflets have significantly calcification. This limitation can be overcome by 3D TEE by imaging the mitral orifice from the LA *en face* view because calcific shadowing is on the ventricular side.

Percutaneous balloon mitral valvuloplasty (PBMV) is an effective therapeutic modality in selected patients with MS. Main predictor of a successful PBMV is MV morphology. Wilkins’ score, based on valve structure, is most commonly used 2DE-based scoring system to predict the procedural success for mitral valvuloplasty. Anwar et al.¹¹⁵ introduced a new 3DE-based score for evaluating patients with MS before valvuloplasty. This score involves the assessment of both mitral valvular and subvalvular apparatus. This score is found to be feasible and reproducible with good interobserver and intra-observer agreement in the evaluation of MV morphology in MS and can provide incremental prognostic information in addition to Wilkins’ score.

The 3DE is also better in detecting complication as it can determine clearly if the increase in valve area is due to commissural splitting or leaflet tearing

Aortic Valve

Aortic valve (AV) has oblique orientation and is more complex than just its three semilunar cusps. AV with aortic root is called as AV complex and can be evaluated by TTE and TEE but for complete assessment of its complex geometry, it has to be imaged through multiple echo windows. With 3DE we can image AV from different perspective with no erroneous geometric assumptions.

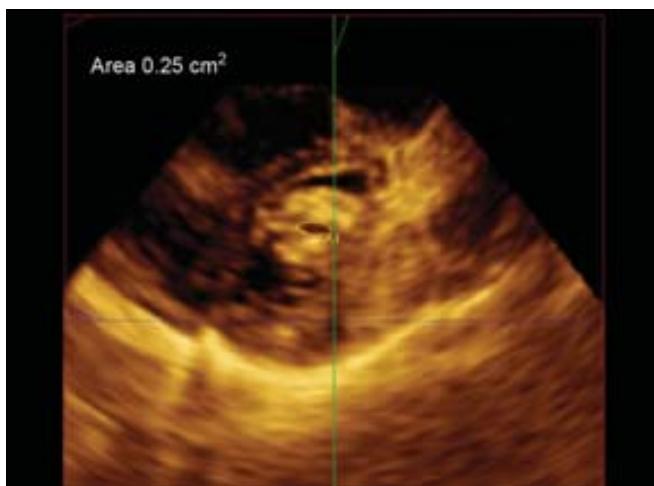

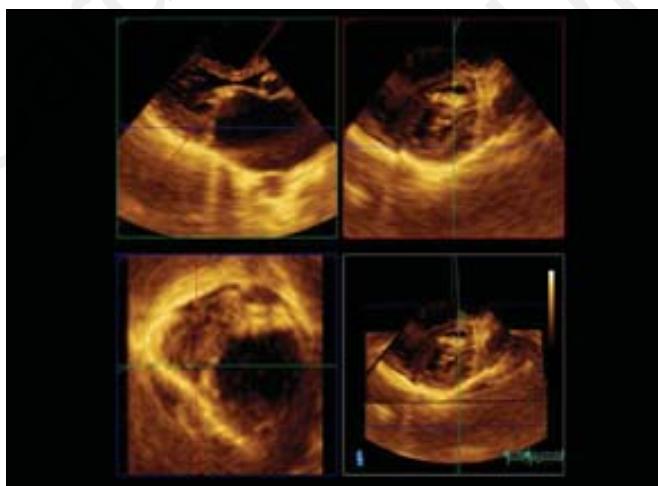

FIG. 11: Mitral valve area planimetry using three-dimensional echocardiography in a patient with rheumatic mitral stenosis. Three-dimensional echocardiography allows accurate alignment of the imaging plane at the leaflet tips so that correct measurement of mitral valve area can be performed.

Aortic Stenosis

Quantification of aortic stenosis (AS) by echocardiography is based on the measurement of gradients derived from transaortic velocities and valve area derived from continuity equation.¹⁰⁶ The 2DE-based calculation of the AV area (AVA) by continuity equation is based on various assumptions: firstly, left ventricular outflow tract (LVOT) is circular and can be described by its anteroposterior diameter in parasternal long-axis view; secondly, the cut plane is exactly parallel to LVOT; thirdly, pulse wave Doppler of LVOT flow is obtained at the same site where the LVOT diameter is measured. Because the LVOT area calculation involves the squaring of LVOT diameter, the LVOT diameter is a potential source of error in the AVA calculated by continuity equation.¹⁰⁶ Accurate measurement of LVOT geometry and size is an essential component in the quantitation of AS severity. Correct size is also important for calculating stroke volume and during interventions like transcatheter aortic valve implantation (TAVI) or for guiding the muscle reduction therapeutic procedures in hypertrophic obstructive cardiomyopathy. It has been shown by both multi-slice cardiac tomography (MSCT) and 3DE studies that LVOT has an elliptical configuration rather than a circular one.^{116,117} Therefore,

LVOT and aortic annulus calculation by 2DE may not give correct values. Three-dimensional TEE has the potential to overcome this limitation of 2DE by direct planimetry of aortic annulus and LVOT areas. LVOT or aortic annulus area by 3D TEE (Fig. 12) has shown good correlation with gold standard MSCT. Even the LVOT area derived from 3D TTE biplane imaging has shown improved accuracy in the stroke-volume measurement¹¹⁸ and AS severity quantification, when compared with direct planimetry.¹¹⁹ Studies have demonstrated that LVOT diameter-based calculations by either 2DE or 3DE result in significant underestimation of AVA (by 16.4% and 12.9%, respectively).¹²⁰ Quantification of AV complex geometry by 3D TEE has also shown good correlation with the measurements obtained by MSCT.¹²¹ Since, 3DE-derived LV volumes has good accuracy and reproducibility, LV stroke volume can also be calculated by subtracting the end-systolic from the end-diastolic 3D LV volume. This can overcome the limitation of conventional continuity equation.⁴ This approach has also been found to have better correlation with the invasive AV area calculation by Gorlin's equation than by using conventional continuity equation.¹²²

In certain cases of AS, Doppler methods are not reliable to assess AS severity, as in patients with small aorta, subaortic

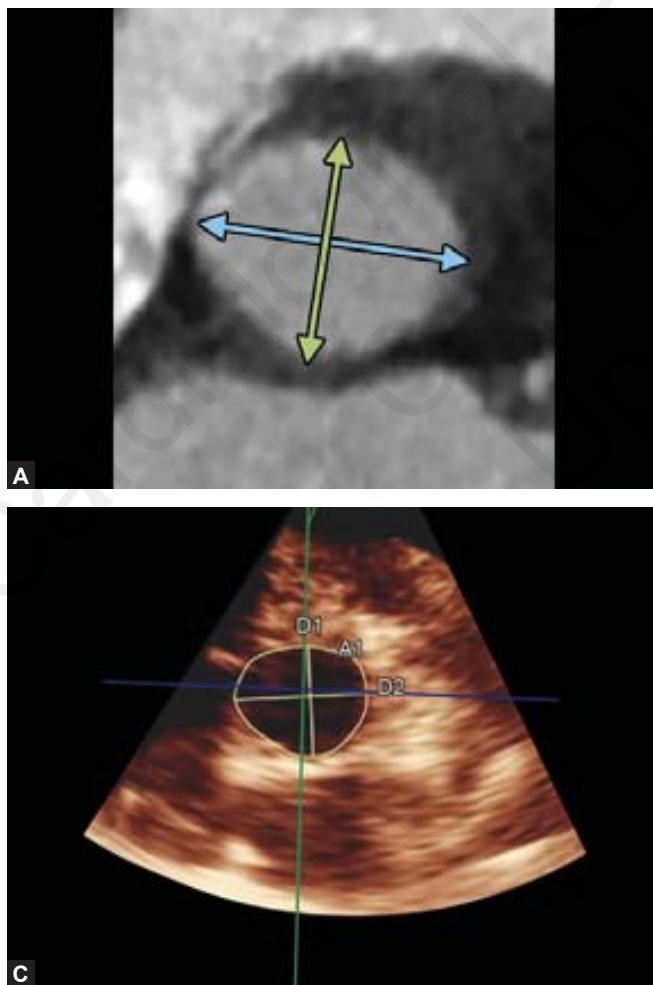

FIG. 12: Advantage of three-dimensional echocardiography for measurement of left ventricular outflow tract (LVOT) area. **A**, Computed tomography reveals oval shape of the LVO; **B**, Single measurement in two-dimensional imaging is likely to underestimate LVOT area; **C**, Three-dimensional echocardiography permits measurement of true LVOT area.

stenosis, significant aortic regurgitation (AR) and LV dysfunction. In these cases, direct AV planimetry becomes important for diagnosis. AVA by 2DE planimetry is prone to errors as there are high chances of off-axis imaging of the AV orifice which is a nonplanar 3D structure, especially in diseases like bicuspid or degenerative valve disease when the orifice is distorted. In addition, aortic annulus shows movement during cardiac cycle with more caudal position during isovolumic relaxation and cranial movement during early systole.¹²³ Therefore, fixed 2D cut plane frequently shows larger AV orifice area rather than true narrowest opening leading to overestimation of AVA.¹²⁴ The 3D TEE planimetry has shown better accuracy than 2D TEE.¹²⁵ Moreover, 3DE also provides information about valvular as well as subvalvular stenosis.

However, AVA planimetry by both 3DE and 2DE is not reliable when there is significant valvular calcification, as orifice tracing will be difficult due to artifacts like shadowing or reverberations, and also in low cardiac output states, as the anatomic area of AV opening is reduced. Another limitation of 3DE is its lower frame rate which hampers its ability to precisely capture the maximum systolic opening of the aortic cusps.

Aortic Regurgitation

Aortic regurgitation can occur due to aortic root dilatation or due to valvular abnormalities such as a bicuspid AV, rheumatic heart disease and degenerative valvular disease. RT-3D TEE can reveal important anatomical differences in various AV diseases causing AR.¹²⁶ AR severity is assessed by various qualitative and quantitative 2DE-based Doppler techniques. Most commonly used method is the ratio of AR jet width immediately below the AV to the inner LVOT width taken in the same frame. Another parameter is VC, which is the size of the jet within the leaflets and extending for a small extent into the LVOT. The assessment of exact size and shape of the VC is important in the quantification of regurgitant lesions. Generally, VCA is considered circular or elliptical, but this assumption is usually incorrect.¹²⁷ In the parasternal long-axis or apical views, only one dimension of the AR jet is visualized. Therefore, the measured size or area is based on an assumption regarding its shape. A parasternal short-axis view at the level of the AV leaflets on 2DE with color Doppler would probably define the VCA in 3D, but because of cardiac motion, it is difficult to ensure that the measured jet size is within the leaflets and not further downstream where it tends to be larger. For reliable VCA measurements short axis echo plane should be exactly parallel to the VC, which is difficult to ensure on 2DE. Whereas, a pyramidal dataset, acquired by RT3D echo, can be cropped in multiple transverse planes at any desired angle and this allows the alignment of the plane exactly parallel to the VC in a short-axis or perpendicular to the direction of AR jet in long axis, at or just below the AV level. This approach has good accuracy, when compared with magnetic resonance, angiography or comprehensive conventional Doppler evaluation.¹²⁸⁻¹³⁰ The 3DE-derived regurgitant volume was found to have high correlation to the

velocity encoded-MRI-derived regurgitant volume ($r = 0.94$ and -13.6 to 15.6 mL/beat, respectively). The 3DE has the potential to obviate the limitations of 2DE color Doppler and is a useful supplement to 2D TTE.

Tricuspid Valve

Tricuspid valve (TV) assessment is very important in many cardiovascular diseases. The valve has three leaflets—septal, anterior, and posterior, but all three leaflets cannot be well visualized in one view using either TTE or TEE. Whereas, 3DE provides *en face* views of TV and thus enables visualization of the entire TV from any perspective. "*En face*" views (Fig. 13) may be particularly useful in localizing leaflet pathology such as prolapse, vegetations, or perforation and are also helpful in localizing the origin of regurgitant jets and performing planimetry of the tricuspid orifice area. In patients with optimal transthoracic acoustic window, evaluation of TV anatomy and function with 3D TTE is often feasible, though its evaluation requires more experience compared with MV 3D evaluation.¹³¹

Tricuspid Regurgitation

Tricuspid regurgitation (TR) can be classified into two main categories—primary TR and secondary TR. Primary TR occurs when there is leaflet abnormality as seen in Ebstein's anomaly, carcinoid heart disease, and TV prolapse. In secondary TR, valve leaflets are normal and TR is caused by abnormalities of the structures supporting the valves, such as dilatation of tricuspid annulus (TA) and/or RV dilatation and dysfunction or pulmonary hypertension. The 3DE has been found to be advantageous over 2DE for assessment of TV pathologies and the location of the TR orifice.¹³²⁻¹³⁴ This modality is also useful in patients with intracardiac devices to detect the location of lead and its relationship to valve leaflets and significant TR.¹³⁵⁻¹³⁷ One of the studies revealed that 45 out of 100 patients had TV leaflet interference due to device lead and most commonly affected is septal leaflet. Device lead

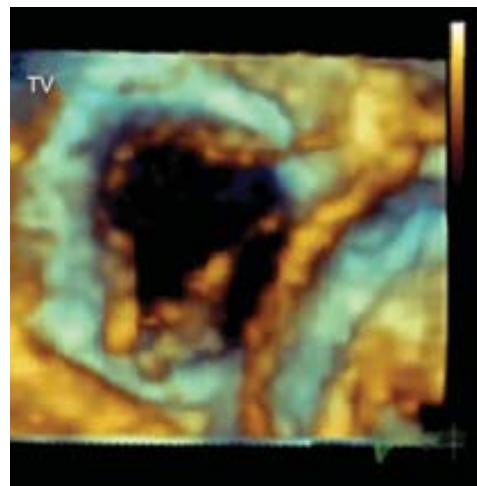

FIG. 13: *En face* view of the tricuspid valve as visualized from the ventricular aspect. All three tricuspid valve leaflets are visualized simultaneously.

interference increases the likelihood of developing significant TR by more than 10-fold.¹³⁶ TR is less commonly seen when the lead is placed in a commissural position.¹³⁵ Therefore, it was suggested that 3DE should also be done to assess lead interference in patients with significant TR.¹³⁶ Three-dimensional echocardiography also allows us to locate the anatomical regurgitant orifice of TR and to measure the VC, which was found to be more often ellipsoid than circular.¹³⁸

Tricuspid Annulus

Tricuspid annulus (TA) size and function plays vital role in the genesis of secondary TR. The accurate analysis of the TA is also required to assess the need for a combined procedure on the TV in patients undergoing cardiac surgery for left-sided valve diseases. Significant TA dilatation is defined by a diastolic diameter more than 21 mm/m² or more than or equal to 40 mm in the four-chamber transthoracic view, and is considered as a criterion for concomitant tricuspid procedure in case of left-sided valve surgery.¹³⁹

The TA is a complex nonplanar oval structure. Dilatation of the TA occurs mainly in the septolateral direction, resulting in more circular shape.¹⁴⁰ The recommended 2D transthoracic view for measurement of TA diameter is the apical four-chamber view^{139,141} as this view has better interobserver agreement compared with other views.¹⁴² The TA diameter varies according to the site of measurement, with reference values ranging between 25 mm and 39 mm.^{143,144} It's a dynamic structure and shows variability in size during the cardiac cycle, with an approximately 20% reduction in annular circumference with atrial systole.¹⁴⁵ Studies have shown that the diameter of TA is consistently underestimated by 2DE whereas 3D TTE obtained diameters has shown better correlation with those obtained from MRI.¹⁴⁶ Various studies have revealed that 3DE-based analysis of TA geometry and size has shown good feasibility.^{139,143,144,147-151} Various measurements can be obtained from 3DE, including major and minor TA diameters, TA fractional shortening, TA area, and TA fractional area change. The 3DE has determined that not only dilatation, but structural modifications of TA also contribute in the genesis of functional TR. The extent of TV tethering can also be quantified with 3D echocardiography in terms of the tenting volume and tenting angle of the three leaflets.^{152,153} All these parameters such as quantification of TA enlargement, the mode of leaflet coaptation and the degree of tenting are significantly important in making a surgical decision about TV repair or replacement. Normative data about TA diameter and function are limited. In fact, the 2D view and in which phase of cardiac cycle TA should be measured is still a matter of debate.¹⁴⁵ Because TA diameter is usually underestimated by 2DE, it seems necessary to redefine normal TA values with 3D imaging. Furthermore, more complicated analysis of the nonplanarity of TA can also be performed from 3D acquisitions, which have potentially important mechanistic and therapeutic implications for TV repair.^{143,147}

Tricuspid Stenosis

Most common cause of tricuspid stenosis (TS) is rheumatic heart disease, affecting up to 8% of patients.¹⁵⁴ The 2DE estimates the severity of TS by detecting the thickening of TV leaflets, restricted valve opening and by estimation of the tricuspid transvalvular pressure gradient by continuous wave Doppler.¹⁵⁵ However, on 2DE it is not possible to visualize all three leaflets simultaneously and therefore, planimetry of TV area is not possible with 2DE. RT3D-TEE provides short-axis views of the valve with simultaneous viewing of the three leaflets and their junction with the annulus, enabling planimetry of TV with high accuracy. As of now we have limited data on the use of 3DE in patients with TS and we need more studies to assess its feasibility and accuracy. However, the additional knowledge obtained by 3DE can still be useful in the diagnostic and therapeutic decision making in patients with TV involvement.

Infective Endocarditis

Transesophageal echocardiography plays a pivotal role in the diagnosis and management of infective endocarditis (IE). Therefore, TEE is done in almost all suspected cases of IE.¹⁵⁶ The 2D TEE has sensitivity of 85–90%, with a specificity of approximately 90–100% in the detection of vegetation¹⁵⁷ and is also useful in evaluating complications of IE like abscess (sensitivity 90% and specificity 90%)¹⁵⁸ fistulae, pseudoaneurysms, and perforated leaflets. 3DE can provide better visualization about the entire cardiac structure so, it may have an incremental value over 2DE, especially when large vegetation are present. Hansalia et al.¹⁵⁹ compared 3D TEE and 2D TEE in 13 patients with valvular vegetation and concluded that during surgery 3D TEE was superior in determining the overall presence and exact site of valvular vegetation. These authors also suggested the possibility that 3D TEE can measure the volume of vegetation, and they showed low interobserver variability between measurements performed by means of 3DE. The improved spatial orientation of 3D TEE can provide better information regarding the relationship between vegetation, prosthesis, and adjacent structures. These advantages of 3DE might enable better risk stratification, surgical decision-making, and operative planning. In one study, it was found that¹⁶⁰ only 48% of abscesses detected intraoperatively correlated with preoperative 2D TEE findings. Because abscesses are not limited to specific tissue planes and can extend in directions beyond the planes, 2D TEE may not provide complete information. Moreover, 3D TEE has been found to be superior in identifying the sequelae of IE in prosthetic heart valves, especially in locating and evaluating prosthetic dehiscence, perivalvular abscesses, and valvular perforation.^{159,161-164} At present 3D TEE should be used as a supplement to standard 2D and its major limitation, i.e. low frame rate should always be kept in mind as it may impair detection of smaller vegetation.

Prosthetic Valves

Transesophageal echocardiography provides better images of prosthetic valves than TTE. However, 2D TEE can fail to identify important findings as the entire prosthetic valve cannot be seen in single image. RT3D TEE allows comprehensive imaging of prosthetic valve components and is also useful in detecting associated complications (Fig. 14). This is extremely helpful in the evaluation of mechanical prosthetic valves where 2D image quality is usually suboptimal due to acoustic shadowing. Because 3D images can be cropped into multiple planes, deeper cardiac structures can be visualized more clearly when compared to 2D TEE. The 3D TEE has been found to be particularly helpful in the assessment of prosthetic valve endocarditis¹⁶⁵ as the “en face” view of prosthetic valves allows the identification of valve dehiscence, para-prosthetic leaks and involvement of adjacent cardiac structures. It has been shown that 3D imaging identifies additional vegetations which are not seen on 2D TEE¹⁶⁵ and can also help in distinguishing vegetation from loose suture material.

These advantages of 3D TEE can help in complete assessment of the prosthetic AV and MV and associated complications (Fig. 15).¹⁶⁶ Although, the visualization scores for AV are lower than for MV prostheses.¹⁶⁶

TRANSCATHETER INTERVENTIONS FOR VALVULAR HEART DISEASE

Recently transcatheter valve implantation and repair have emerged as promising therapeutic procedures for patients with valvular heart disease. Procedures like TAVI and mitraclip have been found to be noninferior when compared to surgery in high-risk patients. Echocardiography plays a central role in selecting suitable patients for these interventions and for monitoring of patients during and after the procedure. The 3DE is particularly useful in intra-procedural guidance as it allows visualization of cardiac structures in RT and therefore, facilitates safe manipulation of catheters, guide wires and device deployment. The 3DE helps in achieving high success rates in these procedures while avoiding potential complications.

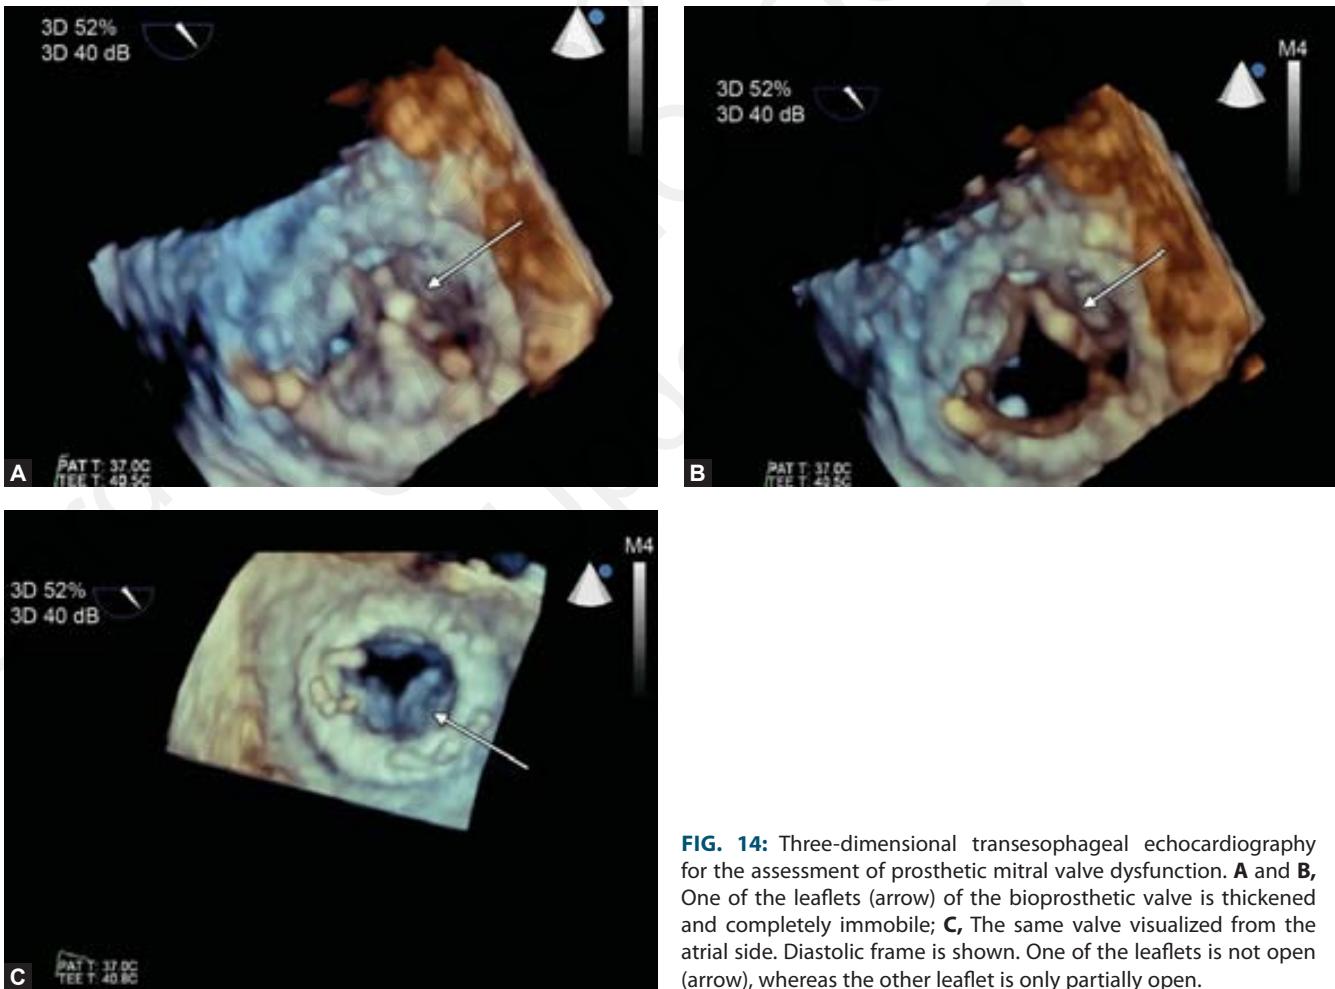

FIG. 14: Three-dimensional transesophageal echocardiography for the assessment of prosthetic mitral valve dysfunction. **A** and **B**, One of the leaflets (arrow) of the bioprosthetic valve is thickened and completely immobile; **C**, The same valve visualized from the atrial side. Diastolic frame is shown. One of the leaflets is not open (arrow), whereas the other leaflet is only partially open.

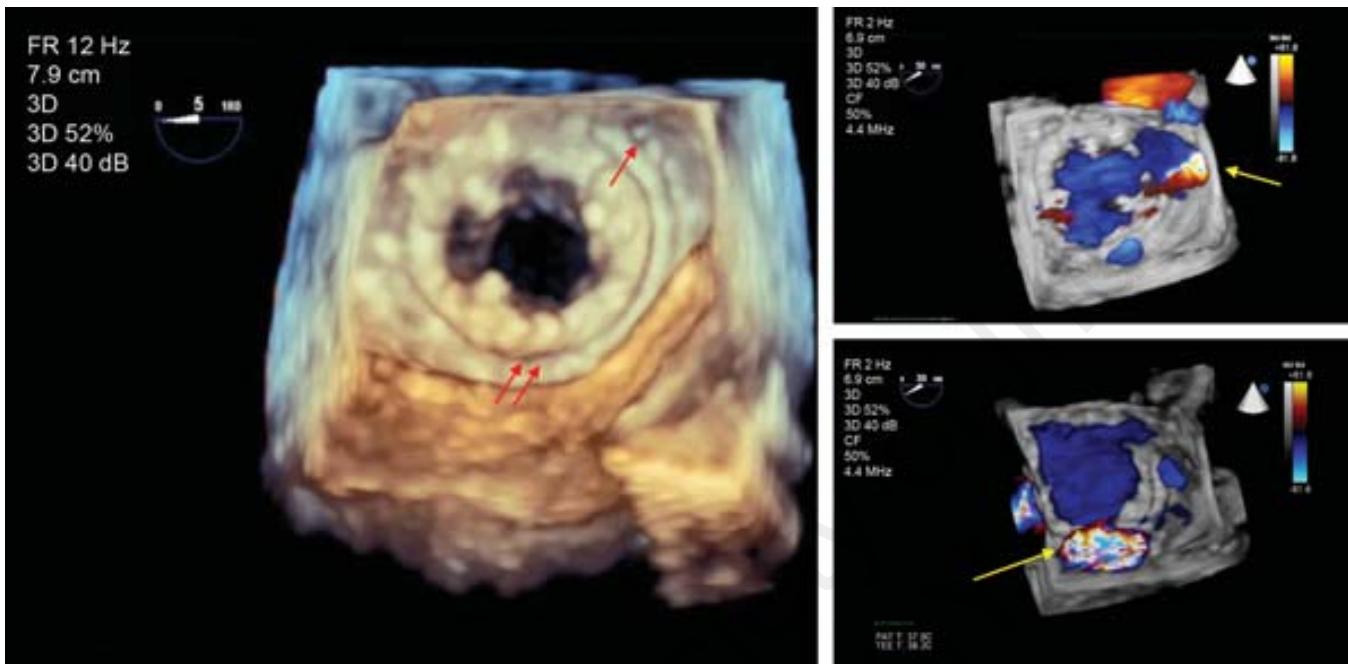

FIG. 15: Paravalvular defects around a bioprosthetic mitral valve. Left—gray scale image showing the location of the defects (arrows); Right—color Doppler confirming the presence of mitral regurgitation through these defects.

Paravalvular Leak (PVL) Closure

Transcatheter closure of PVL requires accurate assessment of the number, site and size of each defect and its relationship to the prosthesis and suture ring (Fig. 15). RT3D TEE, when compared with 2D TEE, is found to be superior in assessing these parameters as 3DE provides *en face* views of the prosthesis from both ventricular and atrial prospective. As a result, it helps in deciding if the procedure is feasible in a patient and it also shortens the procedure time because it facilitates catheter manipulation, device sizing and positioning. RT3D TEE has been found to be especially helpful during atrial trans-septal puncture and in guide wire and catheter manipulation through the defect (Fig. 16). 3D imaging is particularly advantageous as it allows visualization of the whole length of the intracardiac catheters and the attached devices and their position in relation to surrounding structures.^{167,168} 3D TEE plays an important role in choice of closure device, as well as the adequacy and success of the procedure.¹⁶⁹ Currently, for occlusion of small paravalvular leaks Amplatzer patent ductus arteriosus (PDA) device are used and Amplatzer ventricular septal defect devices are used to occlude larger paravalvular leaks (Figs. 16 and 17).

Transcatheter Aortic Valve Replacement (TAVR)

One of the most important component affecting the procedural success of transcatheter aortic valve replacement (TAVR) is the precise measurement of AV annulus and the aortic root for appropriate selection of the prosthesis type and valve size.¹⁷⁰ The 3DE-based techniques have shown that the aortic annulus is oval in shape and not circular as assumed in

2DE-based calculations. The 2DE under-estimates maximum aortic annulus dimension due to off-axis imaging.¹⁷¹ Accurate assessment of aortic annulus has been done by 3D TEE-guided direct planimetry and has been shown to have good correlation with results from multidetector CT (MDCT).¹²⁰ Another important measurement for the feasibility of TAVR is the distance of the annulus to the coronary artery ostia. This is usually measured by MDCT. The 2D TEE can measure the distance of aortic annulus to right coronary ostia but the annular ostial distance for left main coronary sinus cannot be measured as it lies in a plane which is not possible to image by 2D TEE. However, this distance can be measured by 3D TEE. Therefore, 3D TEE is an alternative option for these measurements especially in patients who are at higher risk of contrast-induced nephropathy. Compared to 2D, 3D TEE provides better guidance during the procedure like in guide wire manipulation while it passes through the LV, for adequate positioning of the prosthesis in relation to the native valve annulus and surrounding structures.

Mitraclip

Transesophageal echocardiography is an important imaging modality used at all stages of mitraclip procedure. Use of 3D TEE is required for adequate guidance of the clip delivery system towards the MV as 3D TEE provides better understanding of spatial relationship of clip delivery system with the surrounding structures like LA wall and MV. Three-dimensional views are useful in maneuvering the catheters in the LA cavity without touching the wall of LA and also helpful in ensuring that mitraclip device remains perpendicular to the commissure. The 3DE provides *en face* views of the repaired MV which are helpful in confirming the adequacy

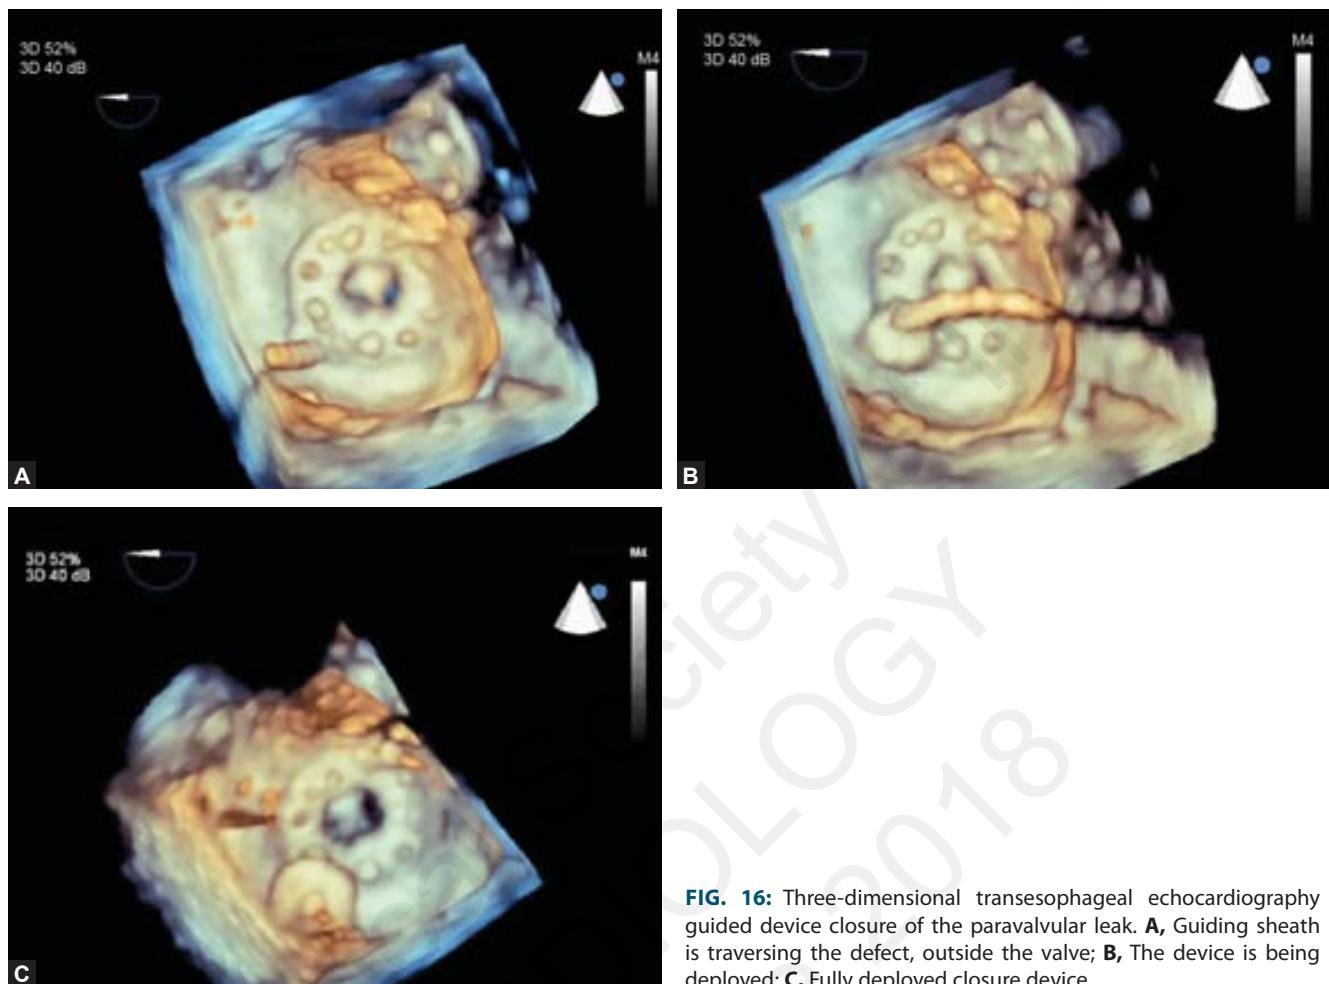

FIG. 16: Three-dimensional transesophageal echocardiography guided device closure of the paravalvular leak. **A**, Guiding sheath is traversing the defect, outside the valve; **B**, The device is being deployed; **C**, Fully deployed closure device.

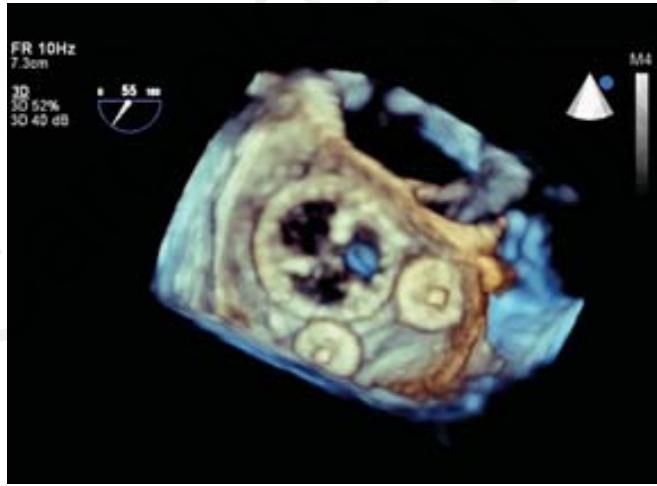

FIG. 17: Same patient as in Figure 15. Both the leaks have been closed.

of the procedure, any eccentricity of the dual orifices created by the device and location and extent of any residual regurgitation. Altıok et al.¹⁷² compared procedural effects of percutaneous MV repair by using RT3D TEE and 2D TEE and 3D TEE was shown to be advantageous in most of the steps of percutaneous mitral repair procedure.

Transcatheter Mitral Valve Replacement

In transcatheter mitral valve replacement (TMVR), 3D TEE is extremely useful in the pre-, post-, and intra-procedural guidance. Measurement of MA is important for correct sizing of the prosthesis and for TMVR planning. Although with 2D TEE the commissural and long-axis views provide the major and minor MA diameter, respectively. However, 2D measurements do not completely describe the complex 3D MA geometry, and produced values are strongly dependent on their exact orientation. Therefore, optimal visualization of the annular plane cannot be guaranteed with 2D TEE. The 3DE has the potential to overcome these limitations as the wide angle 3D mode (zoom 3D) enables complete visualization of the entire mitral apparatus from the MA to tip of papillary muscles. However, the broader sector mode is inferior to the “live” 3D mode in terms of temporal and spatial resolution. The narrow-angle “live” 3D mode is very useful in guiding deployment of device as it has higher temporal and spatial resolution but is not sufficient to visualize the complete MV apparatus.

Although, 3D TEE is advantageous over 2D TEE in SHD interventions, but it is still not recommended as the sole

imaging technique, because of the limitations with 3D TEE-like low frame rate and spatial resolution. Additionally, thin structures like interatrial septum and thin valves may show dropout artifacts resembling real holes and may result in wrong interpretation of 3D images. Ongoing advancements and understanding in 3D technology will further increase the use of this technique for guiding transcatheter interventions in SHD.

CONCLUSION

Over the past two decades, 3DE has evolved into a useful imaging modality for the assessment of cardiac anatomy and function in a variety of clinical settings. The major advantage of 3DE is that it allows comprehensive, spatial depiction of cardiac structures without any geographical assumptions or the need for mental reconstruction. Currently, 3DE has definite incremental utility over 2DE for estimation of LV volumes, assessment of MV pathologies and for guiding certain percutaneous interventions, whereas it has potential role in several other disease conditions. Further, improvements in temporal and spatial resolution of 3DE are needed to fully realize its true potential.

Intervention and Fusion Echocardiography

Shantanu P Sengupta

INTRODUCTION

Structural heart disease (SHD) in elderly is associated with significant valvular heart lesions which demands surgical therapy. But advancing age is associated with higher perioperative mortality and morbidity.^{1,2} Recent times has seen advances in less invasive therapies such as percutaneous or transcatheter interventions for treatment of SHD. Studies have shown that transcatheter aortic valve replacement (TAVR) is equal or better than surgical aortic valve replacement in high-risk surgical group of patients.³ Also the effective closure of the left atrial appendage (LAA) by few recent devices has helped in the reduction of thromboembolic complications in atrial fibrillation.⁴ Also many patients of severe mitral regurgitation have been benefited by percutaneous mitral valve repair using the MitraClip device.^{5,6} The future is also for the use of percutaneous mitral annuloplasty ring implantation or transcatheter mitral valve replacement for mitral valve pathologies.^{7,8}

Advances in cardiac imaging with its clinical implementation has helped in SHD interventions.⁹ SHD interventions demand clear visualization of the important structures in a beating heart. Real-time three-dimensional (3D) transesophageal echocardiography (TEE) and multislice computed tomography (MSCT) have advanced the visualization of complex valvular morphology and helped in performing necessary precise measurements for planning and tailoring of percutaneous therapies.⁹ During SHD intervention, multiple images are simultaneously shown in multiple screens which thus help in coordination of the imager and the interventionist.

Fusing echocardiography onto the fluoroscopy screen enhances workflow and improves procedural outcomes. This article is an effort to understand the concept, knowledge, and current use of fusion echocardiography for various SHD interventions in the present era of cardiology.

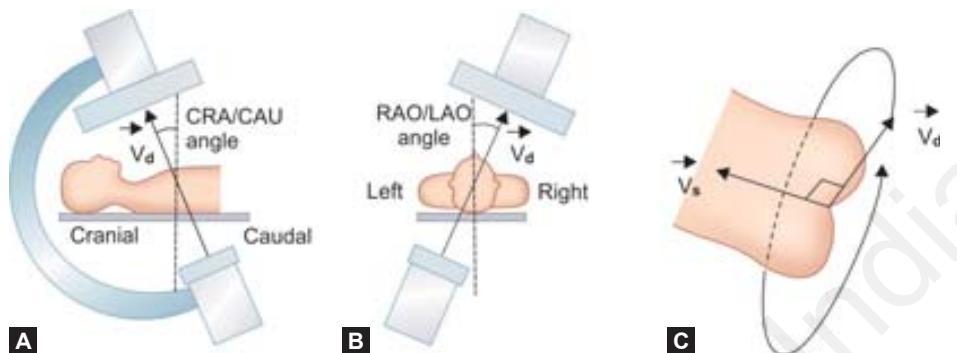

PROBLEMS DURING STRUCTURAL HEART DISEASE INTERVENTIONS

Structural heart disease interventions are generally performed with specialized catheters, wires, guides, sheaths, and implantation devices. This procedure is highly demanding and requires precision. SHD interventions involve a multidisciplinary approach with a strong coordination between cardiac interventionists, imagers, trained nurses, and catheterization laboratory technicians. The imaging specialist guides the interventionists in every step of the procedure with the use TEE probe limited to a narrow (although not fixed) view through the esophagus.^{10,11} This needs to synchronize with the C-arm of the fluoroscopy rotation to allow multiple views of the same cardiac structure (Fig. 1).¹² A successful procedure demands a good communication between interventional cardiologist who works on the catheters and the imager who operates on the 3D echo images. Such an approach requires real-time image coregistration with a sufficient overlay visualization of both imaging modalities.¹³ For this, real-time echocardiography with fusion of fluoroscopy—fusion echocardiography has recently been introduced.^{14,15}

UNDERSTANDING FUSION IMAGING

Fusion of Static Images

Last one decade has seen advances in fusion of static imaging in various forms. Fusion of cardiac computed tomography (CT) images with single-photon emission computed tomography (SPECT) has helped in understanding the relationship of coronary artery anatomy to corresponding ischemic area.¹⁶ Similar results have also been obtained with the fusion of images of MSCT and echocardiography for the identification of ischemic area.¹⁷ For diagnosis of prosthetic valve endocarditis, fusion of cardiac CT with

CAU, caudal; CRA, cranial; LAO, left anterior oblique; RAO, right anterior oblique.

FIG. 1: The angles in fluoroscopy. Vectors V_d and V_s are perpendicular and are optimal angles.

positron emission tomography scan imaging is rewarding.¹⁸ And for the selection of the correct size and type of prosthetic heart valve for TAVR, fusion of MSCT data with models of prosthetic implants has been used recently.^{19,20} However, these fusion imaging uses static images, which are not useful for SHD interventions, which require more dynamic imaging correlation due to presence of beating heart.

Fusion of Dynamic Images

For SHD interventions in beating heart, real-time images are acquired in a hybrid catheterization laboratory. The live images from fluoroscopy and 3D echocardiography get superimposed (Fig. 2).^{21,22} The latest software called EchoNavigator (Philips Medical Systems, Best, The Netherlands) overlaps the real-time (live) images from TEE over the fluoroscopy and is one such example being extensively used for SHD interventions.

Fusion imaging enables the amalgamation of image angle acquired from echocardiographic probe and the fluoroscopic angle. Once the fusion occurs, both the images move cohesively in all angulation simultaneously. The software also uses markers or dots to identify important structures which can be used as landmarks during SHD.

Use of Real-time 3D Fusion Imaging

One of the first steps of many SHD interventions is to make an accurate and safe puncture of the inter-atrial septum (Fig. 3). The procedure type demands the site of the puncture, as in

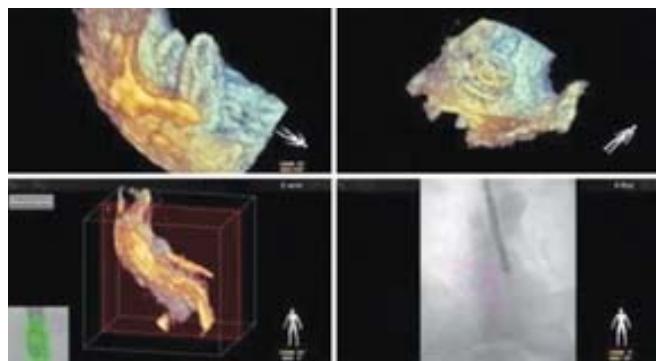

FIG 2: Integration of live images of echo and fluoroscopy.

inferoposterior (i.e., for percutaneous closure of the LAA) or anterosuperior at a level of 4 cm above the mitral annulus (MitraClip implantation). Real-time TEE helps in identifying the actual puncture site.

INTERATRIAL SEPTAL DEFECT CLOSURE

Nonsurgical interventional closures of patent foramen ovale (PFO) and interatrial septal defect are being mostly done in children and adults. Usage of TEE during this procedure makes it safer. Sometimes the passage across PFO is long, narrow, and negotiating the wire can be time consuming and a marker on the fused fluoro-echo image helps in this passage. Also, many times a PFO and small atrial septal defects (ASDs) can coexist. Negotiating the septum without echocardiographic image is not advisable. To achieve complete closure, however, anatomical knowledge is mandatory. Fusion imaging with the use of a marker prevents perforation of cardiac structures and helps in complete ASD or PFO closure with safe deployment of umbrella (Fig. 4).

Closure of Paravalvular Leaks

Paravalvular leaks (PVLs) have been diagnosed and are known complications of surgical and transcatheter valve replacement procedures. These can be targeted and closed by interventional procedures. It requires precise details of the defect for the selection of the appropriate type, size, and number of device.²³ Fusion imaging has been helpful during managing PVL closure as it provides ease in diagnosis and procedural guidance.²⁴ A direct visualization of the defect by real-time TEE improves spatial resolution of the defect, during placement of the guide wire after transseptal puncture.²³

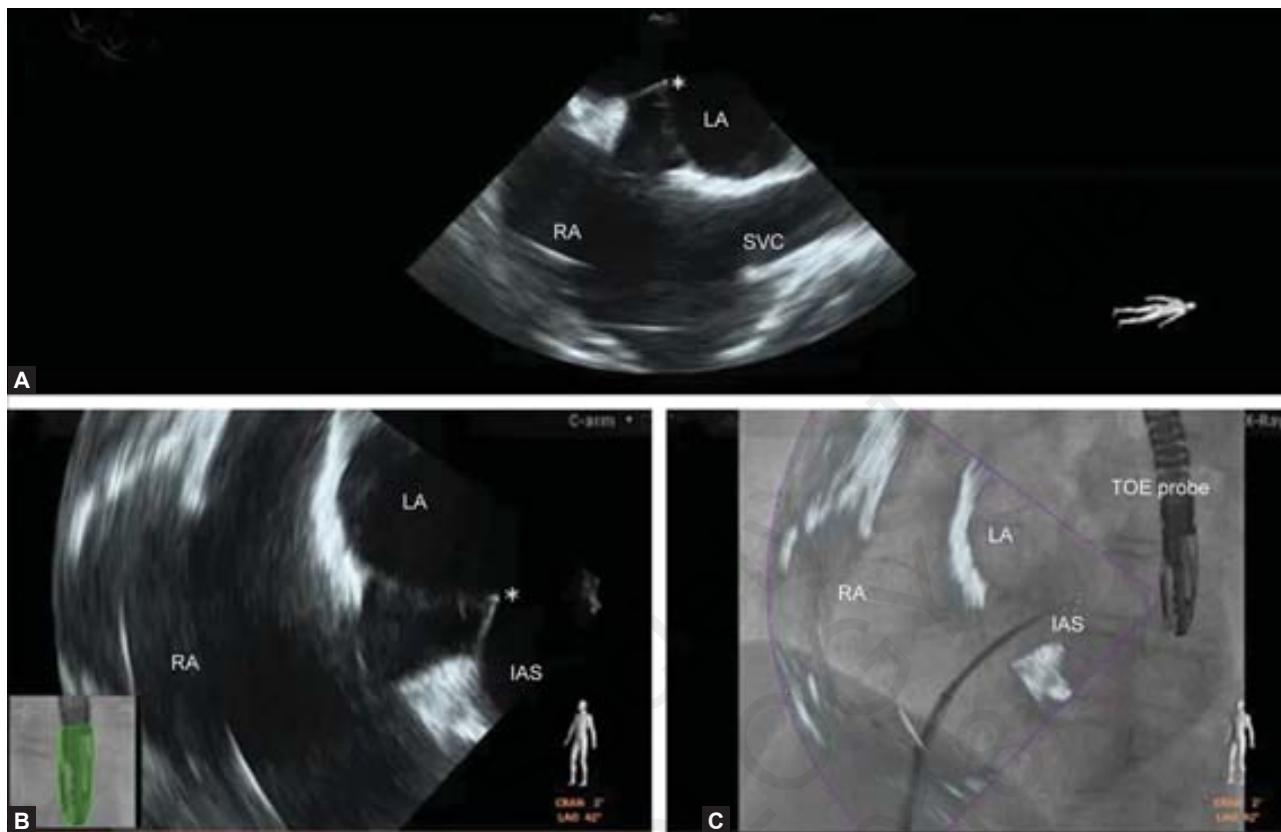

Fusion imaging with EchoNavigator software has been helpful in PVL closure procedures by reducing procedural time, facilitating location of the lesion and evaluating the surrounding structures.²⁵ Also this software is helpful in multiple PVL and avoids the use of contrast agents in patients with renal insufficiency.

Occlusion of Left Atrial Appendage

In nonvalvular atrial fibrillation, systemic anticoagulation is needed. However, in patients where anticoagulation is

FIG. 3: Septal puncture being shown during left atrial appendage closure by fusion imaging.

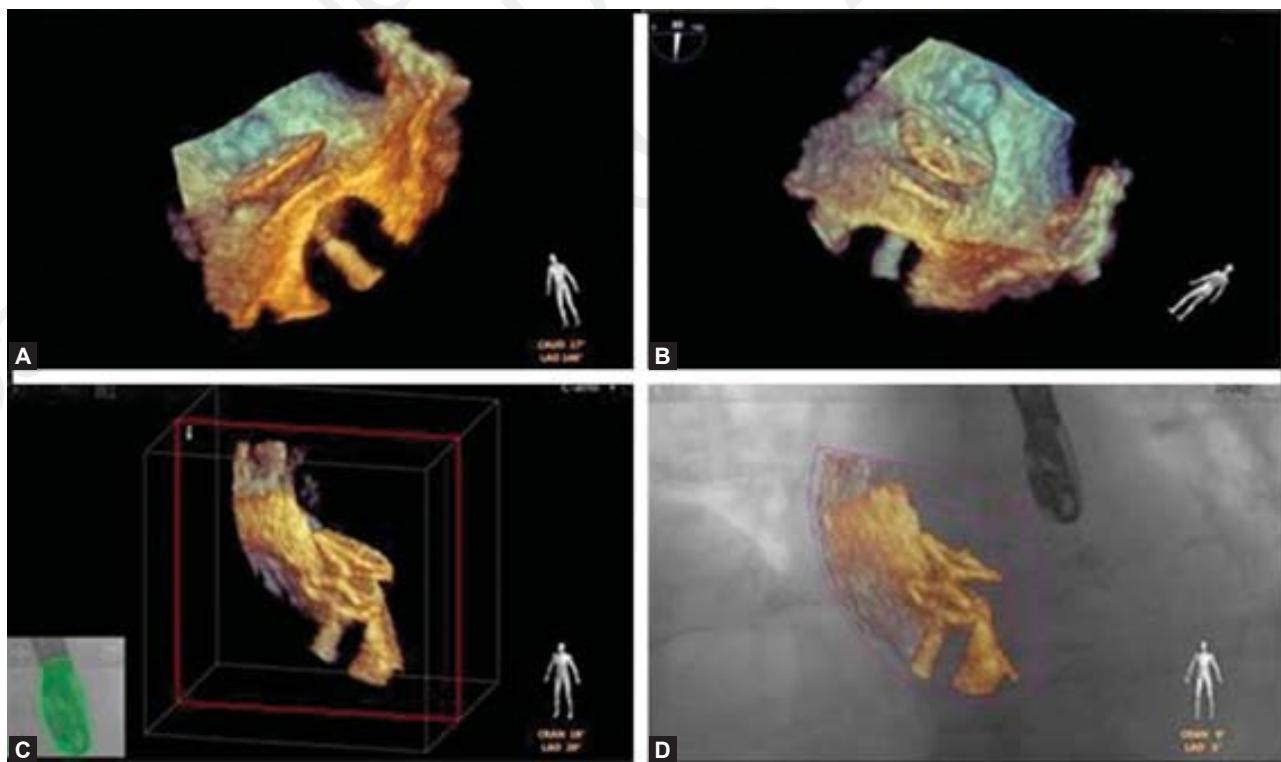

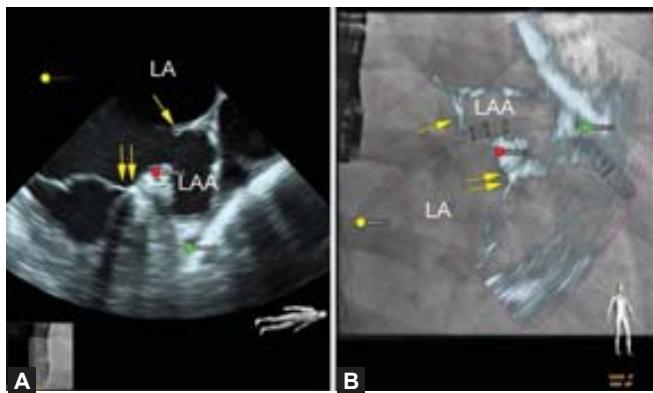

FIG. 4: Atrial septal defect closure being shown by fusion imaging.

LA, left atrium; LAA, left atrial appendage.

FIG. 5: Fusion imaging showing left atrial appendage closure.

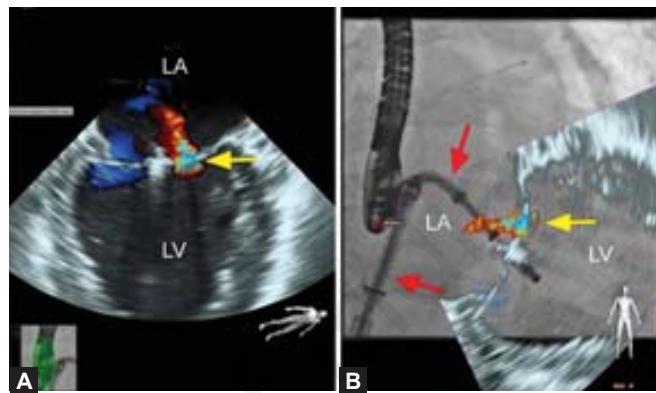

contraindicated, device closure of LAA has been shown to be safe and effective.²⁶ During this procedure, guiding wire is crossed through the interatrial septum into the left atrium and the occluder is placed into the LAA. The complication which is expected is perforation of the LAA wall and laceration of the pulmonary artery which can cause pericardial tamponade and immediate death. Fusion echocardiography helps in preventing this complication.

The markers available in EchoNavigator localize the echocardiographic images which appear in the coregistered X-ray images. This allows positioning and alignment of the catheter in the LAA and facilitates the placement of the closure device.²⁷ These markers can be placed at any level like at the LAA orifice at the level of the circumflex artery or the orifice of the left upper pulmonary vein or at the tip of the LAA.²⁸ Many times it has been seen that 3D orientation of the LAA can be challenging because of the complex structure.²⁹ The direct overlay of the real-time 3D TEE echocardiographic information before, during, and after the procedure is helpful to understand the complex relationship between the device and the anatomy of the LAA (Fig. 5).

MITRAL VALVE INTERVENTIONS

Percutaneous Mitral Valve Repair Using MitraClip

Precision is the key during maneuvering the MitraClip device during mitral valve repair. This prevents complications like perforation of the aortic root or left atrial wall. The best way is to direct visualize the mitral valve apparatus by 3D TEE with offline reconstruction techniques. Fluoroscopy also helps in localizing the orientation of guiding system with respect to the structures of the MitraClip and its grippers. Fusion imaging helps in combining these two modalities and compliments the understanding of the orientation of changes during the procedure. During this procedure, localization of the exact site of transseptal puncture in the fossa ovalis is crucial for successful device delivery. The EchoNavigator system helps in localizing the exact location for the transseptal puncture on the TEE images. The same marker simultaneously appears

LA, left atrium; LV, left ventricle.

FIG. 6: Fusion imaging during MitraClip procedure.

on fluoroscopy together with the echocardiographic image. This augments the localization of precise puncture site and assures the crossing of the device through the interatrial septum.

Fusion imaging is helpful for the safety of the MitraClip procedure. It helps the interventional cardiologist to locate three echocardiographic orientation points (interatrial septum at puncture site, crista terminalis between pulmonary vein and the LAA and the center of the mitral valve) into the fluoroscopic image (Fig. 6). The main complication during this procedure is perforation of the atrial septal wall by the MitraClip leading to cardiac tamponade.

Transcatheter Mitral Valve Replacement

There has been an increase interest and usage of transcatheter mitral valve replacement in last couple of years. This includes valve-in-ring by either transseptal or transapical approach and transapical valve-in-valve options.^{30,31} During this procedure, the annuloplasty ring or valve prosthesis can be used as markers. Fusion imaging is however be used for choosing the proper access site. The correct position and function of the implanted prosthetic valve is usually controlled by TEE and is seen on fusion imaging.

Fusion imaging is a mandate for the recently introduced mitral valve prostheses that will be used as percutaneous valve-in-native-valve procedure.³⁰ If fluoroscopy is used alone, important landmarks are not seen; e.g., during transcatheter mitral valve replacement interventions, mitral annulus or the aortomitral connection are not visible on fluoroscopy alone. For this simultaneous use of 3D TEE is mandatory. In addition, the orientation of the prosthesis is of crucial importance, and proper alignment can be achieved by fused imaging. With the more usage of interventional cardiology for SHD management, there is a great future for real-time fused imaging in this field of managing mitral valve pathologies.

AORTIC VALVE INTERVENTIONS

Transcatheter aortic valve implantation (TAVI) has now been accepted as the treatment of choice for patients with severe

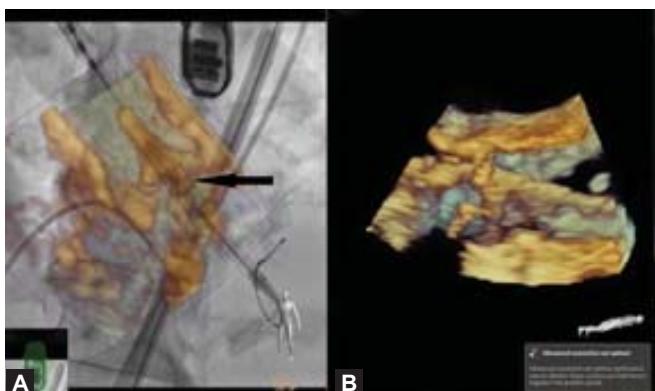

FIG. 7: Fusion imaging during transcatheter aortic valve replacement procedure.

aortic stenosis patients who are in high risk for surgery.⁴ Three-dimensional TEE is very useful before, during and after aortic valve implantation as it facilitates precise aortic annular sizing and exact delineation of the hinge points during valve deployment.³²

In order to optimize TAVI procedural safety and effectiveness, fusion imaging enables a precise knowledge of the anatomy of the aortic root and its surrounding structures.¹⁷ During TAVI interventions, important landmarks of the aortic root such as the leaflets, the coronary cusps, the sinotubular junction, the anatomic ventriculo-arterial junction, the aortic-mitral curtain and the virtual ring formed by the hinge points of the aortic valvar leaflets are not visible on fluoroscopy but on echocardiography. In addition, the orientation of the prosthesis is crucial for procedural success. The EchoNavigator system allows the transfer of specific echocardiographic markers onto the fluoroscopic image (Fig. 7). This enables marking of the level of the annulus and correction of the position of the gantry to the point where all three hinge point markers derived from echocardiography create one orthogonal plane, and thus facilitating catheter guidance and prosthesis placement.¹⁸ It is important to generate a straight line of perpendicularity in order to reach the correct image plain for implantation of the valve.¹⁹ Fusion imaging helps in this.

CONCLUSION

The need of fusion imaging is going to increase due to an increase in aging population going for SHD interventions. The EchoNavigator system from Philips has been an advancement which has helped in fusion of echo and fluoroscopic data in real-time during percutaneous cardiac interventions. It has also helped in better communication between interventional cardiologist and cardiac imager. In conclusion, fusion imaging using the EchoNavigator system has now become a robust tool for SHD intervention and has the advantage of being safe, accurate, and effective. The system is now being used in many procedures where real-time 3D TEE information is important for precise completion of the procedure.

Interpreting a Nuclear Stress Test

GN Mahapatra

INTRODUCTION

Interpretation of a nuclear stress test most commonly known as myocardial perfusion single-photon emission computed tomography (SPECT) and stress positron emission tomography (PET) myocardial perfusion scintigraphy (MPS) are the most important and commonly performed noninvasive cardiac imaging test. The investigation plays an important role in the diagnosis of cardiovascular disease, establishing prognosis, assessing the effectiveness of therapy, and evaluating myocardial viability. Advancing technology and continuous improvements have been largely responsible for the success of the nuclear stress test. These include progressive hardware improvement of SPECT technologies, newer radiopharmaceuticals and new quantitative software. At present, a majority of stress MPS are performed with electrocardiogram (ECG)-gated SPECT which helps in evaluating both myocardial perfusion and cardiac function simultaneously. Although a variety of stress techniques are available, but exercise stress test is the preferred method because it provides several important prognostic data in addition to increasing coronary blood flow. Nuclear pharmacological stress must be considered if there is a contraindication to exercise stress testing. Thallium-201 (Chloride Tl-201), technetium-99m (Tc-99m)-sestamibi and Tc-99m tetrofosmin, N-13 ammonia, rubidium-82 (Rb-82) and very recently F-18-fluoropiridaz stress PET myocardial perfusion studies are the currently used radiopharmaceuticals.^{1,2} It should be noted that many artifacts and pitfalls in interpretation can potentially compromise nuclear stress test. It is therefore important that the technologist and the interpreting physician should be aware of potential sources of error to take appropriate steps to limit them beforehand, whenever possible. These can help preempt them or else correct them if they occur and if they cannot be eliminated, recognize their potential impact and factor it in the interpretation of the study.³

The major indications for nuclear stress test either of single photon emission computed tomography and computed tomography (SPECT-CT) or MPS, SPECT-CT are for the diagnosis of coronary artery disease (CAD) risk stratification in patients with known CAD, assessment of therapy and interpretation and assessment of myocardial viability before percutaneous intervention or bypass surgery. Therefore, it is essential the referring and interpreting physicians are in close collaboration to ensure appropriate indication for the study, optimal patient preparation and effective use of the test results in patient clinical management.

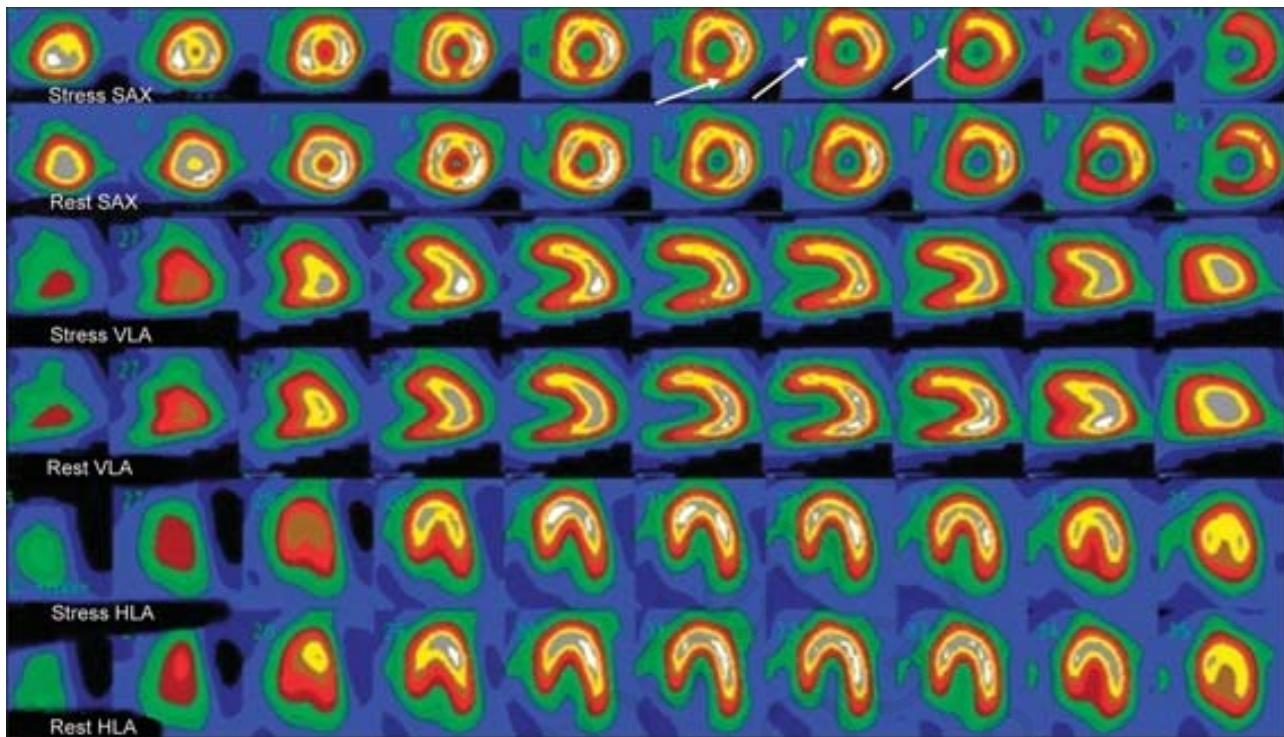

APPROACH TO INTERPRETATION

A systematic and consistent approach should be taken for the interpretation of MPS-SPECT images and should incorporate the following:

- Identify the presence of potential sources of image artifact and the distribution of extracardiac tracer activity during the evaluation of raw images in cine mode
- Ensure that the rest and poststress images are properly aligned
- Interpretation of images with respect to the location size, severity and reversibility of perfusion defects as well as cardiac chamber sizes and especially for Tl-201, presence or absence of increased pulmonary uptake
- Incorporation of the results of quantitative perfusion analysis
- Functional data obtained from gated images should also be considered
- Consideration of clinical factors that may influence the final interpretation of the study.

Normal Myocardial Perfusion Scan and Variants

Both rest and stress images must be evaluated carefully for any recognized artifacts before visual interpretation.⁴

HLA, horizontal long axis; SAX, short axis; VLA, vertical long-axis.

FIG. 1: Normal myocardial perfusion single-photon emission computed tomography (myocardial perfusion scintigraphy) in a 55-year-old man referred because of positive exercise stress test. Both stress and rest images demonstrate normal radiotracer distribution. A mild decreased uptake in basal inferior wall and septum is normal due to membranous septum (white arrows). The top two rows are short-axis (SAX) images of the left ventricle at stress and the second row the corresponding SAX images at rest. The next two rows are vertical long-axis images at stress and rest. The bottom two rows are horizontal long axis at stress and rest.

A normal myocardial perfusion study is characterized by homogeneous radiotracer distribution in both stress and rest images. Slightly diminished activity in the apex may be observed and can be accounted for physiological apical thinning usually limited to the apex and not extending to the anterior wall. Normal thinning of the basal membranous septum and basal inferior wall causes perfusion defect in the corresponding segments. Focal increased activity in and at insertion of papillary muscle (2 o'clock and 6 o'clock position) may give a false impression of a defect adjacent to or between them showing these in long-axis images.

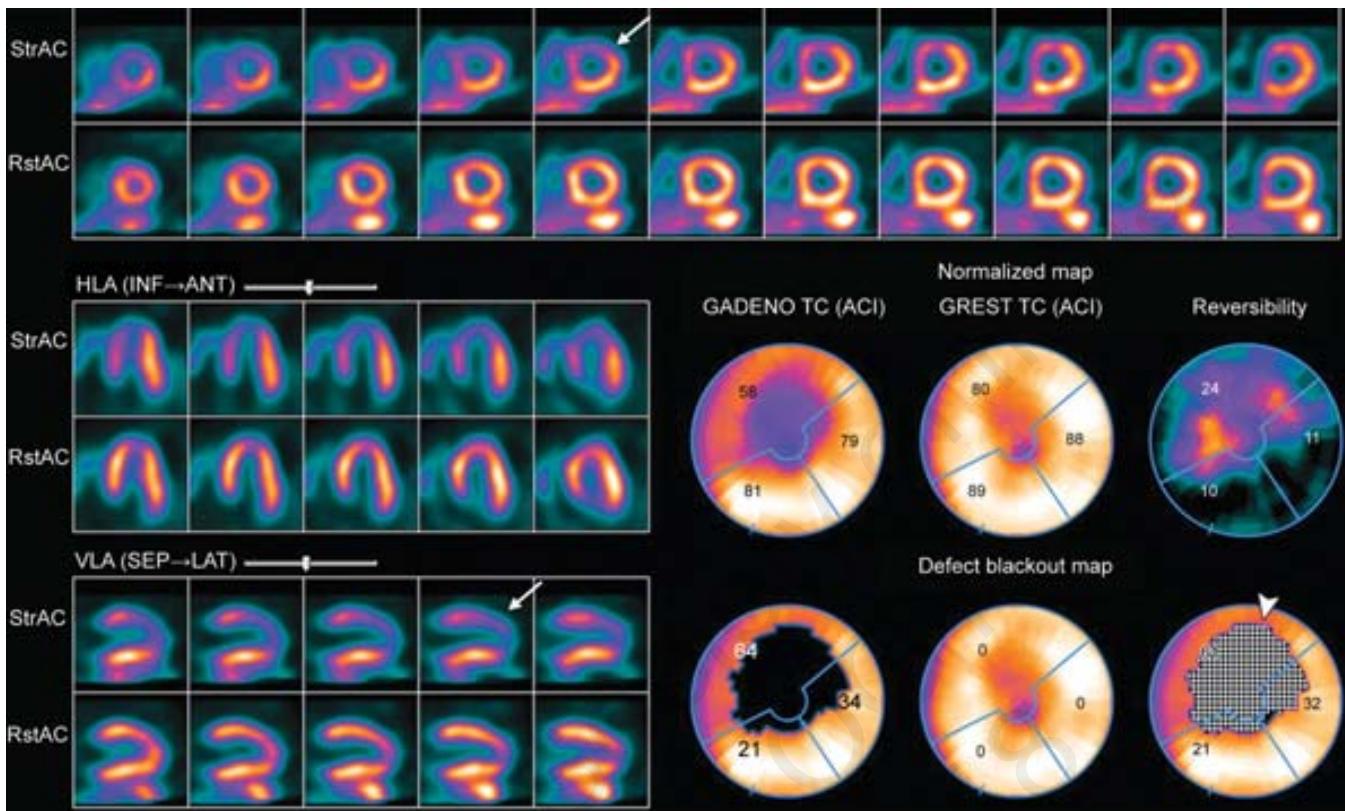

Attenuation Correction and Artifacts

A long recognized major factor limiting the specificity of SPECT for the detection of myocardial perfusion defects is attenuation of photons within the body. The impact of attenuation artifacts depends on the attenuation characteristics of the tissues imaged with the energy of the radio tracer. Various attenuation correction methods have been used.⁵ When used in conjunction with quantitative analysis, they can significantly increase the specificity of SPECT myocardial perfusion imaging.⁶

Artifacts of Soft Tissue Attenuation

Soft tissue attenuation for example in the breast is a common reason for artifactual decrease in radio tracer activity in the anterior myocardial wall and may affect the depiction of activity in the septal and lateral walls as well depending on the patient's body habitus. If the breast is in the same position during stress and rest imaging, the apparent perfusion defects will be present on both sets of images. ECG-gated SPECT perfusion images in such case demonstrate normal wall motion and normal wall thickness, the apparent fixed defect is an artifact of soft tissue attenuation instead of an area of myocardial infarction. Other clues to the nature of such a defect may include a noncoronary distribution of the abnormality and the observation of large, dense breasts at cinematic review of the raw images.

Another attenuation artifact observed commonly in the inferior myocardial wall is a common-site of fixed or variable attenuation artifacts produced by the left hemidiaphragm. Again, the ECG-gated SPECT perfusion images will demonstrate normal wall motion and thickness if no perfusion defects are present, confirming the artifactual nature of the abnormalities.⁷⁻¹⁰

ACI, attenuation-corrected images; ANT, anterior; GADENO TC, electrocardiogram-gated stress imaging with regadenoson and a technetium-99m-labeled tracer; GREST TC, electrocardiogram-gated rest imaging with a technetium-99m-labeled tracer; HLA, horizontal long axis; INF, inferior; LAT, lateral wall; RstAC, attenuation-corrected rest; SEP, septum wall; StrAC, attenuation-corrected stress; VLA, vertical long axis.

FIG. 2: An attenuation-corrected stress and rest myocardial perfusion imaging examination performed with single-photon emission computed tomography or computed tomography showing a large reversible perfusion defect in the territory of the left anterior descending artery.

A substantial number of these artifacts can be corrected with the use of an attenuation correction technique like low-dose breath hold CT scan obtained on a hybrid SPECT-CT system. It would then be possible to compare attenuation corrected images from a particular patient both quantitatively and qualitatively with attenuation corrected images in data bases from patients with normal cardiac perfusion. In addition, if breast attenuation degrades the quality of cardiac perfusion images, the imaging examination can be repeated with patient in the prone position.^{5,6}

Artifacts of Subdiaphragmatic Radiotracer Activity

Prominent subdiaphragmatic activity may be seen in organ adjacent to the heart due to hepatobiliary excretion of Tc-99m labeled radiotracers. This is seen predominantly in the liver and bowel but also occasionally in the stomach. Subdiaphragmatic radiotracer activity can affect myocardial perfusion images in several ways. First the scatter radiation from the radiotracer can lead to an appearance of increased perfusion in the inferior myocardial wall that might mask a true perfusion defect in this region especially when the effect of scatter is combined with partial volume effects. Secondly if the highest count is artificially elevated because of scatter, the

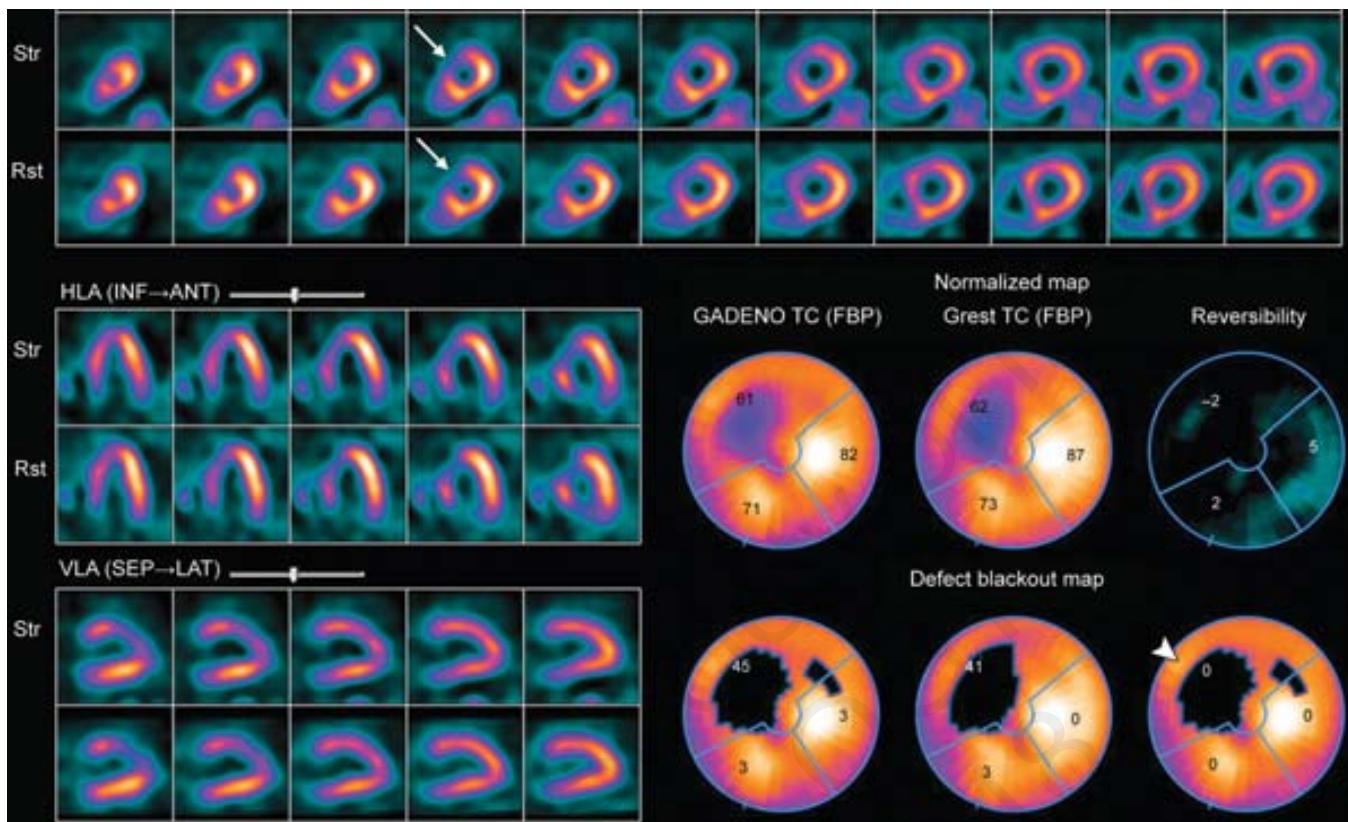

remainder of the left ventricle may appear to have relatively low activity simulating an extensive perfusion defect.^{11,12}

It may be difficult to eliminate the artifacts related to subdiaphragmatic radiotracer activity but several options are available. A repeat image acquisition may be attempted after a delay to allow clearance of the radiotracer from regions adjacent to heart. As with soft tissue attenuation artifacts, repeat imaging with the patient in the prone position can help minimize artifacts caused by—subdiaphragmatic radiotracer activity because the distance between the heart and the subdiaphragmatic organs may be decreased.

Last for patients who are unable to achieve symptom limited maximal exercise-induced stress, it may be helpful to combine the administration of a vasodilator with a low-level exercise protocol tailored to the abilities of the individual patient. The additional exercise induced stress even induced by low-level exercise may prevent subdiaphragmatic activity by reducing splanchnic blood flow to the viscera.

Motion Artifacts

One of the most common sources of artifacts of myocardial perfusion imaging is patient motion usually related to respiration. A careful review of raw images with a rotating cinematic display is best to detect these artifacts. Evaluation

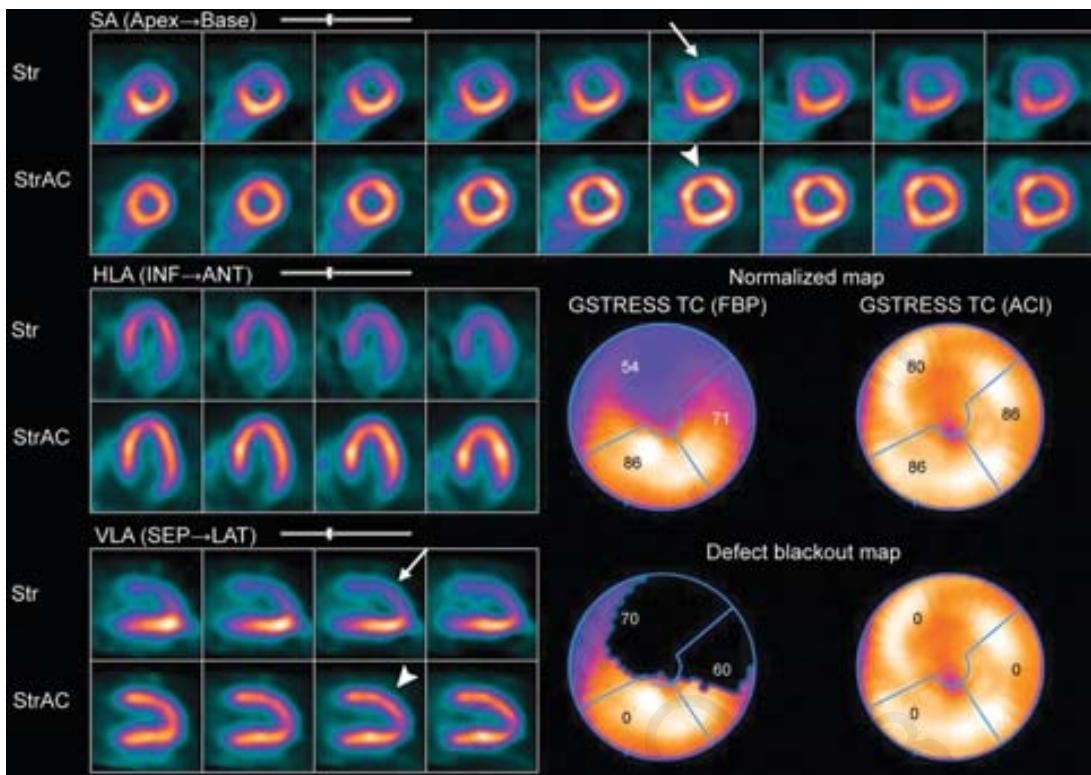

ANT, anterior; FBP, filtered back projection images; GADENO TC, electrocardiogram-gated stress imaging with regadenoson and a technetium-99m-labeled tracer; REST TC, rest imaging with a technetium-99m-labeled tracer; HLA, horizontal long axis; INF, inferior; LAT, lateral wall; Rst, rest; SEP, septum wall; Str, stress; VLA, vertical long axis.

FIG. 3: Shows stress and rest myocardial perfusion imaging performed with single-photon emission computed tomography or computed tomography. Perfusion images and polar maps demonstrate a large fixed anteroseptal perfusion defect, a finding indicative of an infarct in the territory of the left anterior descending artery (arrows). Defect blackout map shows a blackened region. A feature indicative of a fixed perfusion defect (infarction).

SDS, summed difference score; SRS, summed rest score; SSS, summed stress score.

FIG. 4: Shows the summed stress score, summed rest score, and summed difference score from the same single-photon emission computed tomography or computed tomography myocardial perfusion imaging examination as in figure 6. A summed stress score of 12 indicates an intermediate risk for a hard cardiac event over the subsequent 12 months. Summed stress scores of less than 3 are considered normal, whereas scores of 4–7, 8–12, and 13 or higher are indicative of low, intermediate, and high risk for a hard cardiac event.

ACI, attenuation-corrected images; ANT, anterior; FBP, filtered back projection images; GSTRESS TC, electrocardiogram-gated stress imaging obtained with technetium-99m-labeled tracer; HLA, horizontal long axis; INF, inferior; LAT, lateral wall; SA, short axis; SEP, septum wall; Str, attenuation correction; StrAC, attenuation-corrected images; VLA, vertical long axis.

FIG. 5: Shows stress-only myocardial perfusion imaging performed with single-photon emission computed tomography or computed tomography in a heavy weight female patient shows a large apparent perfusion defect in the anterolateral myocardial wall (arrows) on images obtained without attenuation correction, whereas attenuation-corrected images show no evidence of a defect at this site (arrowheads).

of the sinogram for discontinuities may be especially useful for detecting movement. In the presence of a motion artifact, the heart will be seen in different location on adjacent SPECT projection images.¹³ When the raw projection data are back projected on to the volume reconstruction matrix, there will be inconsistencies that the algorithm cannot correct for and the resultant artifactual defects mimic perfusion abnormalities.¹⁴

If a substantial amount of motion is detected during a study with a Tc-99m labeled radiotracer, repeat imaging can be performed without a second radiotracer injection because the distribution of Tc-99m labeled radiotracers remains relatively fixed for as early as 2 hours.

Alternatively, motion correction software is available that may be useful for eliminating misregistration due to the slight or moderate motion.

Artifacts of Misregistration

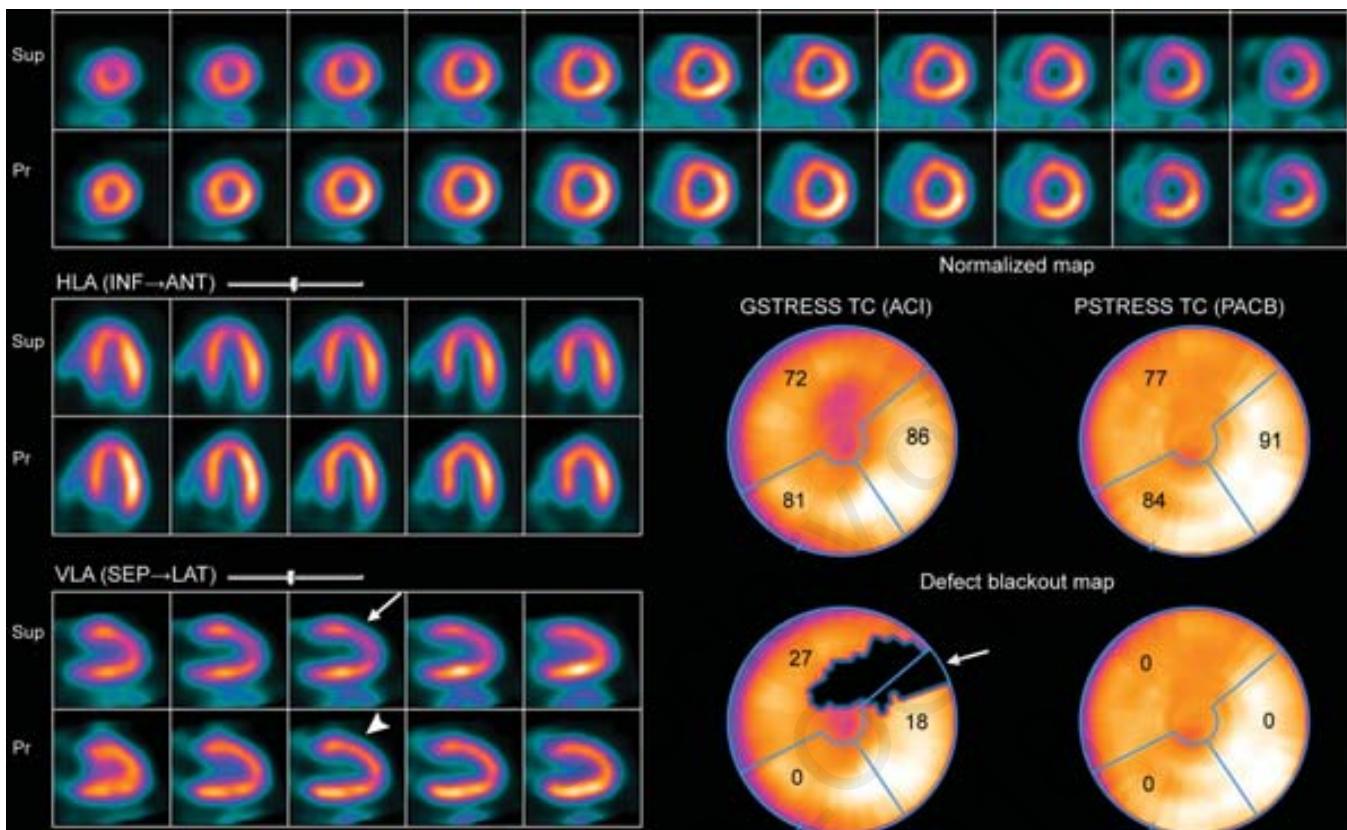

The low-dose CT data obtained for attenuation correction and the SPECT image data are acquired sequentially in the current SPECT-CT system, and patient movement may occur between the two types of acquisitions. Although, the new SPECT-CT system have software to align the SPECT and CT data sets, misregistration may occur if care is not taken in the acquisition and processing of the data sets and may lead to

new and unexpected kinds of artifacts. In order to avoid this misregistration, the importance of a careful review of the CT attenuation map and verification of its accurate coregistration with the SPECT images.¹³

Artifacts of Left Bundle Branch Block

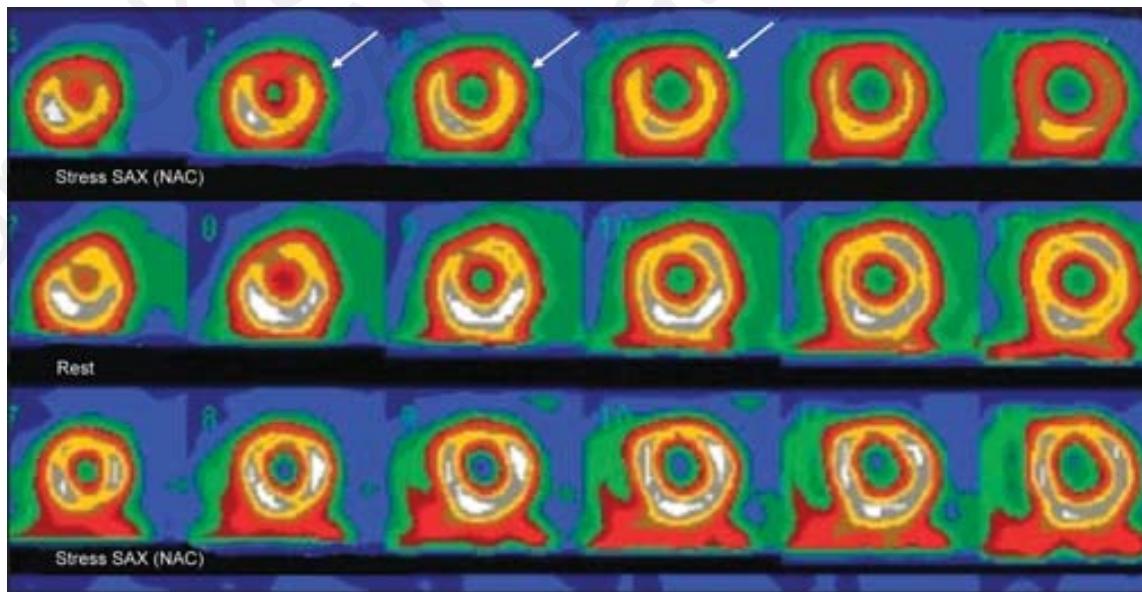

Left bundle branch block (LBBB) patients who undergo perfusion imaging during exercise or dobutamine-induced stress may appear to have a reversible or fixed septal perfusion defect. This results in the apparent septal defect appearing more pronounced when stress is induced, which pushes the heart rate higher than when stress is induced by vasodilators which generally have a limited effect on heart rate. In addition to the appearance of a septal perfusion defect, ECG-gated SPECT studies often demonstrate paradoxical septal motions as clues for LBBB-induced artifacts¹²

In patients with hypertrophic cardiomyopathy, asymmetrical septal thickness may create false widespread perfusion defect because of normalization to the hottest pixel in the septum. In balanced ischemia, MPS can only measure relative perfusion, not absolute quantification. The perfusion abnormalities may not be recognized if there is decreased perfusion to all cardiac walls. Decreased post-stress ejection fraction (EF) and new regional wall motion abnormality compared to rest scan, abnormal transient ischemic dilation

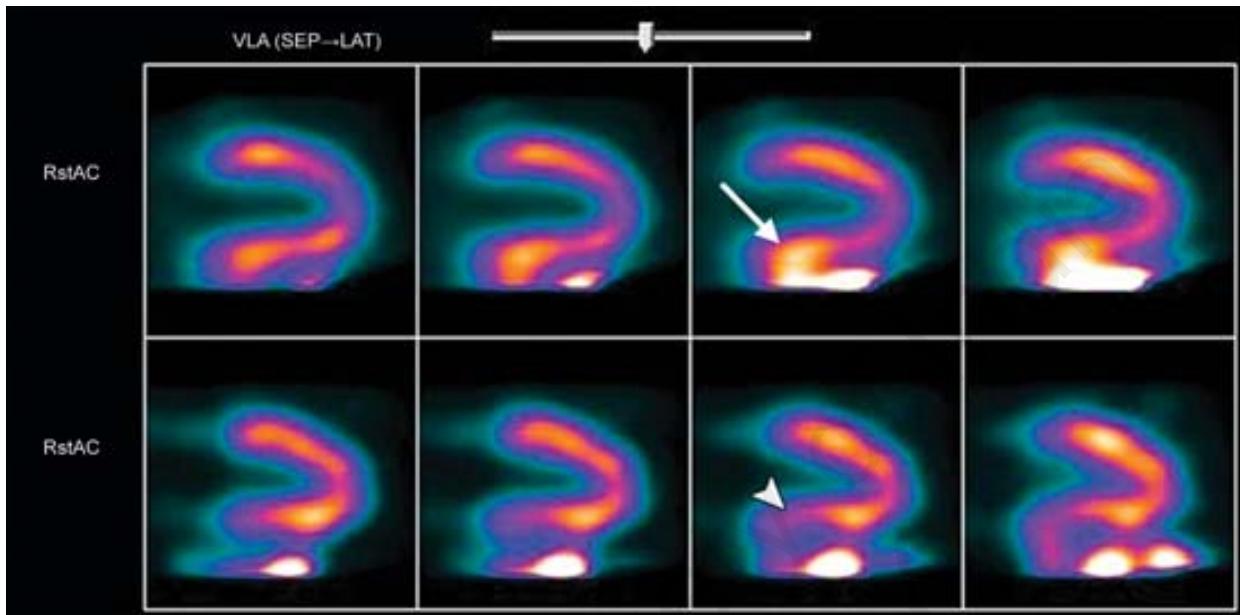

ACI, attenuation-corrected images; ANT, anterior; GSTRESS TC, supine electrocardiogram-gated stress imaging with a technetium-99m-labeled tracer; PSTRESS TC, prone free-breathing stress imaging with a technetium-99m-labeled tracer; HLA, horizontal long axis; INF, inferior; LAT, lateral wall; Pr, prone; Sup, supine; VLA, vertical long axis.

FIG. 6: Shows attenuation-corrected stress-only myocardial perfusion imaging performed with single-photon emission computed tomography or computed tomography) in a normal subject shows different results with the subject supine and prone: an area of reduced perfusion defect is seen in the anterior myocardial wall on supine images (arrows), whereas perfusion appears normal at this site on prone images (arrowhead). The apparent perfusion defect seen in this case is an artifact of soft tissue (breast) attenuation.

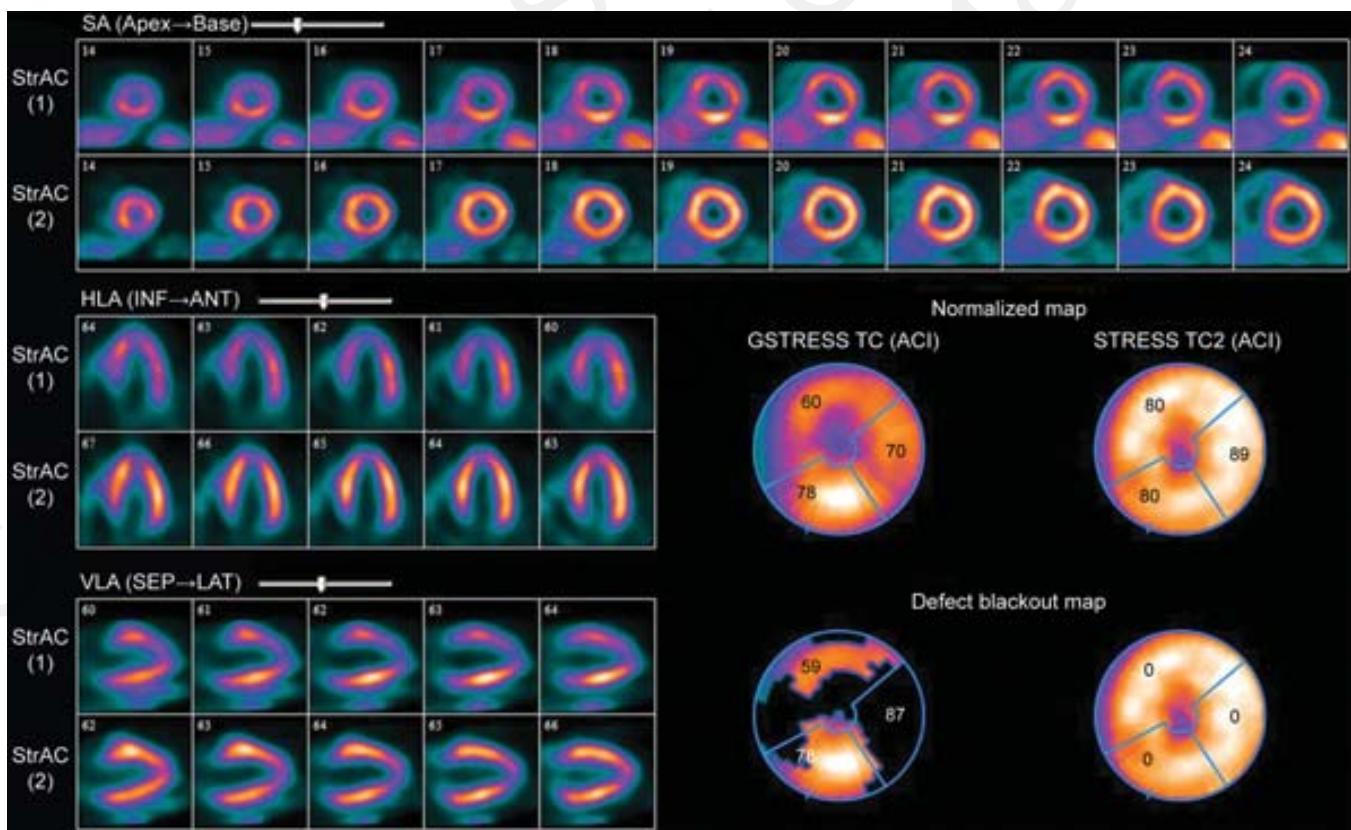

NAC, nonattenuation-corrected; SAX, short axis.

FIG. 7: Shifting breast attenuation in 60-year-old women came with chest pain, the myocardial perfusion scintigraphy was performed with dipyridamole because patient could not exercise owing to severe arthritis. Stress nonattenuation correction (NAC) images show anterior wall perfusion defect (white arrows) with normalization at rest. In the attenuation correction images (lower row) the perfusion defect disappears. Based on this finding the study was interpreted as normal with breast attenuation on NAC images.

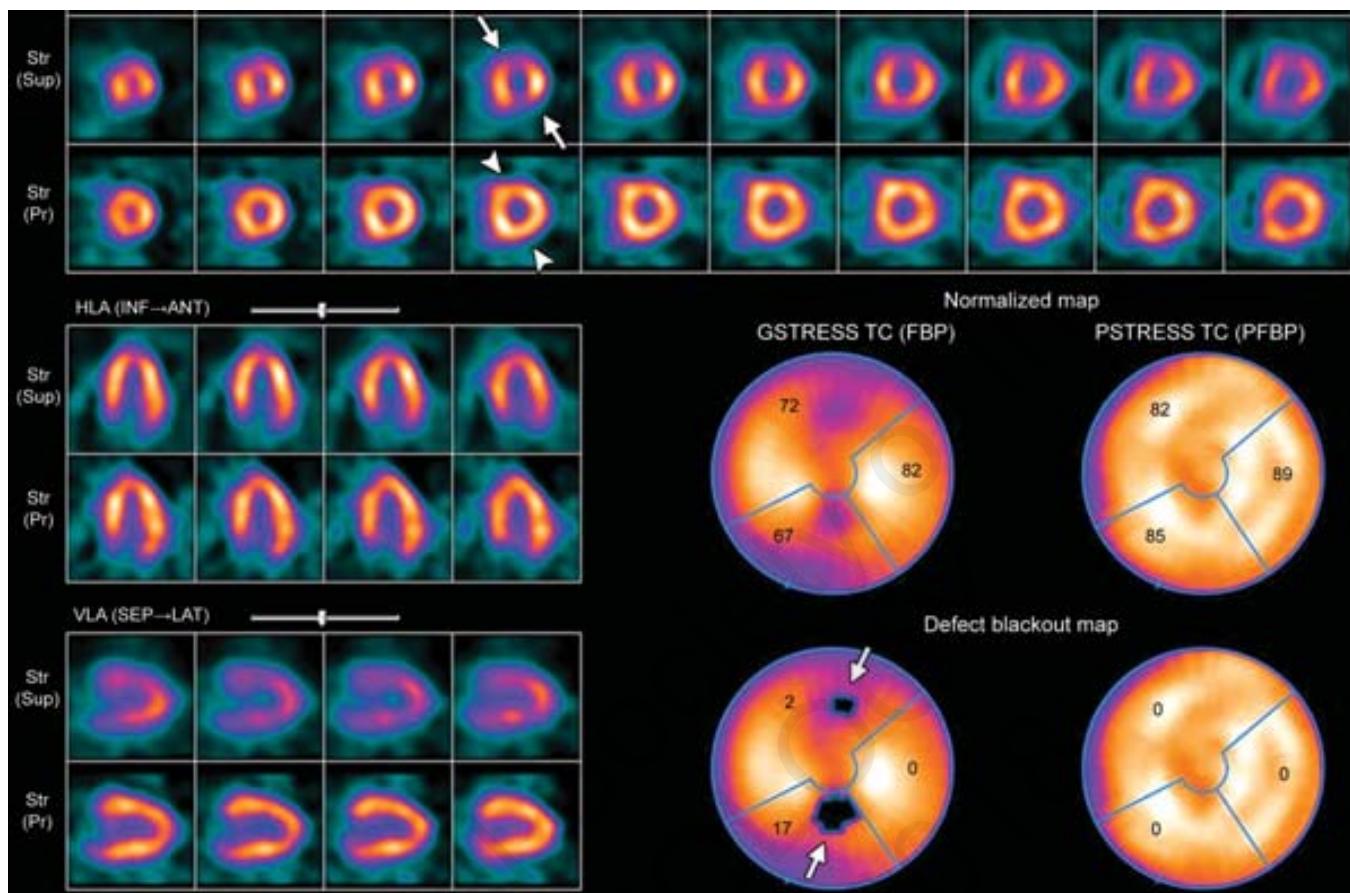

LAT, lateral wall; RstAC, attenuation-corrected resting; SEP, septum wall; VLA, vertical long axis.

FIG. 8: Attenuation-corrected resting myocardial perfusion images obtained with single-photon emission computed tomography or computed tomography show radiotracer activity in the bowel (arrow), a feature that masks the inferior wall defect evident on delayed images (arrowhead).

ACI, attenuation-corrected images; ANT, anterior; GSTRESS TC, electrocardiogram-gated stress imaging with a technetium-99m-labeled tracer; HLA, horizontal long axis; INF, inferior; LAT, lateral wall; SEP, septum wall; SA, short axis; StrAC, attenuation-corrected stress; STRESS TC2, delayed stress imaging after clearance of the radiotracer from abdominal organs; VLA, vertical long axis

FIG. 9: Shows an attenuation-corrected stress myocardial perfusion imaging examination (StrAC[1]) performed with single-photon emission computed tomography or computed tomography shows an extensive artifact in the inferior wall on images and polar maps. The artifact was caused by normalization errors produced by subdiaphragmatic scatter radiation. Repeat imaging (StrAC[2]) after clearance of the radiotracer from abdominal organs showed normal perfusion at the site of the apparent defect.

ANT, anterior; GSTRESS TC (FBP), supine electrocardiogram-gated stress imaging with a technetium-99m-labeled tracer and filtered back projection; HLA, horizontal long axis; INF, inferior; LAT, lateral wall; Pr, prone; PSTRESS TC (PFBP), prone free-breathing stress imaging with a technetium-99m-labeled tracer and prone filtered back projection; SEP, septum wall; Str, stress; Sup, supine; VLA, vertical long axis.

FIG. 10: Shows an attenuation-corrected stress and rest myocardial perfusion imaging examination performed with single-photon emission computed tomography or computed tomography (SPECT/CT) in a patient with chest pain. Initial screen shows a large reversible perfusion defect in the lateral and anterolateral wall (arrow in *a*), an artifact that is due to misregistration of the CT attenuation map and SPECT image dataset. Repeat analysis obtained after reregistration of the SPECT and CT datasets (*b*) shows normal perfusion at the site of the apparent perfusion defect.

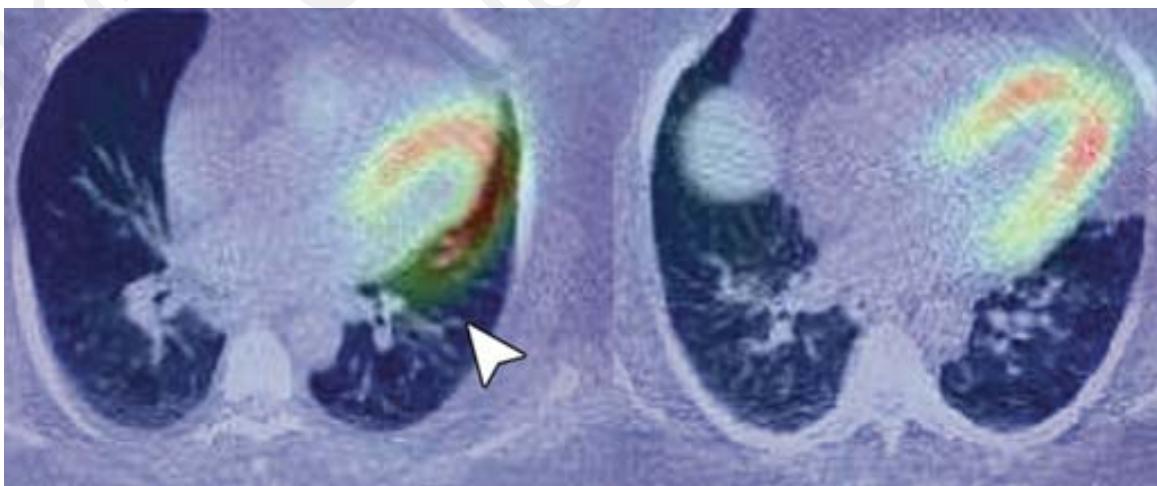

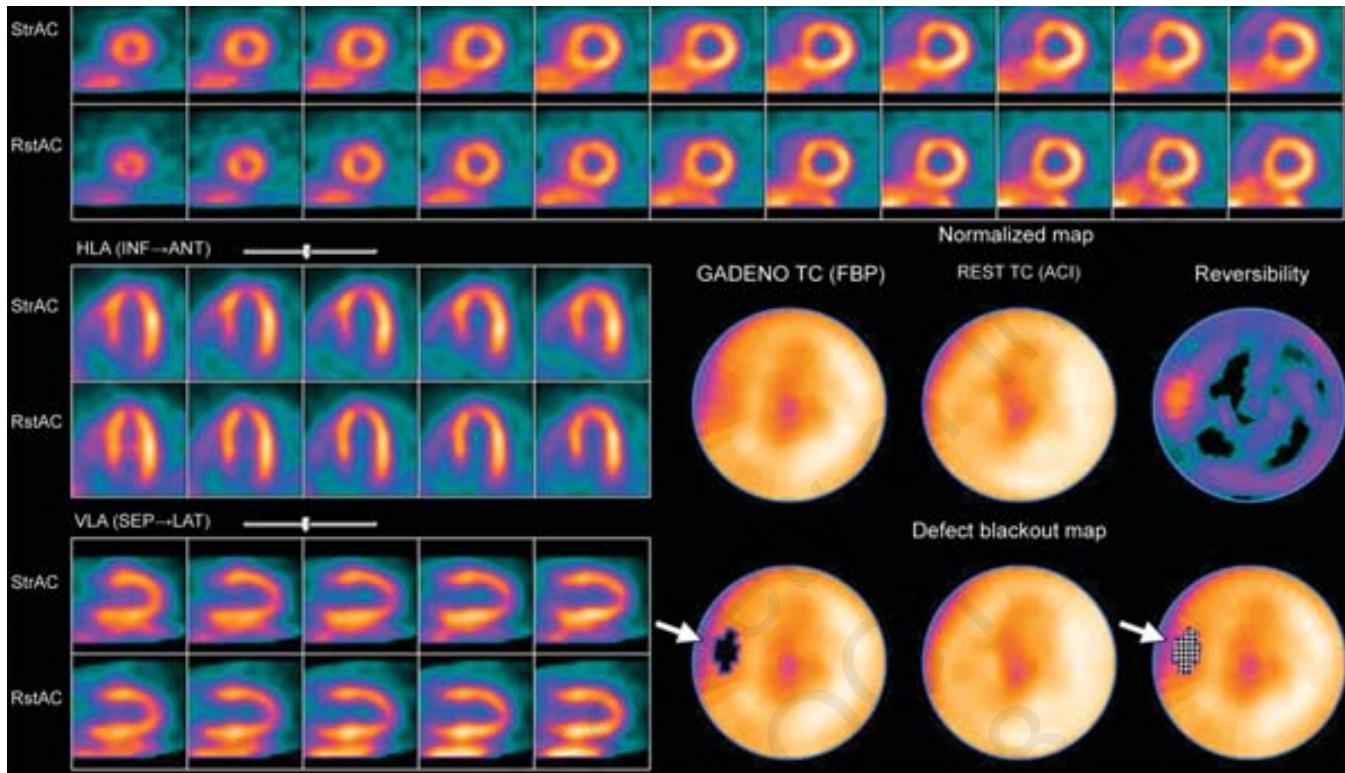

FIG. 11: Fused single-photon emission computed tomography or computed tomography (SPECT/CT) image obtained after the first post processing attempt (left) shows a defect in coregistration, with projection of the lateral wall of myocardium over the lung field (arrowhead). Fused image obtained after proper coregistration of the SPECT and CT datasets (right) shows normal perfusion.

ACI, attenuation-corrected images; ANT, anterior; GADENO TC, electrocardiogram-gated stress imaging with regadenoson and a technetium-99m-labeled tracer; REST TC, rest imaging with a technetium-99m-labeled tracer; HLA, horizontal long axis; INF, inferior; LAT, lateral wall; RstAC, attenuation-corrected rest; SEP, septum wall; StrAC, attenuation-corrected stress; VLA, vertical long axis.

FIG. 12: Shows an attenuation-corrected stress and rest myocardial perfusion imaging examination performed with single-photon emission computed tomography or computed tomography in a patient with a left bundle branch block. Defect blackout maps from stress imaging show a small reversible perfusion defect in the midseptum (arrows), but this region appears normal on the rest images, and the septum is an unusual location for isolated coronary artery disease. Septal perfusion defects, whether reversible or fixed, are most likely to represent left bundle branch block-related artifacts.

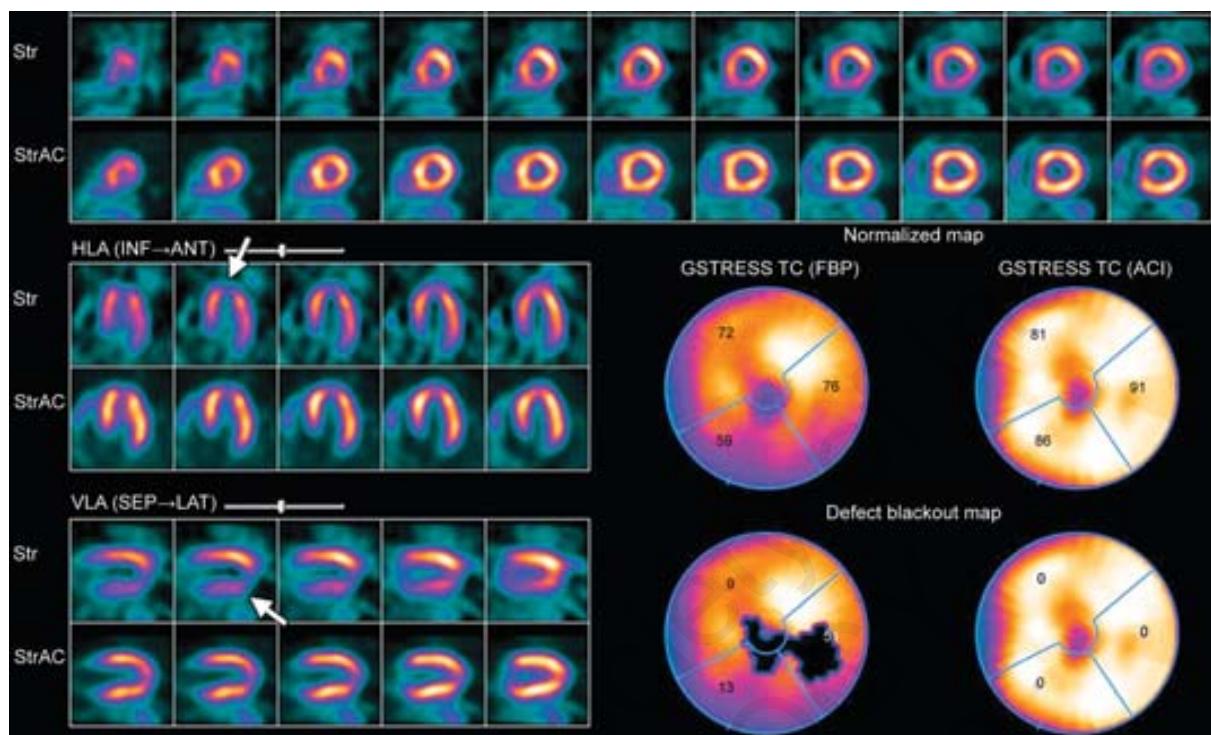

(TID) and abnormal increased lung uptake Tl-201 are some clues pointing toward the possibility of balanced ischemia. Very recently calculation of coronary flow reserve (CFR) in three major arteries holds the key.

Artifact Related to Nuclear Medicine Equipment

Flood-field nonuniformity may be secondary to a defect in the photo multiplier tube, damage in collimator or faulty camera electronics. A daily intrinsic and weekly extrinsic flood field should be obtained in order to detect such abnormalities. SPECT acquisition using a camera with one or more source of nonuniformity typically produces ring artifacts which may create a false myocardial ischemia. Other sources of instrumentation artifacts include error in center rotation, camera head tilt and increased detector to patient distance. Both technologist and physician should be familiar with these potential artifacts and be able to detect and correct them.

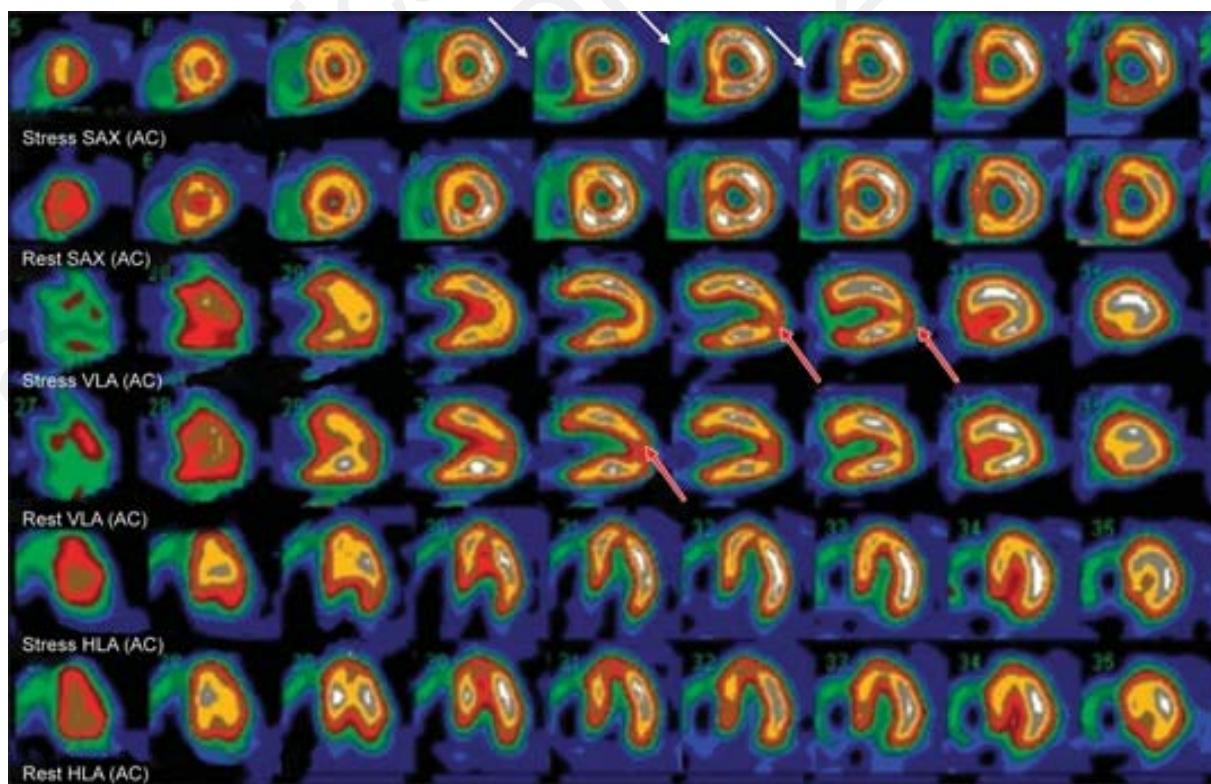

Effect of Normal Apical Thinning

A normal anatomic finding, apical thinning is seen commonly and has a multifactorial etiology. Thinning may be more prominent than usual in some patients and may simulate a perfusion defect. Apical thinning is more apparent on attenuation corrected images and may be accentuated by the scatter correction and resolution recovery process that is commonly incorporated in the reconstruction of attenuation corrected images. Due to the proximity of the apex to the detector, the spatial resolution of the normally thin apical segments of the left ventricle is greater than that of other segments. Vertical and horizontal long-axis cardiac images and polar map displays are best to visualize apparent perfusion defect resulting from apical thinning. ECG-gated stress and rest SPECT images in such cases will show normal wall motion and normal wall thickening. With matching stress and rest perfusion patterns, recognition of preserved wall motion confirms that the apparent perfusion defect is prominent apical thinning and not an infarcted myocardium.⁶

ACI, attenuation-corrected images; ANT, anterior; FBP, filtered back projection images; GSTRESS TC, electrocardiogram-gated stress imaging with a technetium-99m-labeled tracer; HLA, horizontal long axis; INF, inferior; LAT, lateral wall; SEP, septum wall; Str, stress; StrAC, attenuation-corrected stress; VLA, vertical long axis.

FIG. 13: Shows a stress-only myocardial perfusion imaging examination performed with single-photon emission computed tomography or computed tomography, with (StrAC) and without (Str) attenuation correction, shows an apparent small perfusion defect at the cardiac apex on both sets of images (arrows). This commonly observed feature is produced by apical thinning, and it should not be confused with a true perfusion defect; note that left ventricular wall motion and thickness appear normal.

AC, attenuation correction; HLA, horizontal long axis; SAX, short axis; VLA, vertical long axis.

FIG. 14: Normal attenuation correction (AC) myocardial perfusion scintigraphy in 62-year-old women was performed for risk assessment before vascular surgery. In the AC images the right ventricle is clearly visualized, not to be confused with right ventricular hypertrophy (white arrows). The normal apical thing is more severe in AC images, and sometimes appears as a true perfusion defect (red arrows).

CONCLUSION

Accurate interpretation of nuclear stress test particularly of gated SPECT or SPECT-CT myocardial perfusion imaging studies requires both a working knowledge of potential abnormalities and a thorough understanding of the artifacts that can occur in image data acquisition and processing. Factors such as patient motion and improper alignment of the raw SPECT and CT image data sets can lead to propagation of artifacts on the final images. The attenuation corrected images can eliminate defects produced by soft tissue attenuation. However, attenuation correction itself may produce artifacts if the anatomic and scintigraphic images are misregistered in the process. The type of stress study performed also may affect the outcome, because left bundle branch block related artifacts are accentuated by physical stress and minimized by pharmacological stress. Review of the raw SPECT and CT images as well as the final reconstructed images can help prevent misdiagnosis due to artifacts.

Myocardial Viability Assessment: How Do We Apply in Clinical Practice?

Nagendra Boopathy Senguttuvan, Kewal C Goswami

INTRODUCTION

The term “viable” means things that are alive. At the cellular level, the term viable is defined by preserved metabolic, cellular, and contractile functions. According to Cambridge English Dictionary, the meaning of the word viable is “ability to work as intended or to succeed”. The concepts discussed in this chapter are about the myocardial viability, different types of myocardial viability, pathophysiology, and assessment of myocardial viability in the current era.

ENERGY AND ISCHEMIA

When the total coronary artery occlusion duration lasts for less than 15–20 minutes, it does not cause necrosis. The amount of adenosine triphosphate (ATP) in the central region is reduced. In 3 minutes after occlusion, the ATP level is decreased to less than 50% of the preischemic level. The ATP levels are 22% of preischemic level after 3 days of reperfusion. Seven days are required for the ultrastructural changes to occur due to ischemia. There is shortage of the creatine phosphate stores from which ATP is formed. Plasma permeability is increased due to decrease in ATP leading to washout of the metabolites of ATP. This results in shortage of ATP after ischemia. ATP shortage causes decreased myocardial contractility. Myocardial dysfunction is also caused by the calcium influx postischemic reperfusion.¹

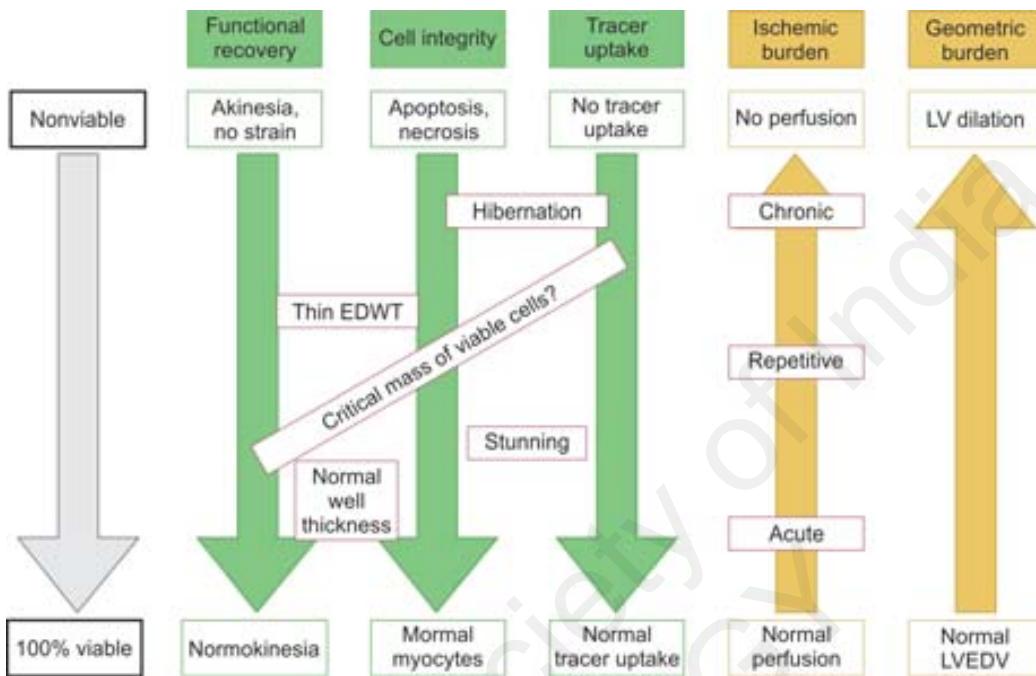

After acute coronary occlusion, the ischemic cascade starts with reversible myocardial contractile dysfunction within seconds. In 20–30 minutes, intracellular edema occurs followed by irreversible myocyte injury in 30–60 minutes and, in 60–90 minutes, vascular endothelial cell injury occurs followed by cellular necrosis and apoptosis.² In myocardial necrosis, transmurality is time dependent as progression is from subendocardium toward subepicardium over 3–6 hours.²

Types of Viable Myocardium

Viable myocardium is referred to as “alive myocardium” and the reference in irrespective of the contractile status of the myocardium.³ When blood flow is abruptly reduced, contractile dysfunction occurs, which persists even after the blood flow is restored, it is called “hit, run, and stun” phenomenon.¹ Viable dysfunctional myocardium is classified into hibernating myocardium and stunned myocardium. In patients with ischemic cardiomyopathy, the cellular changes are not uniform in the viable myocardium. The ultrastructural damage reflects concurrent process of myocardial hibernation and myocardial stunning.⁴

Hibernating Myocardium

Hibernating myocardium occurs due to persistently impaired coronary blood flow. The function of the myocardium may be completely or partially restored by improving the coronary blood flow. Myocardial function is also restored by reducing oxygen demand or by inotropic stimulation.⁴ Hibernating myocardium is an adaptive mechanism to prevent myocyte death and preserve structural integrity of myocardium.⁵ Metabolically, there is activation of the fetal gene program in the hibernating myocardium. Innate mechanism of myocardial protection causes similarities in hibernating myocardium and fetal myocardium.⁶ At cellular level, there is dedifferentiation to embryonic phenotype with loss of myofibrils and sarcomeres, fibrotic changes in extracellular matrix, and increased glycogen storage.⁷ There is switch in the metabolism from fat to glucose metabolism. Glycogen content of hibernating myocardium is increased dramatically. Time taken for recovery may be 6 months or more for severe ultrastructural derangement and 10 days for minor structural abnormalities.⁸ Resting blood flow is reduced in hibernating myocardium. The spectrum of abnormalities assessed from a cellular, metabolic, and functional myocardial perfusion, and global left ventricular (LV) perspective is described in figure 1.⁵

LVEDV, left ventricular end-diastolic volume; LV, left ventricular.

FIG. 1: Spectrum of abnormalities assessed from a cellular, metabolic and functional myocardial perfusion, and global left ventricular perspective.

Stunning Myocardium

The phenomenon of stunning myocardium in dogs was first observed by Heyndrickx.⁹ Heyndrickx observed that ischemic myocardial cells that have been perfused, there is prolonged depression of the regional myocardial function. When myocardium undergoes repetitive ischemic episodes with stress, there is depressed cardiac function known as repetitive myocardial stunning. There is contractile dysfunction in stunned heart with normal perfusion. Myocardial function improves with revascularization.¹⁰ The resting blood flow is preserved and the flow reserve is reduced.¹¹ Hence, myocardial stunning physiology is referred to as “perfusion contraction mismatch”. Incomplete functional recovery of stunned segments between consecutive ischemia episodes results in permanently depressed myocardial function.

REVASCULARIZATION

Depressed LV function in patients with ischemic cardiomyopathy can be reversed using revascularization. Benefits of revascularization are increase in the resting left ventricular ejection fraction (LVEF) and reducing the inducible ischemia, thereby decreasing ventricular remodeling and diastolic dysfunction and thus reducing the symptoms of congestive heart failure (CHF).¹² STICHES (Surgical Treatment for IsCHemic heart failure Extension Study) is a 10-year follow-up study of patients with coronary artery disease (CAD), LV dysfunction (LVEF <33%) and ischemic cardiomyopathy

amenable to coronary artery bypass grafting (CABG). Mortality of patients was reduced by 8% in patients who had CABG along with optimal medical therapy (OMT) when compared to those only on optimal contemporary medical treatment.

MODALITIES OF VIABILITY TESTING

Myocardial viability is tested using ultrasound, nuclear, and magnetic resonance based techniques (Table 1).

- Low-dose dobutamine stress echocardiography (DSE)—LV contractile reserve
- Late gadolinium enhancement with cardiac magnetic resonance (CMR)—identification of scarred myocardium
- Single-photon emission computed tomography (SPECT)—assess myocardial perfusion
- Positron emission tomography (PET)—assess myocardial perfusion, mitochondrial, sarcolemma, inner membrane integrity, intracellular glucose and fatty acid metabolism.

Echocardiography

Echocardiography is used to assess both LV and right ventricular (RV) systolic and diastolic function. Echocardiography can delineate contractile reserve with low dose of dobutamine. Patients with LV end-diastolic wall thickness more than 0.5–0.6 cm with hypokinetic rather than dyskinetic or akinetic myocardium indicates chances of improvement in LV function after revascularization.

TABLE 1: Comparison of diagnostic accuracy of noninvasive cardiac modalities in the diagnosis of myocardial viability

Imaging modality	Number of patients	Number of studies included	Specificity	Sensitivity	Negative predictive value	Positive predictive value
⁹⁹ Tc labeled	721	25	65%	83%	76%	74%
²⁰¹ Tl imaging	1119	40	54%	87%	79%	67%
DSE	1421	41	78%	80%	83%	75%
FDG PET	598	20	58%	93%	77%	85%
Cardiac magnetic resonance						
DSMR	272	9	82%	74%	78%	78%
EDWT	100	3	41%	95%	92%	56%
LGEMR	178	5	63%	84%	78%	72%

⁹⁹Tc, technetium-99m; ²⁰¹Tl, thallium-201, DSE, dobutamine stress echocardiography; DSMR, dobutamine stress magnetic resonance; FDG PET, fluorodeoxyglucose positron emission tomography; EDWT, end-diastolic wall thickness; LGEMR, late gadolinium enhancement magnetic resonance.

Tissue Doppler Imaging

Viable myocardium demonstrates positive velocities in tissue Doppler imaging. Deceleration time (DT) and strain rate are used to assess viability. A DT more than 150 ms predict an increase in LVEF by 5% after revascularization by CABG. Viable myocardium is indicated by increase in peak systolic strain rate from rest to dobutamine stimulation by more than 0.231/s.

Dobutamine Stress Imaging

Contractility reserve and myocardial viability can be assessed with low-dose dobutamine stress imaging. Regional and global LV functional recovery in acute postmyocardial infarction setting and chronic coronary revascularization can be assessed using dobutamine stress imaging. The maximum benefit after revascularization can be seen in the biphasic response. Low-dose dobutamine causes initial improvement in contraction due to the inotropic action and, later at higher doses, chronotropic action of dobutamine causes decrease in contractility. For predicting recovery of contractile function following coronary vascularization, the positive predictive value is 83% and negative predictive value is 81%.¹⁰

Speckle-tracking Echocardiography

It provides reproducible and objective quantification of regional and global myocardial function and detection of myocardial viability. Myocardial viability is assessed by determining the strain and strain rate from the short and long axis of LV myocardial deformation.¹³

Myocardial Contrast Echocardiography

Acoustically reflective high molecular weight inert gases are used in myocardial contrast echocardiography (MCE). The gases form microbubbles in intravascular space and acts as a contrast medium. Segments of myocardium showing homogeneity of contrast intensity indicate viable myocardium. Lack of contrast enhancement indicates nonviable segments due to obstruction or collapse of microvasculature caused by necrotic myocardial cells. The sensitivity and specificity

to predict the recovery postrevascularization are 78–90% and 51–72%, respectively. Combination of DSE and MCE in assessment of myocardial viability has a sensitivity of 96% and specificity of 63%.¹⁴ Likelihood of global LV function improvement following revascularization is indicated by presence of more than three viable segments in MCE.³

Positron Emission Tomography

Positron emission tomography viability assesses both myocardial perfusion and myocardial glucose metabolism.¹³ N-NH₃ (ammonia) and ⁸²Rb (rubidium) are used to assess myocardial perfusion and fluorine-18-fluorodeoxyglucose (¹⁸F-FDG) for myocardial glucose metabolism. In centers where PET perfusion tracers are not available, SPECT perfusion tracers can be used instead. ¹⁸F-FDG tracer is glucose analog and its uptake in the myocardium reflects cardiac glucose utilization. Only the viable myocytes will show uptake of ¹⁸F-FDG, but unlike glucose, FDG is not metabolized further and retention of the ¹⁸F-FDG in the myocytes enables imaging (Table 2).

Oral glucose loading and nicotinic derivatives are used to achieve high glucose level and low free fatty acid level required for maximum cardiac glucose uptake.¹² More than 50% uptake of FDG in PET enables identification of 85% of myocardial LV segments which recovered function 1 year after revascularization.¹⁵ Normal perfusion and FDG uptake indicates stunning. Reduced perfusion and preserved FDG uptake indicates hibernating myocardium (Fig. 2). Scar tissue is reflected by reduced (nontransmural scar) or absent (transmural scar) perfusion and FDG uptake (Fig. 3).

Single-photon Emission Computed Tomography

It is used to assess ischemia and viability. Thallium-201 and technetium-99m (Tc-99m) labeled tracers like Tc-99m sestamibi and Tc-99m tetrofosmin are the commonly used radiotracers for myocardial perfusion SPECT.

For the assessment of myocardial viability with thallium-201, rest-redistribution protocol is followed. After

TABLE 2: Flow metabolism patterns in ¹⁸F-fluorodeoxyglucose positron emission tomography to assess myocardial viability¹⁶

Perfusion	Glucose metabolism	Category
Preserved	Preserved	<ul style="list-style-type: none"> Viable – normal/stunned heart Dilated ventricle in a remodeled heart
Preserved	Reduced	<p>Reverse mismatch (altered glucose metabolism)</p> <ul style="list-style-type: none"> Revascularization early after myocardial infarction (MI) Left bundle branch block Right ventricular pacing Nonischemic cardiomyopathy Diabetes mellitus
Reduced	Reduced	<ul style="list-style-type: none"> Match (nonviable scar)
Reduced	Preserved or increased fluorodeoxyglucose (FDG) uptake	<ul style="list-style-type: none"> Mismatch (viable myocardium in hibernation)

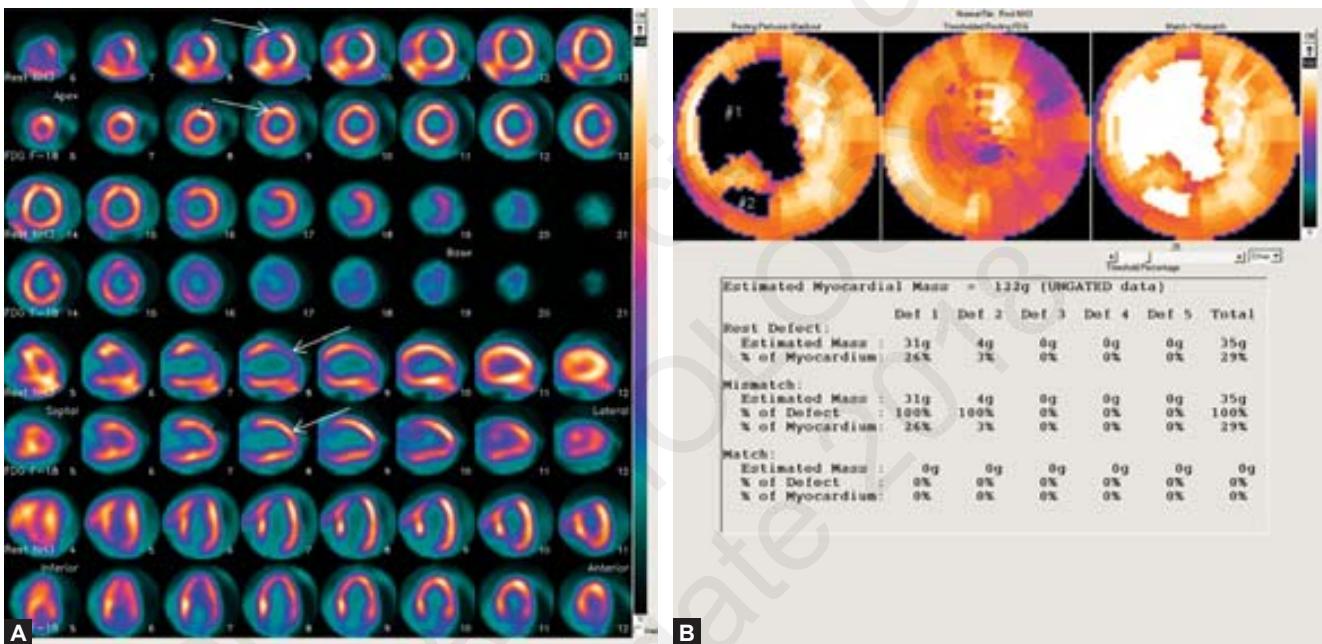

FIG. 2: N-13 NH₃ (ammonia) perfusion and F-18-fluorodeoxyglucose study at rest shows “Mismatch” perfusion and metabolic defect in the anteroseptal wall and apex, consistent with hibernating myocardium.

administration of thallium-201, initial images are acquired after about 20 minutes followed by rest-redistribution images after about 3–4 hours.¹² The initial uptake of thallium is flow dependent and the uptake in the viable myocyte is via sodium potassium adenosine triphosphatase dependent active process. Thallium-201 has unique property of redistribution, a process which is flow independent and the redistribution takes place between the thallium-201 in the blood pool and the viable myocardium till equilibrium is reached. This is particularly important as this flow independent process allows thallium-201 to be taken up by chronically hypoperfused but viable myocardial segments.

Technetium-99m has shorter half-life and better tissue penetration. Tc-99m labeled tracers underestimate myocardial viability when compared to thallium-201 and ¹⁸F-FDG PET. However, quantification of regional radiotracer uptake and nitrate administration before Tc-99m labeled radiotracer injection improves the assessment of myocardial viability.

Quantitative assessment of viability using either thallium-201 or technetium-labeled tracers can be performed using commercially available softwares that can quantify the size of scarred myocardium. A myocardial segment with uptake more than 50% of the uptake in the normal myocardial segments is considered viable myocardium and segments with less than 50% considered as nonviable. Size of the scar can be expressed as percentage of individual coronary territories or as percentage of total LV myocardium.

Cardiac Magnetic Resonance

Cardiac magnetic resonance gives information about myocardial contractility reserve, small myocardial scars and wall thickness. Different techniques used are measurement of wall thickness, late gadolinium enhancement magnetic resonance (LGEMR) and dobutamine stress magnetic resonance (DSMR). The gold standard technique for myo-

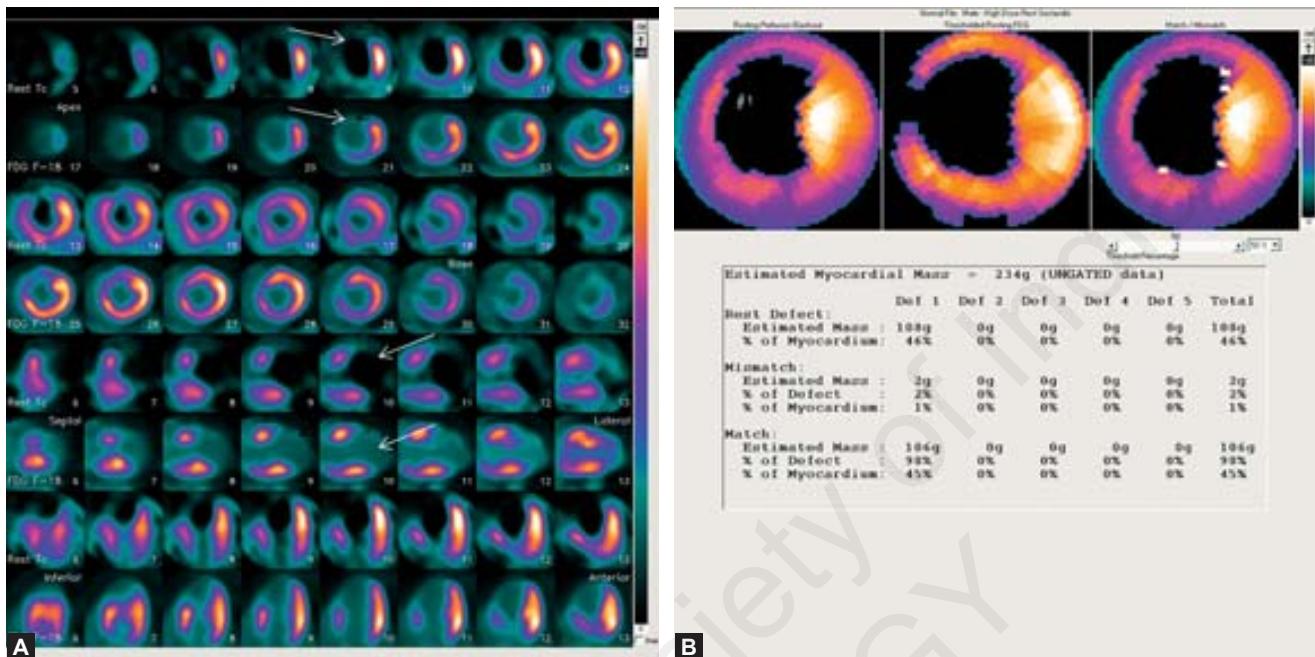

FIG. 3: Tc-99m MIBI perfusion and F-18-fluorodeoxyglucose study at rest shows “Match” perfusion and metabolic defect in the mid and distal anterior wall, distal septum and apex, consistent with scarred myocardium.

cardial scar imaging is LGEMR. Five to ten minutes after gadolinium contrast injection, basic sequence of inversion recovery imaging is done. Nonviable myocardium appears enhanced or bright and normal region appears black or null. Scar tissues have increased extracellular space resulting in increased gadolinium concentration and thereby signal enhancement. Large transmural infarcts due to microvascular obstruction appear as dark core within bright regions of late enhancement. Extent of LGEMR assessed at 12–48 hours post myocardial infarction is related with decreased functional recovery after 6 months. Sensitivity of LGEMR in detecting acute myocardial infarction is 99% and chronic myocardial infarction is 94%.¹⁷ With each gram of scar measured by LGE, the increased risk of major adverse cardiovascular event (MACE) is 5% and death is 4%.¹⁸ Low-dose dobutamine stress is combined with LGEMR to assess contractile reserve. Following administration of low-dose dobutamine, if there is increase in the systolic wall thickness by 2 mm or more, then the myocardium is considered viable. Biphasic response is seen in chronic LV dysfunction and hibernating myocardium. CMR helps in identifying the myocardial necrosis complications like hemorrhage, myocardial edema, LV thrombi, and microvascular obstruction. Limitations of CMR are lower temporal resolution, limited image quality with irregular rhythm, and the need for breath-holding sequence during acquisition (Table 3).

Coronary Computed Tomography

Coronary computed tomography is excellent tool to rule out CAD. Its use in assessing myocardial viability is still experimental.¹⁹

ROLE OF VIABILITY TESTING IN THE MANAGEMENT OF ISCHEMIC CARDIOMYOPATHY

Presence of 20–30% of the left ventricle needs to be hibernating or viable in order to have improvement in LVEF. Reverse remodeling after revascularization was found in patients with residual viability—20% resulting in increase in both end-diastolic and end-systolic volumes. Knowledge gaps are present regarding the application of noninvasive viability testing in patients with LV dysfunction and complex CAD. When ischemic cardiomyopathy patients are treated only with medical therapy, the outcomes are worse. Survival rate is improved with revascularization, when compared to medical treatment only. In a study where 144 patients underwent delayed enhanced CMR, patients with viable myocardium who underwent revascularization had better outcome when compared to medical therapy only.²⁰ Improvement in the regional LV function, exercise capacity, and heart failure symptoms may be predicted by the presence of viable myocardium in noninvasive testing. Positron emission tomography and recovery following revascularization (PARR)-1 study indicated that the scar extent was an independent predictor of recovery of ventricular function after revascularization. Smaller scar have better improvement in LVEF. Combined PET and clinical parameters predict degree of recovery.²¹ PARR-2 study did not show statistically significant reduction in cardiac events in LV dysfunction and coronary disease patients with FDG PET directed therapy when compared to standard care. The limitation of PARR-2 study was that 25% of patients in FDG

SPECT, single-photon emission computed tomography; PET, positron emission tomography; CMR, cardiac magnetic resonance; GFR, glomerular filtration rate; LGE, late gadolinium enhancement; EDWT, end-diastolic wall thickness; DSE, dobutamine stress echocardiography; CCT, cardiac computed tomography.

PET study group were not treated according to PET-guided recommendations. Adherence to PET recommendations for treatment showed significant benefit for FDG PET in group without recent coronary angiography.²² The Ottawa-FIVE study of PARR trial compared the outcome of patients undergoing the FDG-directed therapy and standard therapy. Patients who underwent FDG PET-assisted management had statistically significant reduction in the cardiac events when compared with the standard treatment patients. Patients experiencing the composite endpoints (compared between

the groups were myocardial infarction, cardiac death, and hospitalization in 1 year) was 19% in FDG PET-assisted group versus 41% in standard treatment group.²³ This underscores the importance of experienced, high volume centers where PET-based revascularization was better than standard treatment protocol. According to CHRISTMAS (carvedilol hibernation reversible ischemia trial), the improvement of LV function with carvedilol treatment in ischemic cardiomyopathy patients is dependent on the volume of myocardium affected by ischemia, hibernation or both. There

was no or little improvement in LV function with carvedilol treatment in the absence of viable myocardium.²⁴ STICH (Surgical Treatment for IsCHEMIC heart failure) was done to compare the outcome of OMT alone or OMT plus CABG in patients with LV dysfunction and CAD.²⁵ Patients in OMT plus CABG group had lower rates of mortality.²⁶ Substudy of STICH assessed the role of viability based revascularization.²⁷ Almost 50% of patients had viability based revascularization in a nonrandomized fashion. Though, myocardial viability based revascularization strategy was found to have significant benefit as compared to other strategy in univariate analysis and multivariate analysis after adjustment of baseline variables like ejection fraction and LV end-diastolic volume did not show significant difference. There are lots of limitations of this particular trial. They include utility of SPECT and DSE used to assess myocardial viability which are not the gold standard to assess viability. The result of the substudy was done in a nonrandomized fashion. This emphasized that there exists a lacunae in the field of viability assessment, which needs to be addressed by future large volume randomized studies.

FUTURE DIRECTION

Myocardial viability assessment is important in a patient with multivessel disease and delayed presentation of myocardial infarction. Assessment of viable myocardium helps in decision making of need for revascularization. Its role is not clear in patient with severe LV dysfunction and CAD pending a large patient-based randomized study comparing the role of myocardial viability assessment in revascularization of such patients. Till then, we presume a heart team-based approach where patient remains the cornerstone in making informed decision about the need and kind of revascularization strategy.

Computed Tomography Coronary Angiography—Essentials for Cardiologists

Priya Jagia, Arun Sharma

INTRODUCTION

Computed tomography coronary angiography (CTCA) is increasingly being used in clinical context with the advent of technical refinements and introduction of third-generation CT scanners. It has established itself as the investigation of choice to rule out significant coronary artery disease (CAD) in low to intermediate risk symptomatic patients. Its use has now expanded beyond classic coronary stenosis detection to encompass plaque characterization, vulnerability detection, detection of coronary anomalies, patency of grafts and stents, treatment planning, and follow-up of patients, depending upon different clinical scenarios. This has reduced the negative catheter angiography in low to intermediate risk patients and resulted in substantial decrease in unnecessary radiation exposure to the cardiologists in catheterization laboratory.

CONVENTIONAL ANGIOGRAPHY OR COMPUTED TOMOGRAPHY CORONARY ANGIOGRAPHY

Coronary catheter angiography (CA) remains the gold standard for luminal assessment of coronary vasculature, but it carries some risks due to its invasive nature and exposure to ionizing radiation. Moreover, the cardiologist is also exposed to the aforementioned radiation repetitively, every time he performs a catheter study. Nearly up to 15–30% of patients undergoing CA turn out to be normal studies^{1,2} adding unnecessary radiation to both the patient and the operator alike. Hence, using CT angiography (CTA) for even a select group of patients will result in substantial reduction in the radiation dose. Use of CTA for obtaining anatomical information noninvasively is very attractive for this reason besides being a much safer noninvasive alternative to CA.

Technical Advancements

At present, CTCA is considered the most robust imaging technique for noninvasive visualization of coronary atherosclerosis. The challenges in evaluation of coronary arteries by CT (cardiac and respiratory motion, temporal resolution, etc.) have now been largely overcome with various advancements of CT technology, most notably being the introduction of dual source CT.^{3–6} The newer third-generation dual source CT scanners provide excellent image quality over a wide range of body sizes and heart rates at much lower radiation doses than the previous generation CT scanners. Extremely fast gantry rotation time combined with larger Z-axis volume coverage per rotation, have enabled single-heartbeat acquisitions in most patients with heart rates of up to 75–85 beats/min.

Low contrast protocols described in various studies have resulted in significant reduction in contrast medium requirements, without any difficulties in contrast medium timing or unsatisfactory vessel enhancement. Moreover, volumetric acquisition has enabled extensive image postprocessing, including multiplanar reformatted and maximum-intensity projection images to create virtual images similar to those obtained with CA.^{5,6}

Diagnostic Performance of Computed Tomography Coronary Angiography

Various studies have demonstrated excellent diagnostic accuracy of CTCA for the detection of coronary stenosis, with a sensitivity of 86–99%, specificity of 92–98% and negative predictive value reaching almost up to 100%.⁷ It can provide detailed information on coronary artery anatomy, and assess both coronary artery atherosclerosis as well as resultant luminal stenosis. Nonobese patients in sinus rhythm (heart rate <65 beats/min) with adequate breath hold and favorable coronary artery calcium (CAC) score provide best

quality images which are comparable to coronary catheter angiogram. Most importantly, it detects early nonobstructive disease which allows for the early institution of medical therapy and lifestyle modifications. It is a rapid and low-cost modality which is usually available round the clock for noninvasive evaluation.

Limitations

Despite being noninvasive study with high accuracy, CTCA still has some limitations in the form of poor visualization of extensively calcified arteries and a poorer spatial resolution in distal most coronary artery segment. Moreover, evaluation may be suboptimal in obese patients and in patients with very high or irregular heart rates.

Patient Selection and Preparation

Optimal CTCA imaging requires proper patient selection and preparation. It depends on multiple factors like clinical indication, pretest probability of CAD and clinical and biochemical test results. A number of risk algorithms are available that can be used to calculate probability of CAD. Patients should be informed about the benefits and potential risks of the procedure. General instructions may include avoidance of caffeine 12 hours prior to the procedure to avoid cardiac stimulation, ruling out history of prior contrast allergy, and ruling out renal dysfunction. They should be instructed to avoid eating solid food 6 hours prior to the study and to maintain adequate hydration both pre- and postprocedure. Beta-blockers or nitroglycerine may be given as per the requirement and the necessary caution must be exercised during their administration. However, with use of third-generation CT scanners, administration of these pharmacologic drugs is relatively lesser.

Coronary Artery Calcium Scoring

High CAC score has been associated with increased mortality and adverse cardiovascular events, independent of other risk factors.^{7,8} Moreover, absence of coronary calcium portends a remarkably favorable prognosis, with almost no patients experiencing adverse cardiac events in next 5 years. CAC scoring is now established as a risk stratification tool to identify high-risk patients who might benefit from further investigation. It can characterize the location as well as the burden of CAD (Fig. 1).

Applications of Computed Tomography Coronary Angiography

Computed tomography coronary angiography has wider applications in current cardiology practice. Knowledge of these applications is essential for judicious use of the technique over and above CA. These indications are briefly described here.

Evaluation of Coronary Artery Disease

Coronary Artery Disease Detection, Characterization, and Quantification

Computed tomography coronary angiography can be optimally used to rule out significant CAD (Fig. 2) in patients

with low to intermediate pretest probability of CAD.⁷⁻¹⁰ It has become possible due to its high negative predictive value. It is also helpful in cases of suspected left main ostial disease as the CA may not able to differentiate between spasm and true stenosis. Coronary evaluation may be needed prior to any major surgical procedure in patients at risk of CAD. It is also helpful in planning percutaneous coronary interventions in chronic total occlusion and evaluation of coronary arteries in post cardiac transplant patients.

Knowledge of normal coronary anatomy (origin, course, branches, and termination) and variants helps in accurate interpretation and reporting of CTCA. Normally, left anterior descending and posterior descending artery run in interventricular groove, while the circumflex and right coronary arteries run in the atrioventricular groove. Hypoplasia of one vessel is generally accompanied by

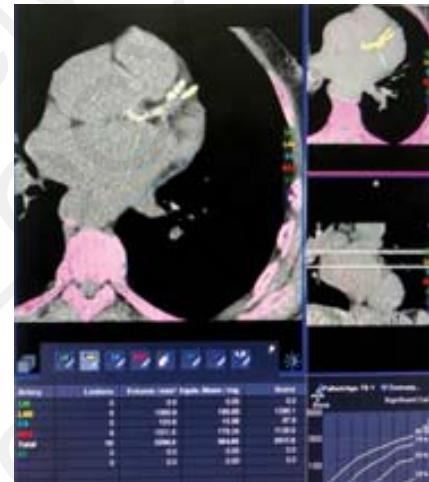

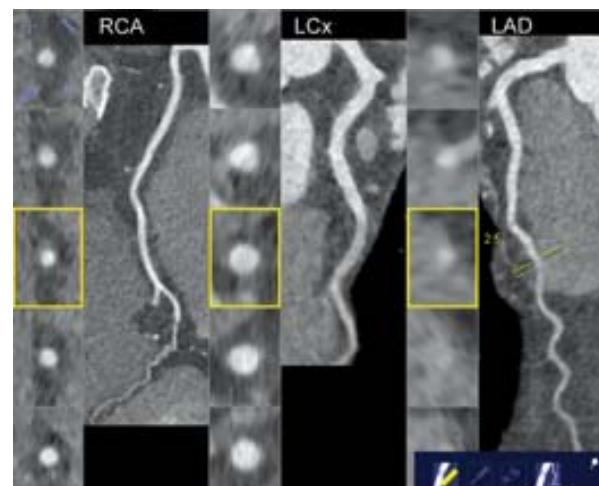

FIG. 1: Computed tomography angiography-derived coronary artery calcium score in a patient with significantly calcified coronary arteries. Color coding of plaque according to each coronary artery helps quantify calcium in each vessel.

LAD, left anterior descending; LCx, left circumflex artery; RCA, right coronary artery.

FIG. 2: Curved multiplanar computed tomography angiography images showing normal coronary arteries. Side panels show the axial cross-sections with diameter and area.

prominence of another vessel. In cases where left anterior descending is small and does not extend to the apex, the posterior descending artery is typically prominent and extends to the apex. If the circumflex is small, there are typically prominent posterolateral branches from right coronary artery. If case of a large ramus intermedius, the diagonals may be small.

Degree of stenosis should be graded and mentioned in the report for baseline and follow-up. Various methods including visual assessment, "end-on" view assessment, diameter on maximum intensity projection images and software calculation of diameter or area. Highest correlation with quantitative CA is seen with cross-sectional area technique with smallest interobserver variability with maximum intensity projection technique.

It is to be borne in mind that stenosis is typically overestimated in areas where heavily calcified plaques are present, and significant decrease in specificity, positive predictive value, and accuracy of CTCA is seen when calcification is greater than 50% of the luminal diameter. Reconstruction of additional dataset using a sharper convolution kernel and use of bone window setting is advocated in such cases to reduce blooming artifacts from calcification.

Plaque Characterization

Characterization and quantification of atherosclerotic plaques may be useful to improve individualized risk stratification. Intravascular ultrasound remains the test of choice in this regard. CTCA using latest scanners is also helpful in characterizing coronary atherosclerotic plaques (Figs. 3 and 4) as it can identify lipid, fat, or calcium depending upon attenuation difference.¹¹⁻¹³ Further, it helps in ascertaining the vulnerability of the plaque as plaques with high lipid content have been shown to be more vulnerable and prone to rupture, whereas calcified plaques are thought to be more stable.

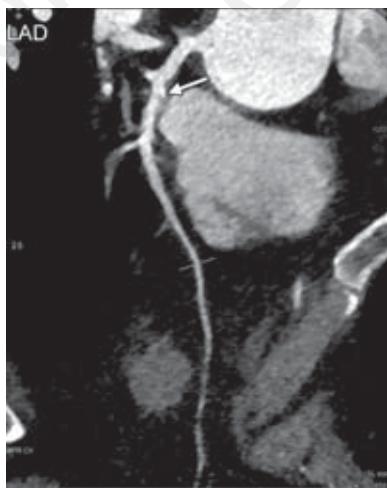

FIG. 3: Computed tomography angiography image showing mild disease with eccentric calcific plaque in proximal left anterior descending artery (arrow).

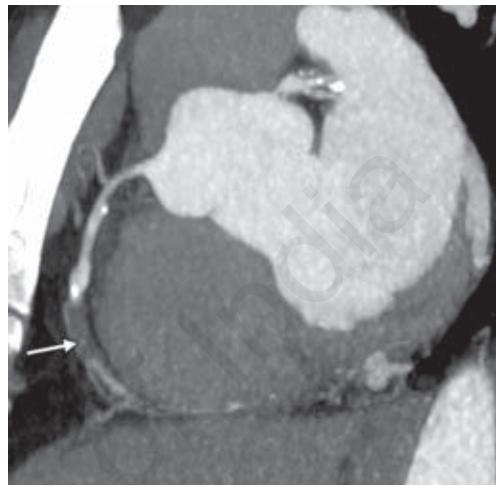

FIG.4: Computed tomography angiography image showing complete occlusion of mid right coronary artery (arrow) with calcific plaques in proximal and mid-part.

Computed Tomography Fractional Flow Reserve

Conventional CA with measurement of FFR by means of a pressure wire technique is the established reference standard for the functional assessment of CAD.^{14,15} Computed tomography fractional flow reserve (CT-FFR) has emerged as a noninvasive method for direct assessment of CAD and plaque characterization with high (75% vs. 44%) diagnostic accuracy.^{16,17} Growing CT-evidence has validated the diagnostic accuracy of CT-FFR techniques compared with invasive FFR. The technique uses computational fluid dynamics to calculate "3-vessel" FFR from already acquired coronary CTA images. Its advantage over CA-derived FFR is that it is entirely noninvasive and no vasodilators are required as computational models allow CT-FFR to be calculated across a physiologically realistic range. CT-FFR has the potential to streamline and rationalize the care of patients suspected of having CAD and improve outcomes while reducing overall healthcare costs.

Myocardial Perfusion

Recently, the ability of dual-energy CT (DECT) to characterize tissue composition and organ perfusion has been demonstrated. Moreover, cardiac perfusion-imaging with DECT seems to correlate with fixed perfusion defects in technetium-99m (99mTc) sestamibi single photon emission computed tomography (SPECT).^{18,19} Evaluation of myocardial perfusion using DECT may complement anatomic evaluation of the coronary arteries by gauging the hemodynamic significance of detected stenosis. However, further studies are needed to determine the diagnostic accuracy of these perfusion defects detected by DECT, their predictive value, and their impact on patient care.

Evaluation of Bypass Grafts

Computed tomography coronary angiography is the investigation of choice (sensitivity of 96.1%, specificity of 96.3%)

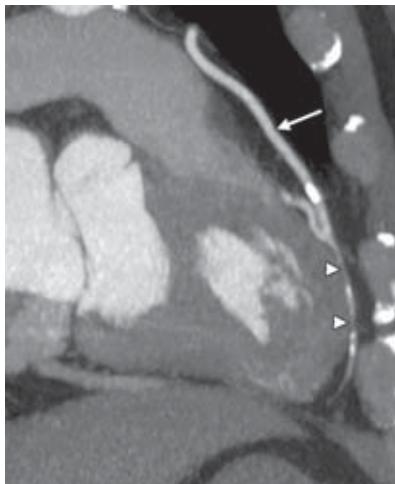

FIG. 5: Computed tomography angiography of a post coronary artery bypass graft patient showing patent left internal mammary artery—left anterior descending artery (LAD) graft (arrow) with diffuse distal LAD disease (arrowheads).

FIG. 6: Computed tomography angiography image showing patent stent in left anterior descending artery (arrow) with normal distal artery (arrowhead).

for evaluation of bypass graft patency (Fig. 5) in acutely symptomatic post coronary artery bypass graft (CABG) patients.^{20–22} Another potential indication of CTCA in the setting of prior bypass grafting is surgical planning, providing a road-map on graft location, anatomic landmarks, and anastomotic sites before redo CABG surgery.^{20–22} In patients with internal mammary grafts, the scan should extend superiorly to the level of the clavicle to rule out subclavian stenosis. Proximity of the grafts to the sternum should be mentioned in the report to avoid damage during a redo sternotomy. However, artifacts from surgical clips may limit graft evaluation by cardiac CTA (CCTA) and the distal anastomosis in particular is difficult to assess at times. Still, the evaluation of the native vessels, often calcified, remains the most challenging aspect of CCTA in post-CABG patients.

Evaluation of Coronary Stents

Computed tomography coronary angiography is also helpful in evaluation of patency of coronary stents (Fig. 6). Moreover, stent fracture can also be delineated well. Studies have reported high diagnostic accuracy (negative predictive value: 97–98%, accuracy: 84–93%) of CTCA for in-stent restenosis of stents greater than 3 mm diameter.^{23,24} However, depiction of in-stent intimal hyperplasia, particularly in small vessels still remains a challenge for CTCA. Beam-hardening and streak artifacts caused by metallic stent struts significantly impair the visualization of the coronary artery lumen and make it difficult to diagnose in-stent intimal hyperplasia by means of CTCA.²⁵ Artifacts caused by metallic stent struts provoke attenuation defects that may mimic in-stent restenosis. Obesity, smaller stent diameter (<3 mm), increased strut thickness and thicker stent material have been shown to adversely affect the accuracy of CTCA. Iterative image reconstruction further improves in-plane stent visualization in cases of smaller stents and should preferably be used in combination with thinner collimation.²⁶

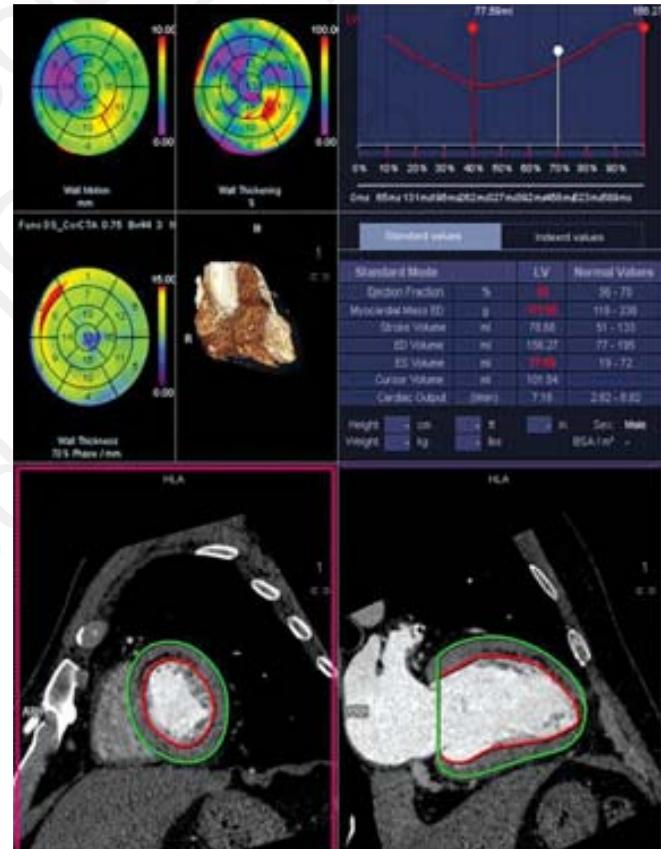

FIG. 7: Functional assessment using computed tomography which shows decreased ejection fraction (50%) in a patient earlier ischemic insult. Dark areas of hypoperfusion are seen in the anterior wall of left ventricle myocardium.

Ischemic Heart Disease and Cardiac Function

With the use of current postprocessing techniques, regional wall motion abnormalities and ejection fraction calculation (Fig. 7) can be ascertained from retrospective CTCA without

doing any additional data acquisition.^{18,19,27,28} Hence, early detection of subclinical functional abnormalities is possible in asymptomatic patients with myocardial dysfunction, especially those with diabetes. However, it is important to note that magnetic resonance imaging still remains the investigation of choice for functional and myocardial assessment.

Computed Tomography Coronary Angiography for Coronary Evaluation in Congenital Heart Disease

Computed tomography coronary angiography is extremely helpful in excluding anomalous coronary origins in pediatric population with simultaneous evaluation of cardiac and extracardiac morphology and airway or lung parenchymal changes.²⁹⁻³¹ It can also demonstrate interarterial anomalous coronary course which has therapeutic implications. Moreover, demonstration of the course of coronary artery can be helpful to avoid coronary injury during surgical reimplantation. It is also useful in diagnosis and follow-up

of patients with Kawasaki disease, where it delineates exact morphology of coronary aneurysms and associated changes. All the possible recommended indications for doing coronary CTA are summarized in box 1.

CONCLUSION

Computed tomography coronary angiography has gained wider application and acceptance in current cardiology practice. One must be acquainted with native radiological appearances and postoperative imaging findings of various cardiac pathologies for optimal interpretation of test results. Further advancements in evaluation of coronary plaque morphology, plaque vulnerability, myocardial perfusion, and CT-FFR may allow even more complete noninvasive cardiac assessment in future. Moreover, it may provide a highly effective method of cardiac risk stratification to facilitate early implementation of preventive cardiac care.

Appropriate clinical indications for doing computed tomography coronary angiography

- Nonacute chest pain patients suspected of ischemic chest pain:**
 - In low and intermediate pretest CAD probability when patients are unable to exercise/ECG results are uninterpretable
- Acute chest pain patients suspected of acute coronary syndrome:**
 - Acute chest pain with normal ECG/enzymes
 - For low or intermediate pretest probability patients with uninterpretable ECG/nondiagnostic ECG or with unclear myocardial enzymes
- Patients suspected of ischemic chest pain after coronary revascularization:**
 - Graft patency evaluation after coronary artery bypass graft
- Symptomatic patients with coronary artery stents:**
 - With coronary stent greater than 3 mm in diameter
- CT coronary angiography in pediatric population:**
 - Coronary artery congenital anomalies
 - Complex congenital heart disease
 - Postoperative evaluation in congenital heart diseases
 - Symptomatic Kawasaki heart disease patients with no prior testing
 - For follow-up of patients with Kawasaki disease
- Evaluation of the ventricular structure and systolic function:**
 - Assessment of left ventricular function in patients with acute MI / heart failure if other noninvasive imaging tests are inadequate
 - Quantitative assessment of right ventricular function
 - Assessment of right ventricular morphology in ARVC
- Heart failure newly developed or newly diagnosed in patients with no history of CAD in low- to intermediate-risk**
 - Coronary artery assessment prior to noncoronary cardiac surgery

ARVC, arrhythmogenic right ventricular cardiomyopathy; CAD, coronary artery disease; CT, computed tomography; ECG, electrocardiogram; MI: myocardial infarction.

Current Indications for Cardiac Magnetic Resonance Imaging

Mona Bhatia, Shashank Jain

INTRODUCTION

Cardiac diseases are among the leading causes of death worldwide. While echocardiography has stood the test of time being noninvasive, nonionizing, easily available, portable and relatively cost-effective, its dependence on operators and acoustic window are among some of its limitations. Cardiac magnetic resonance imaging (MRI) is an excellent tool, nonionizing, currently capable of exceptional spatial, and temporal resolution. Cardiac MRI is capable of not only assessing cardiac structures, but ventricular volumes, function, myocardial perfusion, and tissue characterization with specific sequences to enable diagnosis of edema, ischemia, infarction, scars, myocardial iron content, and flow parameters through different pulse sequences. Hence, cardiac MRI is rapidly growing in the field of cardiac imaging, with a growing number of clinical applications for diagnosis, prognostication, to guide management and follow-up patients to improve clinical outcome. Recent years have seen cardiac MRI play a pivotal role in assessment of myocardial viability, distinguishing different cardiomyopathies, pericardial disease, cardiac masses, congenital and valvular heart diseases, and aortic and pulmonary vessel evaluation.^{1,2} Emerging applications include coronary artery, plaque imaging, and vessel analysis besides guiding therapeutic electrophysiology and interventional procedures.¹

TECHNICAL ASPECTS OF CARDIAC MRI

Image Acquisition

Cardiac MRI can be performed on both 1.5T and 3T scanners. During cardiac image acquisition, respiratory and cardiac motion are the prime culprits for image degradation. Hence, breath-holding and electrocardiogram (ECG)/vector cardiogram gating are essential to ensure optimal image acquisition and quality during a specific phase of the cardiac cycle.³

Imaging Planes

While majority of MRI is obtained in the axial, coronal, and sagittal planes, cardiac imaging is often acquired in specific planes as the vertical long axis (two-chamber view), horizontal long axis (four-chamber view), short axis, and three-chamber view.

Imaging Protocols and Sequences

Imaging protocols and sequences need to be tailored to the clinical question. Each pulse sequence is specific, broadly being divided into black-blood or bright-blood sequences. The black-blood spin-echo sequences have higher resolution and are preferred for morphological and anatomic evaluation. The stack of short-axis cine images, from base to apex are used for volumetric analysis and functional evaluation.⁴ The high accuracy and reproducibility of MRI is responsible for making cardiac MRI the “gold standard” in the calculation of ventricular volumes, as end-diastolic, end-systolic and stroke volumes, besides determination of ejection fraction (EF) (Table 1), cardiac output, and myocardial mass assessment.^{3,4} The excellent contrast between the blood and myocardium on steady-state free precession sequences enables high temporal resolution for accurate and reproducible evaluation of wall motion and ventricular wall thickness. Myocardial tagging with dark grid lines is capable of accurately analyzing cardiac rotation, strain, displacement and deformation of myocardial layers, subendocardial, mid-wall and subepicardial, through the entire cardiac cycle thus evaluating regional myocardial function.^{1,5}

The T2-weighted and short inversion time inversion recovery (STIR) sequences are useful for evaluating myocardial edema. Postadministration of IV injection of 0.2 mmol/kg of a gadolinium-based contrast agent, the initial first-pass perfusion imaging is a reliable indicator of ischemia while T1-weighted fast-field echo inversion recovery sequences 10–15 minutes post-IV gadolinium, generate the late-enhancement images useful for myocardial tissue

TABLE 1: Left ventricle analysis results

End diastolic volume	42.4	mL
End systolic volume	10.9	mL
Ejection fraction	74.3	%
Stroke volume	31.5	mL
Stroke index	19.3	mL/beat/m ²
Cardiac output	2.3	L/min
Cardiac index	1.4	L/min/m ²
Right Ventricle Analysis Results		
End diastolic volume	43.6	mL
End systolic volume	16.2	mL
Ejection fraction	62.8	%
Stroke volume	27.4	mL
Stroke index	16.8	mL/beat/m ²
Cardiac output	2.0	L/min
Cardiac index	1.2	L/min/m ²

characterization, scar assessment, and prognostication. It is also useful in the evaluation of myocardial infarctions, infiltrative processes and in differentiating masses from thrombi.³ Phase-contrast sequences are used for quantifying flow and are valuable in stenosis, regurgitation, transvalvular flow, and evaluation of cardiac shunts. Even pressure gradient across lesions are calculated based on blood velocities.

INDICATIONS AND APPLICATIONS

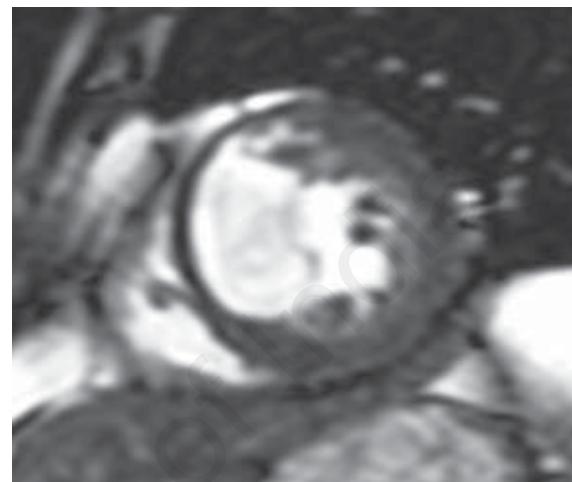

The most frequent clinical applications for cardiac MRI include the following described here.

Ischemic Heart Disease

The three critical questions in evaluation of ischemic heart disease (IHD) are function, ischemia, and viability followed by evaluation of complications, all of which are essential for prognosticating the patient, guiding therapy and follow-up to improve overall patient outcome. Cardiac magnetic resonance (CMR), based on specific sequences can differentiate acute from chronic infarcts, and both qualitatively and quantitatively assess ischemia, distinguish hibernating and stunned myocardium from infarcted myocardium and determine viability.³

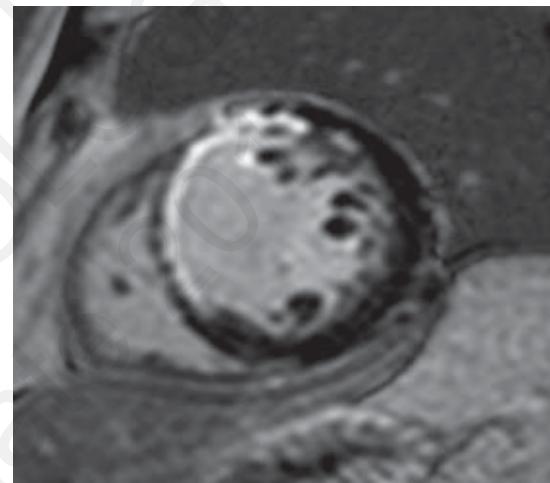

In the evaluation of cardiac function, cardiac MRI is today considered the gold standard for both regional and global myocardial function. Cardiac MRI can reliably assess both left and right ventricular volumes, and quantify end-diastolic, end-systolic, stroke volume, EF, and ventricular mass. Myocardial wall motion and wall thickness (Fig. 1) can be assessed both visually and quantitatively. Myocardial tagging can further be used for depicting strain. Regional wall motion abnormalities may be seen in both acute and chronic myocardial infarctions.

Acute infarctions demonstrate increased signal on T2-weighted imaging due to myocardial edema. Following IV

CMR, cardiac magnetic resonance; LAD, left anterior descending.

CMR, cardiac magnetic resonance; LAD, left anterior descending.

FIG. 2: Short-axis CMR image demonstrating subendocardial late gadolinium enhancement consistent with myocardial infarction in the LAD territory in a case of ischemic cardiomyopathy.

gadolinium administration, first-pass myocardial perfusion is used to delineate areas of ischemia. Delayed hyper-enhancement (DHE) is a reliable indicator of infarction as it is associated with myocyte necrosis (Fig. 2). A bull's eye mapping of all 17 segments of the left ventricle is possible for wall thickness, wall motion, ischemia, infarction, and viability (Fig. 3). Presence of perfusion defects with delayed-enhancement on the MRI study is highly predictive of scar formation.² Combining first-pass and delayed imaging is an indicator of ischemia and viability and predict functional recovery.⁴

Extent and transmurality of delayed enhancement has prognostic implications (Fig. 2) and is inversely proportional to the degree of functional recovery after acute myocardial infarction.² Extent of delayed enhancement in excess of 50%

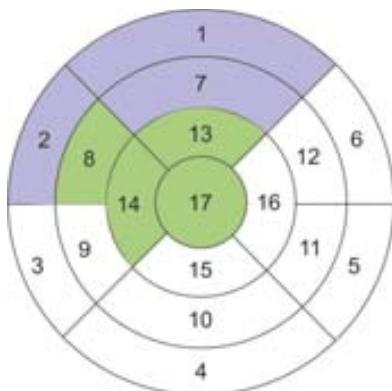

FIG. 3: Bulls eye view of the 17-segment cardiac model depiction percentage of involvement in different segments in a case of ischemic cardiomyopathy.

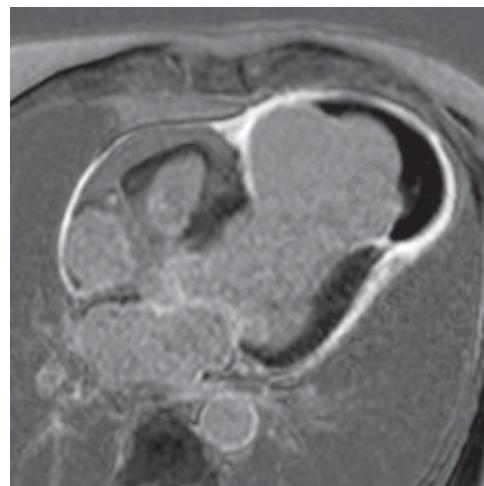

transmurality of the myocardium can predict segments that are less likely to improve function following revascularization or beta-blocker therapy (Fig. 2).

Magnetic resonance imaging today plays a lead role in identifying acute infarction with myocardial edema, ischemia, and differentiating viable myocardium from nonviable myocardium. Wall motion abnormality may be seen in the setting of ischemia, with transient hypoperfusion which can cause myocardial stunning. Adding myocardial delayed enhancement sequences to the cine MRI protocol, helps to differentiate wall motion abnormalities of myocardial stunning, which are reversible, from myocardial infarction and scarring, which are often irreversible.² While both stunning and infarction cause wall motion abnormality, delayed enhancement occurs only with infarcts. Lack of delayed enhancement is seen in stunning.

Similar to stress echocardiography, cine-stress MRI can be used to assess viability without contrast administration during a low-dose infusion of dobutamine (5–10 µg/kg/min).¹ Improvement in left ventricular wall thickening following stress in a poorly functioning segment at rest indicates viability.² Dobutamine and adenosine stress MRI can also be used to detect ischemic myocardium.² DHE can be seen in diseases as myocarditis, cardiomyopathy, sarcoidosis, amyloidosis, and arrhythmogenic right ventricular dysplasia besides acute and chronic infarcts.⁶

The pattern and distribution of enhancement in these disorders helps to differentiate ischemic from nonischemic cardiomyopathy. While ischemic cardiomyopathy starts in the subendocardial zone and extends like a wavefront, to become transmural, in a coronary artery territory, nonischemic cardiomyopathies demonstrate delayed enhancement, which may be linear, patchy or nodular with a preponderance for the mid-wall, epicardial or global endocardial regions, not following a coronary artery territory.⁴

In severe acute myocardial infarctions, the subendocardium may depict an area of nonenhancement surrounded by enhancement. This central region represents microvascular obstruction (MVO). While this may resolve by 2 weeks, leaving only a scar with DHE, the presence of MVO on delayed

CMR, cardiac magnetic resonance; PSIR, phase sensitive inversion recovery.

FIG. 4: Four-chamber postgadolinium-enhanced PSIR CMR image demonstrating extensive transmural late gadolinium enhancement consistent with myocardial infarction in the LAD territory with aneurysmal change in the apex and intracavitary apical thrombus in a case of ischemic cardiomyopathy.

enhanced images is indicative of a poor clinical prognosis.³ Intramyocardial hematomas may also occur as sequelae to severe infarction or reperfusion. Myocardial infarction may progress to myocardial thinning (<6 mm) (Fig. 1) with hypertrophy of the noninfarcted myocardium. Subsequent ventricular dilation, aneurysms, pseudoaneurysms, intraventricular thrombi adjacent to akinetic myocardium after infarction are complications that need further evaluation (Fig. 4).³ Perfusion MRI following infusion of pharmacologic agents as adenosine and persantine, at rest and stress, when compared to standard methods as angiography or radionuclide scintigraphy, have a sensitivity of 67–83% and specificity of 75–100%.¹ Delayed-enhancement MRI has superior spatial resolution for assessment of scar and viability, in particular, for detecting subendocardial infarction, besides additional information on simultaneous anatomic and cine imaging for wall motion abnormalities.²

Myocardial delayed-enhancement cardiac MRI has a good correlation with dobutamine stress echocardiography.⁷ On comparison with single-photon emission computed tomography (SPECT), CMR is superior. While there is good agreement between SPECT and CMR, SPECT depicted all of the nearly transmural infarctions but missed 47% of subendocardial infarctions in a study that were depicted on myocardial delayed-enhancement MRI.^{2,8} On comparison with 18F-fluorodeoxyglucose positron emission tomography (PET) as the standard, myocardial delayed-enhancement MRI demonstrated 96% sensitivity and 84% specificity.⁹

Nonischemic Cardiomyopathy and Myocarditis

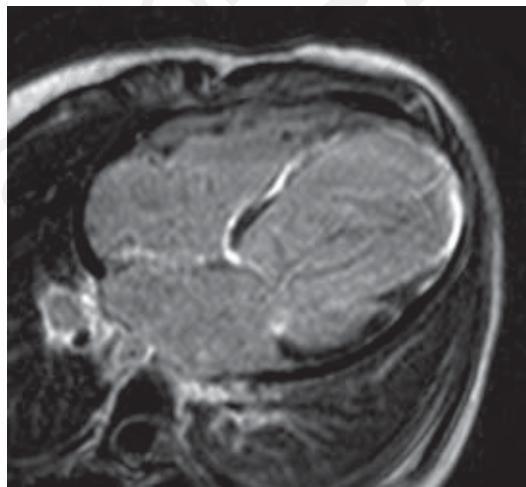

Magnetic resonance imaging can accurately assess ventricular morphology, wall motion abnormalities, function and myocardial wall enhancement pattern which help to

characterize cardiomyopathy and myocarditis.¹ Cardiomyopathies may be classified as dilated, hypertrophic, restrictive, arrhythmogenic right ventricular, and other specific cardiomyopathies.

Dilated Cardiomyopathy

Dilated cardiomyopathy (DCM) is associated with dilatation and functional impairment of the left ventricle (LV) or of both ventricles in the absence of significant coronary artery disease (CAD).¹⁰ The cause may be unclear hence a large number are considered idiopathic. Recognized cases include ischemic, genetic or familial, viral, immune, or toxic origin, or secondary to myocardial dysfunction not attributed to ischemic damage or volume overload.^{11,12} Patients present with progressive cardiac failure, and the long-term prognosis is poor.¹³ Affected ventricles may have normal or thinned walls with hypokinesia, increased cavity volumes, impaired diastolic function,^{14,15} and low EFs. Associated atrial dilatation and valvular dysfunction may occur. CMR is an ideal method to assess DCM¹⁶ to analyze wall thickness, ventricular volumetrics, and delayed-enhancement characteristics to ascertain diagnosis, prognosis, management, and follow-up.¹

The late gadolinium-enhanced sequences in cardiac MRI, in particular, are extremely useful as they help differentiate between dilated cardiomyopathy (CMP) secondary to CAD and other causes of dilated CMP, besides evaluating the degree of fibrosis which might predict outcome. The progressive replacement interstitial fibrosis in DCM is frequently mid-wall in the circumferential fiber layer rather than subendocardial as seen in IHD (Fig. 5).¹⁰ This mid-wall myocardial fibrosis, a predictor of all-cause mortality, cardiovascular hospitalization, sudden cardiac death, and ventricular tachycardia. Thus, cardiac MRI is useful in risk stratification of patients with dilated CMP (Fig. 5).

CMR, cardiac magnetic resonance; LV, left ventricle; PSIR, phase sensitive inversion recovery.

FIG. 5: Four-chamber postgadolinium-enhanced PSIR CMR image demonstrating dilated LV with global wall thinning, and mid-wall to transmural late gadolinium enhancement in a case of dilated cardiomyopathy.

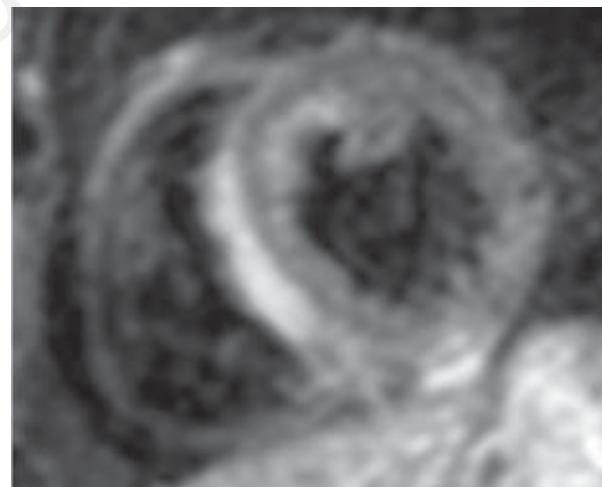

Studies have demonstrated that mid-wall and basal anterolateral wall late gadolinium enhancement (LGE) is an independent predictor of major adverse cardiac events (MACE) in clinically diagnosed DCM patients, with normal coronary angiograms.^{17,18}

Myocarditis

Myocarditis is inflammation of the myocardium due to various etiologies as viral, toxins, drugs, and autoimmune processes.¹⁹ Myocarditis manifests as myocardial edema on T2-weighted images on CMR with associated wall-motion abnormalities, and patchy early and delayed myocardial enhancement postgadolinium contrast administration.¹⁹ In myocarditis, LGE typically spares the endocardium and involves the mid-myocardial and subepicardial layers (Fig. 6).²⁰ The lateral free wall is more commonly involved in Parvovirus B.²¹

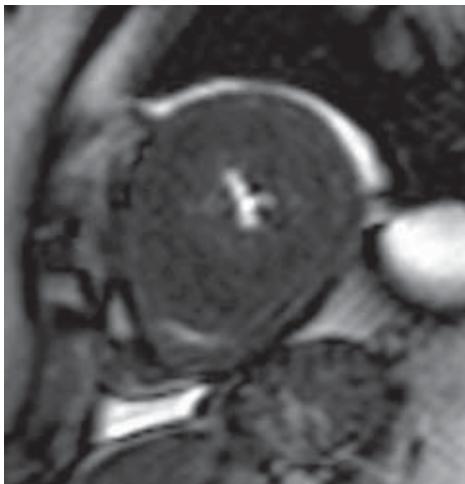

Hypertrophic Cardiomyopathy

Hypertrophic CMP is often genetic or familial, with a 50% autosomal-dominant hereditary pattern, and variable expression.²² Patients are usually asymptomatic or mildly symptomatic, even sudden death may occur.²³⁻²⁵ Hypertrophic CMP involves LV wall thickening, concentric, apical, asymmetric or papillary muscle involvement, although most often it is asymmetric with involvement of the interventricular septum (Fig. 7).¹¹ LV outflow tract obliteration may occur as a consequence, with systolic gradients (obstructive form). Left ventricle ejection fraction (LVEF) can be normal or increased, whereas cavity volumes can be normal or reduced. Altered ventricular compliance may cause diastolic function impairment and valve insufficiency may coexist. Cardiac MRI is excellent in evaluating all these parameters.¹⁴

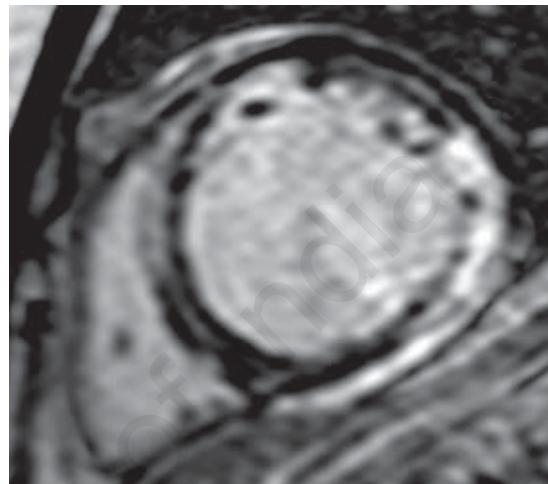

CMR, cardiac magnetic resonance.

FIG. 6: Short-axis T2-weighted CMR image demonstrating myocardial hyperintensity, suggestive of edema in a case of acute myocarditis.

CMR, cardiac magnetic resonance; LV, left ventricle.

FIG. 7: Short-axis CMR image demonstrating concentric LV myocardial thickening in a case of hypertrophic cardiomyopathy.

CMR, cardiac magnetic resonance.

FIG. 8: Postgadolinium-enhanced short axis CMR image depicting mid-wall and epicardial enhancement in a case of nonischemic cardiomyopathy.

Myocyte disarray and interstitial plus replacement fibrosis occur in hypertrophic CMP.²⁶ The myocardium in hypertrophic CMP demonstrates fibrotic scars and signs of myocardial microischemia²³ on late-enhancement images, the extent of which is associated with risk stratification for sudden cardiac death with important prognostic and therapeutic implications²⁶ as these scars act as a substrate for fatal arrhythmia.²³⁻²⁵ As fibrosis detected by LGE is an independent predictor of adverse outcome^{27,28} it has a role in diagnosing and identifying high-risk patients.²⁹ Cardiac MRI is also useful in the follow-up of patients after ventricular septal resection or percutaneous ablation.^{1,3}

Restrictive Cardiomyopathy

Restrictive CMP manifests as reduced ventricular filling and diastolic volume, with resultant atrial dilatation and venous stasis, and usually preserved systolic function.¹¹ The condition may be idiopathic, or secondary to infiltrative or storage diseases (amyloidosis and sarcoidosis), or associated with myocardial disorders as hypereosinophilic syndrome (HES).³⁰ The RV may be enlarged if there is coexistent pulmonary hypertension. LV may demonstrate preserved or reduced systolic function.

One of the important differentials of restrictive CMP is constrictive pericarditis, where reduced ventricular filling and diastolic volumes may be seen in both diseases. Cardiac MRI is extremely useful as it can demonstrate pericardial thickening (>4 mm) typical of constrictive pericarditis, while real time cine images are useful in evaluating diastolic ventricular septal movements and septal motion during respiration.^{31,32} While in restrictive CMP, septal convexity is maintained in all respiratory phases, in constrictive pericarditis, septal flattening may be seen in early inspiration.

Sarcoidosis

Sarcoidosis is a systemic granulomatous disease where cardiac involvement may occur with noncaseating granulo-

matous infiltration in 5–20% patients.^{33,34} Myocardial thickening in sarcoid may resemble hypertrophic CMP. Typical granulomatous changes most often affect the LV lateral wall, papillary muscles, basal interventricular septum, RV subendocardial surface, and RV free wall. The distribution patterns may be patchy or striae-like sparing the subendocardium; while diffuse and transmural patterns occur in advanced disease.³⁵ Associated LV hypertrophy, LV or RV dilatation, septal thinning, systolic and diastolic left ventricular dysfunction, and pericardial effusion may be seen on CMR.²

Sarcoid lesions vary in different stages of the disease. Infiltrates may be diffuse or focal with hyperintensity due to myocardial edema in T2-weighted fat-saturated or STIR images. The lesions may vary from high intensity on T2-weighted sequences to central low intensity on T1- and T2-weighted imaging surrounded by a high-signal ring in different stages.¹ Postgadolinium administration, contrast enhancement may be seen as patchy mid-wall and epicardial in distribution with a predilection for the basal and lateral segments of the left ventricle (Fig. 8). These may represent fibrotic replacement of the myocardium. Cine images may demonstrate LV altered filling patterns consistent with secondary restrictive CMP. Segmental wall motion abnormalities corresponding to the distribution of late-enhancement areas may be seen.³⁵

Hemochromatosis

Myocardial iron deposition may occur due to primary (genetic) hemochromatosis or secondary (transfusion dependent) iron overload.¹⁹ Iron deposition is predominantly subepicardial. CMR can demonstrate extensive signal loss in native T1- and T2-weighted images in a dysfunctional myocardium. An associated abnormally “dark” liver confirms the diagnosis of iron deposition and systemic hemochromatosis.¹ CMR is superior to serum ferritin and liver iron in assessing patients at high risk of

HF and arrhythmia from myocardial siderosis, to guide management, monitor response to iron-chelating agents and prognosticate³⁶ as treatments differ depending on whether the prime target is extraction of iron from the heart or the liver.

Amyloidosis

Amyloidosis is characterized by deposition of amyloid—an extracellular insoluble fibrillar proteins deposition that results from protein misfolding—in tissue. Amyloidosis may be systemic or organ specific. Cardiac amyloid manifests classically as concentric myocardial thickening, similar to that in hypertrophic CMP, with normal or reduced contractility, thickened atrial walls, interatrial septum, batrial dilation, altered transvalvular flow patterns, pericardial, and pleural effusions.

Thickness of the atrial septum or the right atrial posterior wall of 6 mm is fairly specific for amyloid infiltration.^{1,37}

Postadministration of gadolinium, the wash-in wash-out is abnormal as amyloid fibrils accumulate gadolinium. CMR in amyloidosis has unique LGE appearances with circumferential enhancement, preferentially involving the subendocardium but sometimes extending transmurally, diffuse, and heterogeneous (Fig. 9).³⁸ Less often there is patchy focal LGE. The blood pool is atypically dark, reflecting high myocardial contrast uptake and fast blood pool wash-out. Depressed systolic ventricular function and reduced wall compliance manifest as overt restrictive CMP in advanced stages. Characteristic CMR LGE is a stronger predictor of mortality in cardiac amyloidosis compared to ECG and echocardiography.³⁹

Endomyocardial Fibrosis

Hypereosinophilic syndrome with increased eosinophils can be a primary (myeloid or eosinophilic neoplasm), secondary (parasitic infections i.e. Loeffler's syndrome, or other non-

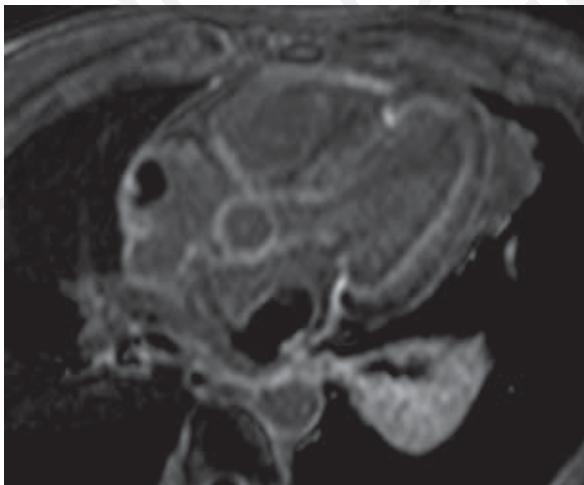

stem cell tumors), or an idiopathic condition. Endomyocardial fibrosis (also termed Loeffler endocarditis) is characterized by fibrosis of the apical endomyocardium (Fig. 10). CMR demonstrates extensive subendocardial fibrosis, obliteration of the ventricular apices, apical thrombus formation, and progressive diastolic dysfunction manifesting as restrictive cardiomyopathy (Fig. 10).^{19,40} The morphologic and functional features can be well quantified by MRI.

Arrhythmogenic Right Ventricular Dysplasia

Arrhythmogenic RV CMP is characterized by progressive fibrous or fibrofatty replacement of the myocytes of the ventricular wall, primarily RV, and clinically manifests as life-threatening ventricular arrhythmias, left bundle-branch block, heart failure, and sudden cardiac death.^{26,41,42} Early diagnosis is key and CMR is the technique of choice. Fatty infiltration, fibrofatty replacement of the RV free walls, wall thinning with systolic and diastolic dysfunction, reduced EF and RV dilatation are seen. Associated regional wall motion abnormalities, with systolic and localized early diastolic bulging, gross dyskinesia, aneurysms of the RV free wall and outflow tract, dysplastic trabecular structures,¹¹ may be seen (Fig. 11).¹ Delayed enhancement of the right ventricular myocardium may have a diagnostic role.^{2,3,43,44}

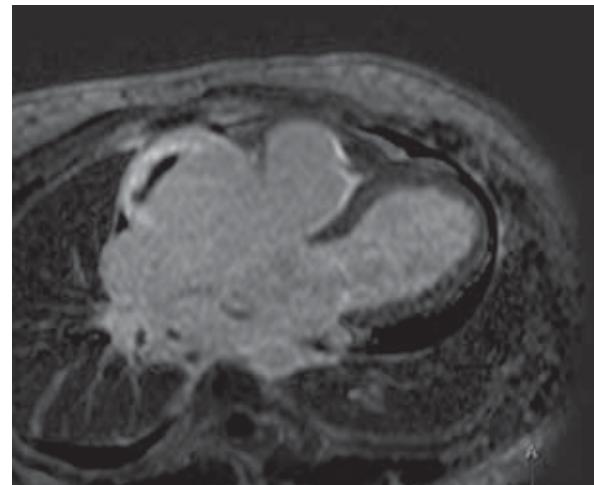

Left Ventricular Noncompaction

Left ventricular noncompaction (LVNC) is a congenital disorder of endomyocardial embryogenesis with arrest in normal process of myocardial compaction characterized by prominent LV trabeculations with deep intertrabecular recesses, resulting in a distinct noncompacted layer lining the LV cavity.⁴⁵ A ratio of noncompacted to compacted myocardium greater than 2.3 has a high specificity and sensitivity.⁴⁶ Findings are most prominent in the left ventr-

cular apex. LVNC may lead to heart failure, malignant arrhythmias, and thromboembolism.¹⁰

Takotsubo Cardiomyopathy

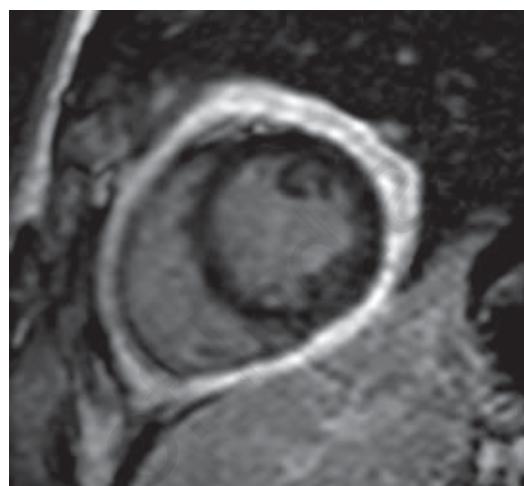

Takotsubo cardiomyopathy (stress cardiomyopathy) is a transient left ventricular ballooning with wall motion abnormalities, including apical akinesia in the absence of CAD.⁴⁷ CMR typically demonstrates myocardial edema but no LGE or fibrosis is seen and cardiac function fully recovers over time.¹⁶

Anderson-Fabry Disease

Fabry's disease is an X-linked inherited disorder of lysosomal metabolism with glycosphingolipid deposition in multiple organs.¹⁹ Cardiac manifestations include LV hypertrophy, increased LVEF, reduced volume, and fibrosis. LGE occurs in specific locations (midbasal lateral LV wall) and the distribution pattern (subepicardial and mesocardial) in patients with Anderson-Fabry disease who have cardiac symmetric hypertrophy.¹⁹

Pericardial Disease

The most common indications for pericardial disease evaluation are constrictive pericarditis, effusion, and tamponade. CMR demonstrates normal pericardium as a thin band (2 mm) of low signal on T1-weighted images, bordered by epicardial and pericardial fat. MRI reliably assesses pericardial thickening, effusion, and fibrous pericarditis (Fig. 12).^{1,4} CMR demonstrates effusions complicated with adhesions, loculations and aids differentiating transudative from exudative, hemorrhagic or chylous effusion based on signal characteristics and contrast enhancement.¹ Associated finding in the ventricles and cardiac valves can be evaluated on cine MRI as small right ventricular

CMR, cardiac magnetic resonance.

FIG. 12: Postgadolinium contrast short-axis CMR image demonstrating a thickened enhancing pericardium in a case of constrictive pericarditis.

chamber, restriction of diastolic filling, biatrial dilation, ventricular or septal alterations, septal bounce, adhesions between the pericardium and epicardium³ with diastolic collapse of chambers in tamponade. MRI has high sensitivity in differentiating constrictive pericarditis from restrictive cardiomyopathy.⁴

Cardiac Masses, Thrombi, and Infections

Magnetic resonance imaging today is extremely useful in delineation of extent, origin, hemorrhage, vascularity, and calcification in cardiac masses² with clear delineation of relationship to other cardiac and neighboring structures.¹ On account of the superior soft tissue contrast and tissue characterization, MRI is useful in the evaluation of cardiac tumors as myxomas, lipomas, metastasis, fibroma, rhabdomyoma, hemangioma, pheochromocytoma, lymphoma, malignant fibrous histiocytoma, and angiosarcoma.⁴

A particular advantage of MRI is its ability to distinguish thrombus from tumor. Unlike a tumor, a thrombus has low-signal intensity on gradient echo images because of the presence of deoxyhemoglobin.^{4,48} In the event of a diagnostic dilemma where a myxoma appears hypointense secondary to calcification or hemorrhage, the differentiation is easily done postcontrast, as enhancement occurs in the tumor but not in the thrombus (Fig. 9).⁴ Lipomas and lipomatous hypertrophy appear brighter on spin-echo T1-weighted sequences. The malignant tumors are more likely to be necrotic, inhomogeneous, heterogeneously enhancing with associated edema and invasion of surrounding structures.

Valvular Disease

Cardiac MRI can be used to evaluate stenotic or regurgitant lesions and quantify the same while also assessing aberrant valvular anatomy. Associated findings as ventricular dilation,

dysfunction, and myocardial hypertrophy can also be assessed, which influence the decision and timing of valve replacement surgery.³

Postcardiac Transplantation

Post heart transplantation, acute cellular rejection with systolic dysfunction and myocardial edema and cardiac allograft vasculopathy are causes of early and late morbidity and mortality, respectively. CMR can be used for the identification of systolic dysfunction and myocardial edema in cardiac transplant recipients allowing early detection of cardiac rejection.⁴⁹ Moreover, LGE-CMR is useful indirectly in the detection of cardiac allograft vasculopathy based on the ability to detect silent myocardial infarctions. Overall, the role of CMR in the transplanted heart is still evolving.

FUTURE DEVELOPMENTS

In the future, contrast-enhanced MRI may be used to guide interventions. These include real-time monitoring of electromagnetic catheter-directed radiofrequency (RF) ablations (e.g., for treatment of atrial fibrillation) within the heart with the potential to provide more.

New treatments for heart failure involve the transplantation of primitive cell types (e.g., stem cells or myoblasts) into the damaged tissue, where they can transdifferentiate into functional tissue.⁵⁰ Stem cell therapy in the heart might further benefit from the combination of molecular imaging methods with interventional MRI techniques.

CONCLUSION

Magnetic resonance imaging is fast emerging as a dominant noninvasive imaging modality in the assessment of cardiovascular diseases.

Cardiac magnetic resonance has the unique capability of delineating detailed anatomical and myocardial functional assessment ensuring differentiation of ischemic from nonischemic cardiomyopathy, with additional features in the characterization of nonischemic cardiomyopathy. CMR is neither operator dependent nor limited by the acoustic window, problems commonly faced in echocardiography. CMR should hence be routinely integrated in the diagnostic workup of patients suspected of nonischemic cardiomyopathies for superior diagnosis, prognostication, management, and follow-up.

SECTION **12**

**Cardiovascular
Pharmacology**

Newer Antianginals

Kewal C Goswami, Anunay Gupta

INTRODUCTION

Due to increased number of cases of coronary artery disease (CAD) over few decades, more and more patients are on antianginal medicines. Despite advances in percutaneous coronary intervention (PCI) and coronary artery bypass surgery (CABG) for ischemic heart disease (IHD), many patients with angina pectoris continue to have angina post-PCI or CABG. Many patients, who are not candidate of either PCI or CABG, continue to have refractory angina despite on maximal doses of conventional therapy such as long-acting nitrates, β -blockers or calcium channel blockers. This chapter reviews newer antianginal drugs (Table 1) available for such patients.

RANOLAZINE

Among all the newer antianginals that will be discussed here only ranolazine is approved by Food and Drug Administration (FDA).

Ranolazine was initially thought to be acting through partial inhibition of fatty acid oxidation, but its antianginal action is due to prevention of calcium overload and the subsequent increase in diastolic tension due to inhibition of late inward sodium channel (Flowchart 1). Initial dosing of

ranolazine is 500 mg bd followed by 1,000 mg bd if patient remains symptomatic.

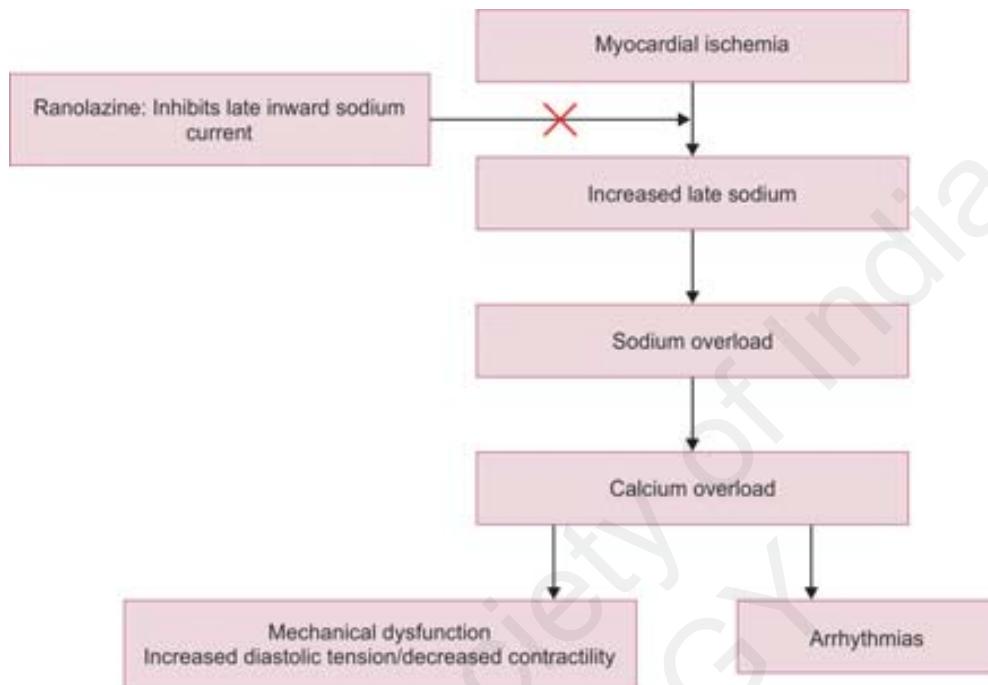

Ranolazine was found to be beneficial in stable angina in MARISA (Monotherapy Assessment of Ranolazine In Stable Angina), CARISA (Combination Assessment of Ranolazine In Stable Angina), and ERICA (Efficacy of Ranolazine in Chronic Angina) trials.¹⁻³ In MERLIN-TIMI 36 (Metabolic Efficiency With Ranolazine for Less Ischemia in Non-ST-Elevation Acute Coronary Syndromes) trial patients with an acute coronary syndrome (ACS), in the subset of 3,565 patients who had prior chronic angina, ranolazine significantly reduced the primary end point of cardiovascular (CV) death, myocardial infarction (MI), and recurrent ischemia due entirely to a significant reduction in recurrent ischemia [hazard ratio (HR) 0.78, 95% confidence interval (CI) 0.67-0.91].^{4,5} Ranolazine was associated with lower rate of worsening angina (HR 0.77, 95% CI 0.55-1.00) and a significant improvement in exercise duration on a treadmill (514s vs. 482 s).^{4,5} Ranolazine failed to improve outcomes in patients who had incomplete revascularization in RIVER-PCI (Ranolazine in patients with incomplete revascularization after percutaneous coronary intervention) trial.⁶ In this trial 2,651 patients were randomized to ranolazine or placebo after incomplete revascularization with PCI. There was no difference in the rate of the primary efficacy end point (time to first occurrence of ischemia-driven revascularization or ischemia-driven hospitalization without revascularization) between the two groups (26% vs. 28%; HR 0.95, 95% CI 0.82-1.10) after a median follow-up of 643 days.

Ranolazine has antiarrhythmic effects also. Its antiarrhythmic properties are based on the frequency-dependent blockade of peak sodium channel current (peak INa) and rapidly activating delayed rectifier potassium current (IKr) in the atria and blockade of late phase of the inward sodium current (late INa) in the ventricles.⁷ In MERLIN-TIMI 36 trial, it was associated with 3% lower frequency of ventricular tachycardia (VT), a 10.3% lower incidence of supraventricular tachycardia, and a 0.7% reduction in the onset of new atrial

TABLE 1: Newer antianginals

Approved	Not approved/Investigational
• Ranolazine	• Fasudil
• Ivabradine	• Testosterone
• Nicorandil	• Allopurinol
• Trimetazidine	• Endothelin receptor blockers: Bosentan
	• High-dose statins
	• Molsidomine
	• L-arginine
	• GLP-1 analogs

GLP-1, glucagon-like peptide 1.

FLOWCHART 1: Mechanism of action of ranolazine.

fibrillation (AF).⁸ Ranolazine is effective in prevention of AF in patients with ACSs, prevention as well as conversion of postoperative AF after cardiac surgery, conversion of recent-onset AF, and maintenance of sinus rhythm in recurrent AF.⁷ Ranolazine significantly improved glycated hemoglobin (HbA1c) (fall of 0.3%) and recurrent ischemia in patients with diabetes mellitus and reduced the incidence of increased HbA1c in those without evidence of previous hyperglycemia.⁹

Most important adverse effect with use of ranolazine is increase in QTc interval. In a review of 746 patients, ranolazine was associated with mean QTc prolongation of 2.4 ms in patients who were treated for almost 3 years. Even though there is a dose-dependent increase in QTc interval, torsade de pointes has not been reported due to lack of reverse use dependence seen with ranolazine.¹⁰

NICORANDIL

Nicorandil is a nicotinamide derivative and an efficacious antianginal drug with a nitrate moiety in its chemical structure. Its efficacy is similar to that of nitrates, with several unique effects on the CV system. Nicorandil causes sustained dilation of both the arterial resistance and conductive vessels, hence causing significant dilation of the coronary artery and increasing coronary blood flow. The mechanism causing coronary vasodilation is dual first is nitrate donor and second appears to be due to activation of adenosine triphosphate (ATP)-dependent potassium channels (Flowchart 2). Dose is 5–20 mg bd.

The effect of nicorandil (20 mg twice per day) on coronary events was evaluated in the IONA (Impact Of Nicorandil in Angina) trial of 5,126 patients with chronic stable angina

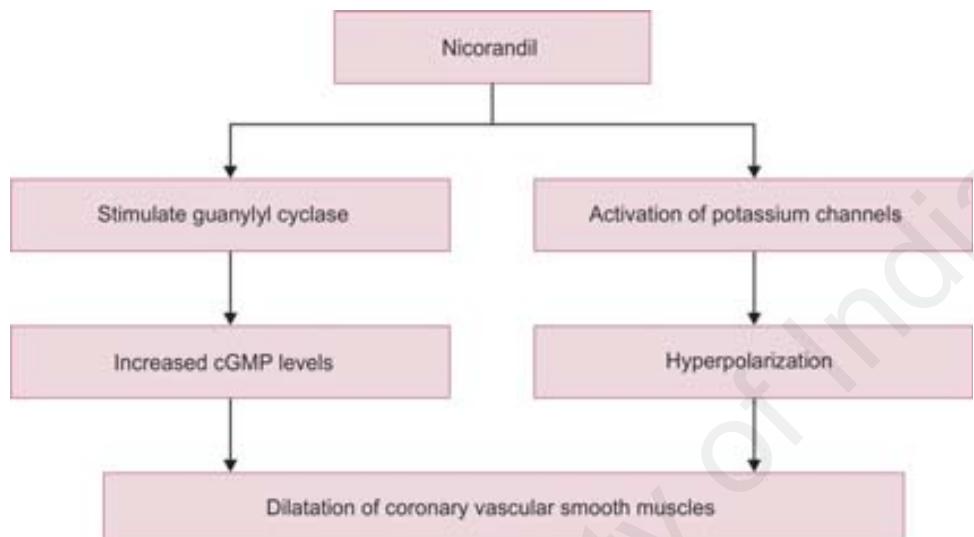

who were receiving other standard therapies.¹¹ After a mean follow-up of 1.6 years, nicorandil reduced the primary end point (coronary death, nonfatal MI, or unplanned hospitalization for angina) by 17% (13 vs. 15.5 for placebo, HR 0.83, 95% CI 0.72–0.97). There was significant reduction in the secondary end point of death and nonfatal MI (4.2% vs. 5.2%) and significant reductions in the incidence of an ACS (6% vs. 7.6%) and all CV events (14.7% vs. 17%). However, a point to highlight was that IONA was an outcome study and worsening of anginal status was not significantly different in patients taking nicorandil compared to those on placebo (22% vs. 24%, respectively).¹¹

Common adverse effects include headache (>10% of cases; especially on initiation of treatment), flushing, and dizziness. Mucosal ulceration is rare (<0.01%), ranges from multiple intractable oral aphthous ulcers to anal fissure and rectovaginal fistula.¹²

IVABRADINE

Ivabradine, a selective sinus node If channel inhibitor, is a therapeutic innovation in the treatment of ischemia. Ivabradine can reduce heart rate (HR) without affecting cardiac systolic function, hence was recommended as a second-line antianginal agent. It has been shown to increase exercise capacity and reduce anginal frequency and severity. Its dose is 5–7.5 mg bd.

In a recently published landmark SIGNIFY (Study Assessing the Morbidity–Mortality Benefits of the If Inhibitor Ivabradine in Patients with Coronary Artery Disease) trial randomly assigned 19,102 patients with stable CAD without clinical heart failure (HF) and a HR of 70 beats/min or more to

cGMP, cyclic guanosine monophosphate.

FLOWCHART 2: Mechanism of action of nicorandil.

ivabradine or placebo.¹³ All patients were treated with optimal medical therapy including aspirin, statin, angiotensin-converting enzyme inhibitor, and a β -blocker. The majority of patients (63%) had Canadian Cardiovascular Society (CCS) class II or higher angina. It was seen that ivabradine group had a HR that was about 10 beats/min lower than those in the placebo group. CCS class II angina or higher, patients in the ivabradine group more frequently improved their CCS angina class (24.0% vs. 18.8%; $p = 0.01$). Among patients with angina CCS II angina or higher, there was an increase in the incidence of the primary end point which was a composite of death from CV causes or nonfatal MI (7.6% vs. 6.5%; HR 1.18, 95% CI 1.03–1.35). Ivabradine failed to improve outcomes cardiac outcomes in all patients with stable CAD and left-ventricular systolic dysfunction in BEAUTIFUL (morbidity-mortality Evaluation of the If inhibitor ivabradine in patients with coronary disease and left-ventricular dysfunction) trial.¹⁴ In a subgroup analysis it was seen that in patients with HR more than or equal to 70 beats/min with limiting angina, there was a 73% reduction in hospitalization for MI (HR, 0.27, 95% CI, 0.11–0.66) and a 59% reduction in coronary revascularization (HR, 0.41, 95% CI, 0.17–0.99). Hence, ivabradine should not be used in stable angina patients who do not have clinical HF.¹⁵

Adverse effects seen with ivabradine include visual “flashing lights” known as phosphene which are seen in up to 16% of patients, which are usually only mild-to-moderate in intensity and transient. They result from blockage of the If current in the retina, which is similar to the cardiac If current.¹⁶ Other side effect is sinus bradycardia which may require discontinuation.

TRIMETAZIDINE

It acts by metabolic modulation. It is fatty acid oxidation inhibitor and acts via selective inhibition of 3-ketoacyl coenzyme A thiolase, therefore increases the efficiency of myocardial energy production (Flowchart 3). It inhibits

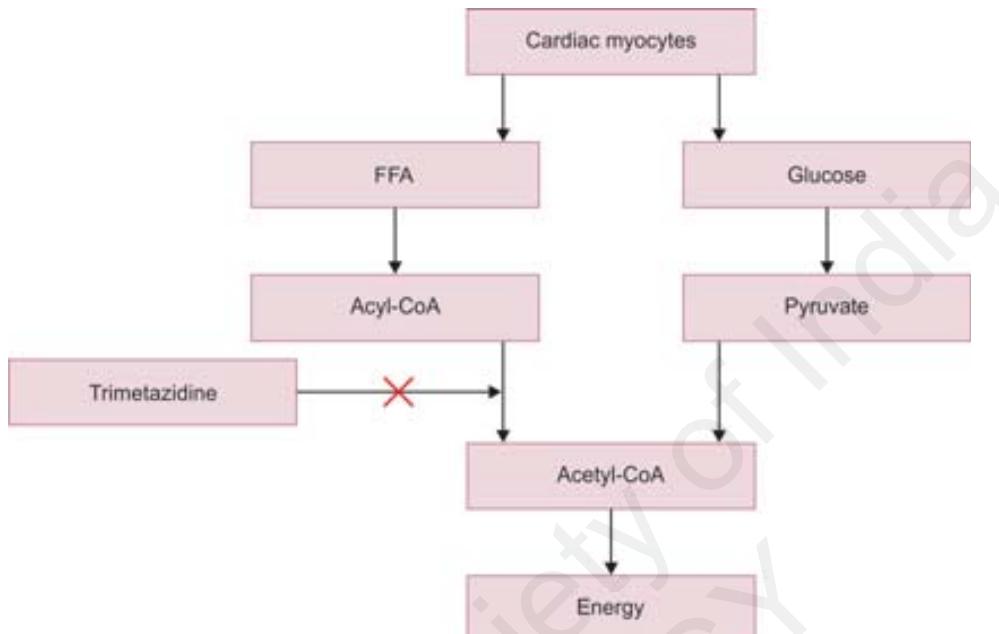

reduction of intracellular ATP levels via conservation of cellular metabolism in ischemic regions and stimulates myocardial glucose consumption through inhibition of fatty acid metabolism. Its dose is 35 mg bd.

A Cochrane collaboration meta-analysis of trimetazidine use in stable angina found that trimetazidine significantly reduced attacks of angina, use of nitrates, and time to onset of ST-segment depression in patients.¹⁷ It is also beneficial in patients with HF. In a meta-analysis on its role in HF, trimetazidine lead to left ventricular end-systolic volume reduction [weighted mean difference (WMD) 10.37 mL; 95% CI 15.46–5.29; $p < 0.01$], improvement in the New York Heart Association (NYHA) class (WMD 0.41; 95% CI 0.51–0.31; $p < 0.01$), and exercise duration (WMD, 30.26; 95% CI 8.77–51.75; $p < 0.01$). Trimetazidine also had a significant protective effect for all-cause mortality (RR 0.29; 95% CI 0.17–0.49; $p < 0.00001$) and CV events and hospitalization (RR 0.42; 95% CI 0.30–0.58; $p < 0.00001$).¹⁸

Common side effects are gastrointestinal disturbances, dizziness, and headache. It can uncommonly cause reversible movement disorders.¹² Table 1 summarizes mechanism of action, dosing, and side effects newer antianginals.

FASUDIL

It is an inhibitor of Rho-kinase that is involved in the vascular smooth muscle contractile response and may be of benefit in patients with stable and microvascular angina (i.e., angina with normal coronary arteries). In a multicenter, placebo-controlled trial, 84 patients with stable angina were randomly assigned to fasudil (titrated to a dose of 80 mg twice daily) or placebo.¹⁹ Fasudil leads to a significantly greater time to more than or equal to 1 mm ST-segment depression at both peak (172 s vs. 44 s with placebo) and trough (93 s vs. 24 s) but there was no difference in time to angina, frequency of angina or nitroglycerin use, or CCS functional class. Fasudil is not available in India.

CoA, coenzyme A; FFA, free fatty acid.

FLOWCHART 3: Mechanism of action of trimetazidine.

TABLE 2: Mechanism of action, dose, and adverse effects of available newer antianginals

Drug	Dose	Mechanism of action	Adverse effects
Ranolazine	500–2000 mg bd	Inhibition of late inward sodium channel	Nausea, prolongation of QT interval
Nicorandil	20 mg bd	ATP sensitive potassium channel activator	Headache, mucosal ulcers
Ivabradine	5–7.5 mg bd	Inhibition of funny If channel in sinus node	Phosphenes, sinus bradycardia
Trimetazidine	35 mg bd	Metabolic modulator	Gastrointestinal side effects, movement disorders

ALLOPURINOL

It is a xanthine oxidase inhibitor. It is used in the prevention of recurrent gout. Its mechanism of action is inhibiting xanthine oxidase in vascular endothelium and hence preventing formation of superoxide free radicals formation. By reducing oxidative stress and improving endothelial-dependent vasodilation it decreases myocardial oxygen demand in patients with HF. However, it is rarely used to treat angina.

In a crossover study, allopurinol (600 mg/day) was compared to placebo, it significantly increased the median time to ST depression (298 s vs. 249 s, respectively, from a baseline of 232 s) and median total exercise time (393 s vs. 307 s, respectively, from a baseline of 301 s).²⁰ However, in view of lack of definitive evidence further evaluation of allopurinol is must before it can be used as an antianginal agent.

ENDOTHELIN RECEPTOR BLOCKERS

Endothelin (ET) receptor blockers act by producing vasodilation by inhibiting vasoconstriction produced by ET. They block ET-A and ET-B receptors. Because of vasodilator effect these agents help in relieving angina.

However, no clinical trials to date have examined the role of ET receptor blockers for reducing anginal symptoms. Furthermore, selective ET-A receptor blockade may have an adverse effect. In a small report of 30 patients undergoing PCI, it was seen that compared with intracoronary saline, an intracoronary injection of a selective ET-A receptor blocker prevented the normal reduction in myocardial ischemia on repeat balloon inflations.²¹

TESTOSTERONE

Testosterone act by improving endothelial dysfunction and may be used as an effective antianginal agent. In a trial of 46 men with stable angina a daily low dose (5 mg) transdermal testosterone patch for 12 weeks, significantly increased the time to 1 mm ST-segment depression on treadmill exercise testing compared to placebo (309 vs. 361 seconds at 12 weeks).²² But there are multiple side effects of long-term use of aldosterone; further evidence is needed before testosterone can be considered as a therapy for angina.

HIGH-DOSE STATINS

Statins are used in all patients with stable IHD. There is increasing evidence that high-dose statin therapy reduces

the incidence of anginal episodes in patients with stable IHD. AVERT (A Very Early Rehabilitation Trial after stroke) trial aggressive lipid lowering therapy with atorvastatin 80 mg led to a reduction in the rate of hospitalization for worsening angina compared to patients treated with angioplasty.²³ Similarly in the DUAAL (Double Blind Atorvastatin Amlodipine Study) trial, 311 patients with stable IHD, were randomly assigned to one of three treatment arms: amlodipine 10 mg/day, atorvastatin 80 mg/day, or amlodipine 10 mg/day plus atorvastatin 80 mg/day.²⁴ The primary efficacy end point, the number of ischemic episodes during 48-hour ambulatory electrocardiographic monitoring, decreased significantly from baseline (>66%) in all three groups. There was no significant difference in outcome among the three groups, with more than 50% of patients becoming free of episodes of transient myocardial ischemia at 26 weeks.

MOLSIDOMINE

Molsidomine dilates venous capacitance vessels (reducing preload), dilates coronary arterial segments, exerts a platelet stabilizing effect by inhibiting thromboxane, and has a nitric oxide-donating effect. It has been available in Europe since 1977 but has not been approved by the US FDA.

INVESTIGATIONAL DRUGS

The L-arginine, glucagon-like peptide 1 (GLP-1) mimetics and dipeptidyl peptidase-4 (DPP-4) analogs, mildronate, and estrogen/progesterone are other investigational drugs for angina and at present do not have a role in clinical practice.

CONCLUSION

Newer antianginals (Table 2) as discussed earlier are effective therapy in patients with CAD. They can be used as an add-on therapy in patients over conventional antianginals. Ivabradine should not be used as an antianginal in patients without HF in view of results of SIGNIFY trial. The choice of newer antianginals should be individualized and based on the severity of symptoms, drug tolerance, and comorbidities.

Newer Antihypertensives

TK Mishra

INTRODUCTION

Hypertension (HTN) is the single most common preventable risk factor for cardiovascular disease (CVD) and the number one cause of all cause mortality and morbidity globally. Affecting more than a billion people worldwide, HTN is responsible for 9.4 million deaths per year.¹ The morbidity due to the disease (measured by healthy life-years lost) has surged by 43% over the last 30 years owing to the aging of the population, and a 10% rise in the prevalence in HTN. The economic burden to society in the US alone is a staggering 46 billion dollars. Moreover, with the recent American College of Cardiology/American Heart Association (ACC/AHA) guideline redefining HTN as blood pressure (BP) more than 130/90 mm Hg, an additional 15% of the general adult population is labeled as hypertensive.

About 75% of the world's burden of HTN (639 million people) is found in the developing world. The crude prevalence of HTN in India has been found to be 25.3% including a disconcerting 12.1% in the 18–25 years age group. Gupta et al. found a steady increase in age-adjusted HTN prevalence in an urban population over the past 25 years.² The incidence in rural and urban India is 25% and 33%, respectively. From this pool, only about one-fourth of rural and half of the urban patients are aware of their condition. Again, only 25% of rural and 38% of urban Indians are being treated for HTN. Soberingly, an abysmal 10% rural and 20% urban patients have HTN under control.

The four major classes of antihypertensive drugs represented by the acronym "ABCD" [A = angiotensin-converting enzyme inhibitors (ACEi) or angiotensin-receptor blockers (ARBs); B = β -blockers; C = calcium channel blockers (CCBs); D = diuretics] continue to be the bulwark of therapy. Yet, due to various reasons, HTN remains uncontrolled in 50% of patients worldwide and up to 70% in Asian countries. In select clinical or trial settings, 70–80% reach target BP levels, many of whom find it difficult to adhere to cumbersome multidrug regimens. Besides, an unmet need for therapy exists in certain groups

such as treatment resistant hypertension (TRH), patients with comorbidities and those unable to tolerate the conventional drugs. Even after accounting for noncompliance, 10–15% of patients remain in the category of TRH defined as office BP more than 140/90 mm Hg, in spite of treatment with three or more antihypertensive drugs (inappropriate dose) including a nonpotassium sparing diuretic, and not due to secondary HTN. About 0.5% suffer from refractory HTN where BP is uncontrolled on five or more drugs. Suboptimal management of comorbidities like heart failure (HF) and renal failure contributes to uncontrolled HTN. Hence, the need for newer efficacious drugs with additional benefits of target organ protection to uniformly achieve the HTN control target of 50% set by the World Health Organization (WHO) global monitoring framework.

NEWER DRUGS FOR HYPERTENSION

The mineralocorticoid receptor antagonists (MRA) have emerged as an option in TRH where the putative mechanism is salt retention due to aldosterone breakthrough in patients on ACEi or ARB. The strongest evidence came from the PATHWAY-2 trial which compared spironolactone with bisoprolol (β -blocker), doxazosin (α -blocker), and placebo as a fourth add-on drug in patients of TRH.³ Over a 3-month follow-up, the reduction in home BP recordings by spironolactone was twice that of the other drugs with the greatest benefit in patients with low renin levels. Other long-term observational studies confirm that this BP-lowering effect is sustained and durable. Bobrie et al. in a study of 167 patients of TRH displayed that sequential nephron blockade (spironolactone followed by loop diuretic) causes greater fall in BP than sequential ACEi- β -blocker therapy. Spironolactone acts best when serum potassium is less than 4.5 mEq/L and also reduces albuminuria in diabetics independent of its hemodynamic effect. Major side effects are type 4 renal tubular acidosis, gynecomastia, impotence, and hyperkalemia. However, the incidence of hyperkalemia in PATHWAY-2 was low-allaying

apprehension about combining it with ACEi or ARB. For patients who experience gynecomastia with spironolactone, amiloride is a viable alternative. Amiloride is an indirect aldosterone inhibitor acting on the epithelial sodium channel (ENaC) in the collecting duct. Unlike the target sites of thiazide and high ceiling diuretics, this distal most channel has no further downstream channels to neutralize increased sodium resorption. Hence, small increments in ENaC activity can elevate BP considerably. In a study of 98 patients of TRH, introduction of either spironolactone or amiloride reduced BP significantly with a greater reduction by amiloride. The second generation MRA eplerenone is more selective for mineralocorticoid receptors but is less potent as an antihypertensive and needs twice daily dosing.

Sacubitril or valsartan (LCZ696), a first in class combination of ARB and neprilysin inhibitor (ARNi), is emerging as promising therapy for HTN. While valsartan reduces BP by inhibiting the RAS, the neprilysin inhibitor promotes salt excretion by the natriuretic peptides, hence acting as a diuretic without undesirable effects like hypokalemia or hyperuricemia. The landmark trials, Prospective Comparison of ARNi and ACEi to determine Impact on Global Mortality and Morbidity in Heart Failure (PARADIGM-HF) and PARAMOUNT that established the role of ARNi in HF also revealed that LCZ696 caused greater BP reduction than the comparator drug (enalapril or valsartan). The PARAMETER study compared the efficacy of LCZ696 (200 mg/day uptitrated to 400 mg/day) and olmesartan (20 mg/day uptitrated to 40 mg/day) in 454 elderly patients of HTN.⁴ After 52 weeks of follow-up, both drugs were equally efficacious in reducing central aortic systolic pressure (CASP), central aortic pulse pressure (CAPP), and nocturnal BP. Moreover, while 47% of patients taking olmesartan required add-on drugs to achieve BP control, only 32% receiving LCZ696 did so. LCZ696 caused a greater fall in N-terminal pro b-type natriuretic peptide (NT-proBNP) implying greater distensibility of the arteries. It has also been shown to effect a greater reduction in left ventricular mass than olmesartan. In an Asian study comparing various doses of LCZ696 with placebo, Kario et al. demonstrated the greater BP lowering effect of the drug as compared to a Western population especially at lower doses along with an excellent tolerability and safety profile. High salt consumption in Asians possibly renders them more sensitive to the natriuretic effect of the drug. Subsequently, in a study of 261 Asian patients of systolic HTN, Wang et al. confirmed the superiority of LCZ696 over placebo as a second drug in patients uncontrolled on amlodipine (5 mg). In the light of the mounting evidence, LCZ696 could be a viable option in certain subgroups such as elderly with resistant HTN especially with systolic or nocturnal or salt sensitive HTN with the added benefit of prevention of HF. However, a possible concern with long-term use of the drug is decreased catabolism of amyloid beta (A β) peptide leading to Alzheimer's disease. While the short survival of HF patients precludes such events, the long duration of treatment coupled with a compromised blood brain barrier in hypertensive patients will necessitate prolonged neurological monitoring.

Clevidipine is a parenteral ultra-short-acting latest generation dihydropyridine CCB with high arteriolar selectivity, small volume of distribution and rapid clearance resulting in a half-life of about 1 minute. In the VELOCITY trial of 126 patients presenting with acute HTN [systolic blood pressure (SBP) >180 mm Hg], clevidipine effected a reduction of SBP by 6% at 3 minutes followed by 27% reduction at 18 hours without any major adverse effects. Subsequent subset analysis of renal failure and acute HF patients reproduced the favorable results of the overall trial. The study concluded that clevidipine is a safe and effective drug in management of acute severe HTN at a dose of 2 mg/hr followed by target BP based titration of infusion for 18 hours or more. The ECLIPSE trial compared clevidipine with nitroglycerine, nitroprusside, and nicardipine and concluded that it is not only a safe and effective drug but also provides more precise BP control than nitroglycerine and nitroprusside.⁵ Clevidipine is administered as a nonweight based initial dose of 1–2 mg followed by doubling of dose every 90 seconds till target BP is reached. The required dose in most patients is 4–6 mg/h. An ongoing trial of parenteral clevidipine versus urapidil in hypertensive patients of intracerebral hemorrhage will further clarify the efficacy of clevidipine as compared to conventional antihypertensives.

The premium placed by regulatory authorities on CV safety data of novel antidiabetic drugs has spurred investigators to uncover CV benefits of such drugs. The sodium-glucose cotransporter-2 (SGLT2) inhibitors (empagliflozin, canagliflozin, and dapagliflozin) all reduce BP by 3–5/2–3 mm Hg without any increase in incidence of orthostatic hypotension. In the EMPA-REG OUTCOME trial, use of empagliflozin resulted in a 38% reduction in CV death and 39% reduction of incident or worsening nephropathy.⁶ The SGLT2 inhibitors cause weight and BP reduction by promoting sodium and water loss. Hence, diuretics are to be used cautiously in combination. In a meta-analysis comparing glucagon-like peptide-1 receptor antagonists (GLP1-RA) with insulin and glimepiride, exenatide, and liraglutide lowered BP by 1–5 mm Hg. Dipeptidyl peptidase-4 (DPP-4) inhibitors, sitagliptin, and vildagliptin have been shown to have mild antihypertensive effect. The combination of GLP1-RA with SGLT2 inhibitors was tested in the DURATION-8 trial. Exenatide plus dapagliflozin reduced SBP by 4.2 mm Hg as compared to 1.3 mm Hg with exenatide and 1.8 mm Hg with dapagliflozin alone. A large meta-analysis of 61 observational studies in healthy adults concluded that even a 2 mm Hg reduction in SBP lessens stroke mortality by 10% and mortality from ischemic heart disease and other vascular causes by 7%.⁷ Considering the heightened CV risk of diabetics, the BP lowering effects of the newer antidiabetics should strongly influence choice of antihyperglycemic therapy.

Azilsartan medoxomil is the eighth ARB approved by the FDA for the treatment of HTN. It is highly selective with a 10,000 times higher affinity for angiotensin 1 (AT1) receptor than for angiotensin II (AT2) receptor. Time course studies show that compared to other ARBs, the drug-AT receptor dissociation is more gradual. Experimental evidence indicates

that azilsartan may exert some of its beneficial effect through peroxisome proliferator-activated receptors gamma (PPAR γ) pathway activation. In a meta-analysis of 17 trials, azilsartan was shown to provide superior and sustained 24 hours antihypertensive effect as compared to ramipril, candesartan, valsartan, or olmesartan (at their highest approved doses) with similar safety profile. Confirming its efficacy in Asian patients, a Korean study found satisfactory BP reduction with a favorable benefit risk profile. It is the only drug approved as a fixed drug combination (FDC) with chlorthalidone on the basis of a titrate to target study that found this combination to be more effective than Olmesartan and hydrochlorothiazide.⁸ The starting dose of azilsartan is 40 mg once daily (20 mg for patients >75 years of age) which may be increased to 80 mg once daily with full effect reached by 4 weeks.

A FDC of nebivolol and valsartan (5/80 mg tablet—Byvalson) was approved by the FDA in 2016 on the basis of a phase III double blind dose-escalating placebo controlled trial. Treatment with the combination lowered both SBP and diastolic blood pressure (DBP) more than each individual drug with similar adverse effect profile.

EMERGING MOLECULES

A number of research molecules with novel mechanisms of action are in various stages of preclinical or clinical development (Table 1). Activation of the renin–angiotensin system (RAS) in the brain is postulated to be contributory to HTN. Aminopeptidase A (APA) converts angiotensin II to angiotensin III which stimulates central sympathetic drive

and vasopressin release. RB150, a selective APA inhibitor, is being investigated as a centrally acting antihypertensive and has been found to be safe in healthy volunteers without any change in heart rate or BP.⁹ It is the subject of a phase IIa placebo controlled trial to assess its efficacy in stage 1 and 2 HTN. The angiotensin III/AT2 receptor arm of the RAS has vasodilator and natriuretic effects, actions antagonistic to the AT2/AT1 receptor arm. Compound 21 (C21) is a potent and highly selective AT2 receptor agonist which on account of its anti-inflammatory and antiapoptotic effect may also be useful in preventing target organ damage especially diabetic nephropathy (DN). Phase 1 testing in healthy volunteers is currently underway. The carboxypeptidase enzyme ACE2 converts AT2 to angiotensin (1–7), which antagonizes HTN induced target organ damage via Mas receptor. Agents that promote this conversion include ACE2 activators, Mas receptor, and AT2 receptor agonists. Diminazene aceturate (DIZI) is an ACE2 activator currently used in treatment of African trypanosomiasis but remains to be investigated in HTN. A Mas receptor modulator, CGEN-856 is still in the preclinical stage. An ACE2 modulator, recombinant human ACE2 (rhACE2) induced a sustained (>24 h) fall in AT2 with a good safety profile in a phase I clinical study on healthy subjects and is undergoing phase II studies.¹⁰ A new renin inhibitor VTP-27999 is the subject of a phase II clinical trial.

Finerenone is a nonsteroidal mineralocorticoid antagonist with higher selectivity than spironolactone and higher affinity than eplerenone. Two class IIb trials in HF and DN [mineralocorticoid receptor antagonist tolerability study-HF (ARTS-HF) and ARTS-DN] found it to be equally effective

TABLE 1: Emerging molecules

Drug class	Drug	Stage of development
Aminopeptidase inhibitor	RB150	Phase IIa
AT2 receptor agonist	C21	Phase I
Mas receptor modulator	CGEN-856	Preclinical
ACE2 modulator	rhACE2	Phase II
Renin inhibitor	VTP-27999	Phase II
Mineralocorticoid receptor antagonist	Finerenone	Phase III
Aldosterone synthase inhibitor	LCI699	Phase II
Dual-acting endothelin-converting enzyme-neprilysin inhibitor	Daglutril	Phase II
Natriuretic peptide receptor agonist	PL-3994	Phase II
NO releasing COX inhibitor	Naproxcinod	Phase III
Soluble guanylate cyclase inhibitor	Riociguat	Phase III
Intestinal Na ⁺ /H ⁺ exchanger 3 inhibitor	Tenapanor	Phase II
VIP receptor agonist	Vasomera	Phase I
PDE5 inhibitors	Tadalafil KD027	Marketed Phase II
Imidazoline receptor blocker	Moxonidine	Marketed

AT2, angiotensin II type 2; ACE2, angiotensin-converting enzyme 2; NO, nitric oxide; COX, cyclooxygenase; VIP, vasoactive intestinal peptide; PDE5, phosphodiesterase type 5.

as spironolactone in reducing BNP and albuminuria with lower incidence of hyperkalemia.¹¹ Two phase III studies on efficacy and safety of finerenone in DN are currently recruiting (FIDELIO-DKD and FIGARO-DKD). The aldosterone synthase inhibitor LCI699 is being examined for antihypertensive effect in a phase II trial. Daglutril is a dual endothelin converting enzyme and neprilysin inhibitor which was studied in a cohort of diabetic and hypertensive patients with nephropathy on losartan therapy. It was found to be safe and reduced BP but had no effect on albuminuria. PL-3994, a natriuretic peptide receptor agonist, was found useful in combination with ACEi in a phase II clinical study. Drugs acting on nitric oxide and soluble guanylate cyclase pathway have been tried in HTN. Naproxinod is a cyclooxygenase inhibiting nitric oxide donating (CINOD) compound derived from naproxen that reduced BP in hypertensive patients and is currently being tested in phase III trials. Riociguat, approved for use in pulmonary HTN, has been shown to reduce systemic BP in experimental studies. Tenapanor, a small molecule inhibitor of the Na^+/H^+ exchanger isoform 3, lowers gastrointestinal absorption of sodium and thereby, may be useful in HTN. A phase II clinical trial found tenapanor useful in treatment of hyperphosphatemia in patients on hemodialysis.¹² Vasomera (a VIP receptor agonist) is a potent vasodilator that reduced BP in early phase I clinical studies. The phosphodiesterase type 5 (PDE5) inhibitors, tadalafil and KD027, have vasodilatory effect and are being investigated for HTN therapy. Stimulation of imidazoline receptor II in the medulla oblongata inhibits the sympathetic nervous system to reduce BP. Moxonidine is a second generation centrally acting antihypertensive with low toxicity on account of greater selectivity for II receptor as compared to α_2 -receptor.

FUTURE PROSPECTS

Nanoparticles are a recent technological innovation to bypass various constraints in oral absorption and improve bioavailability of a drug. Most of the antihypertensives have low bioavailability due to low solubility and high permeability. In a nanoparticulate drug delivery system, the drug is combined with a nontoxic and biodegradable excipient enabling it to surpass impediments such as unfavorable pH, poor intestinal permeability, cytochrome P450 (CYP450)-mediated first pass metabolism and p-glycoprotein-mediated efflux. This complex is absorbed by various mechanisms such as paracellular transport (tight junctions), clathrin-mediated transport and caveolae-mediated endocytosis. In a murine model, combination of candesartan with soy lecithin sequestered the drug from acidic pH of stomach and increased bioavailability by 12 times.¹³ Nanoparticles may also be used to deliver increased drug concentration in specific target organs. Chronotherapeutics aims to achieve maximal drug concentration at a specific time in keeping with the circadian rhythm of the disease determinant. Used in conjunction with nanotechnology, it can enhance drug efficacy and optimize outcomes.

Nanoparticle mediated gene therapy of HTN entails gene silencing through cleavage of target mRNA by small interfering RNA (siRNA) and disrupting protein synthesis. Vasquez et al. employed AT 1147 siRNA to silence AT1a receptor and preventing AT2 activity. When administered alone, the siRNA are rapidly catabolized by the nucleases in blood and cells. The combination of siRNA with nanoparticles protects it from degradation and allows it to reach the target site. Nolte et al. used an intravenous liposomal nanoparticle, lipoplex to target β 1-adrenoceptor synthesis and achieved sustained BP reduction for 12 days.¹⁴

CONCLUSION

In spite of this plethora of molecules in the pipeline, no new molecule with a unique mechanism of action has entered the market in the last 20 years. The availability of a repertoire of time tested antihypertensive drugs (often generic) with high efficacy and placebo-like tolerability necessitates that any new drug will have to be more effective and equally safe to secure a place in the antihypertensive basket. The cost of introducing a new drug in the market (about 750 million to 1.5 billion dollars) has also dampened the enthusiasm of the industry and veered its interest toward nonpharmacological therapy of HTN. However, with sustained efforts toward study of newer candidate molecules and increasing emphasis on end organ, protection beyond BP control, it is hoped that the future will provide newer drugs for the hypertensive population in general and high-risk subgroups in particular.

Newer Agents for Dyslipidemia

Iyengar SS, Saleha N

"Whenever science makes a discovery, the devil grabs it, while the angels are debating the best way to use it"

—French Quotes

INTRODUCTION

Atherosclerotic cardiovascular disease (ASCVD) is the leading cause of mortality and morbidity globally and locally. There is a significant increase in mortality rates from cardiovascular disease (CVD) and ischemic heart disease (IHD) in India. There is a 32.7% increase in years of life lost (YLL) from 1990 until 2016.¹ In contrast to this increase in mortality in India, USA, developed countries in Europe and most middle-income countries, including China have shown a 30–70% decline in CVD mortality in the past 50 years.^{2,3}

Dyslipidemia, which is a disorder of lipid and lipoprotein metabolism, constitutes one of the major modifiable risk factors for ASCVD. It includes primarily three abnormalities, namely elevated low-density lipoprotein cholesterol (LDL-C), elevated triglycerides (TGs), and low high-density lipoprotein cholesterol (HDL-C).

Statins continue to reign supreme and remain a major cornerstone for treatment of atherogenic dyslipidemia (AD). However, they reduce the ASCVD risk by only 15–37%.⁴ Continued research to meet the unmet needs of statin therapy has led to the development and emergence of various newer and nonstatin group of drugs to tackle the residual risk of ASCVD in patients who do not reach the target goals of treatment. Nonstatin drugs are also needed in those who do not tolerate statins, and usually have to be added in subjects or patients who have very high LDL-C, as is seen in familial hypercholesterolemia (FH).

In this chapter, we review the newer agents for treating dyslipidemia.

EZETIMIBE

It was one of the first new class of agents which was approved by the US Food and Drug Administration in October 2002. It reduces plasma cholesterol by inhibiting its absorption

from the small intestine via Niemann-Pick C1-L 1 (NPC1L1) protein; this leads to decreased amount of cholesterol normally available to liver cells, leading them to absorb more from circulation and thus lowering levels of circulating cholesterol.

As an adjunct to diet, it may be used to reduce total cholesterol (TC), LDL-C, apolipoprotein B (apoB), and non-HDL-C in patients with hyperlipidemia on statin not reaching the target goal. In statin intolerant patients, it may be used singly. It is frequently used with statin in patients with FH. Ezetimibe is also used to reduce sitosterol and campesterol in patients with homozygous (Ho) sitosterolemia (phytosterolemia).

It is to be used in the dosage of 10 mg PO daily, to be taken either more than 2 hours before or more than 4 hours after bile acid sequestrants (BAS) if used in combination. Mean reduction of LDL-C is 18% with monotherapy and around 25% when combined with statins.⁵ It is generally well tolerated, adverse effects include upper respiratory tract infection, diarrhea, arthralgia, sinusitis, and pain in extremity.

In the IMPROVE-IT trial, which was a large, double blind, randomized trial involving 18,144 patients with recent acute coronary syndrome (ACS), addition of ezetimibe to moderate intensity statin resulted in incremental lowering of LDL-C and reduced primary composite endpoint of cardiovascular (CV) death, nonfatal myocardial infarction (MI), unstable angina (UA) requiring rehospitalization, coronary revascularization more than 30 days after randomization, or nonfatal stroke. The median follow-up was 6 years.⁶

The SHARP trial, which was a randomized double blind trial of 9,270 patients with chronic kidney disease, with no known history of MI or coronary revascularization, simvastatin plus ezetimibe reduced LDL-C and reduced primary endpoint of first major ASCVD event compared to placebo over a median follow-up of 4.9 years.⁷

A prespecified analysis of IMPROVE-IT trial focused on the 4,933 (27%) patients with diabetes. They were compared to 13,202 nondiabetic patients. The beneficial effects of adding ezetimibe to statin therapy was “enhanced” in patients with diabetes and also in those who were not diabetics but were at high risk for ASCVD.⁸

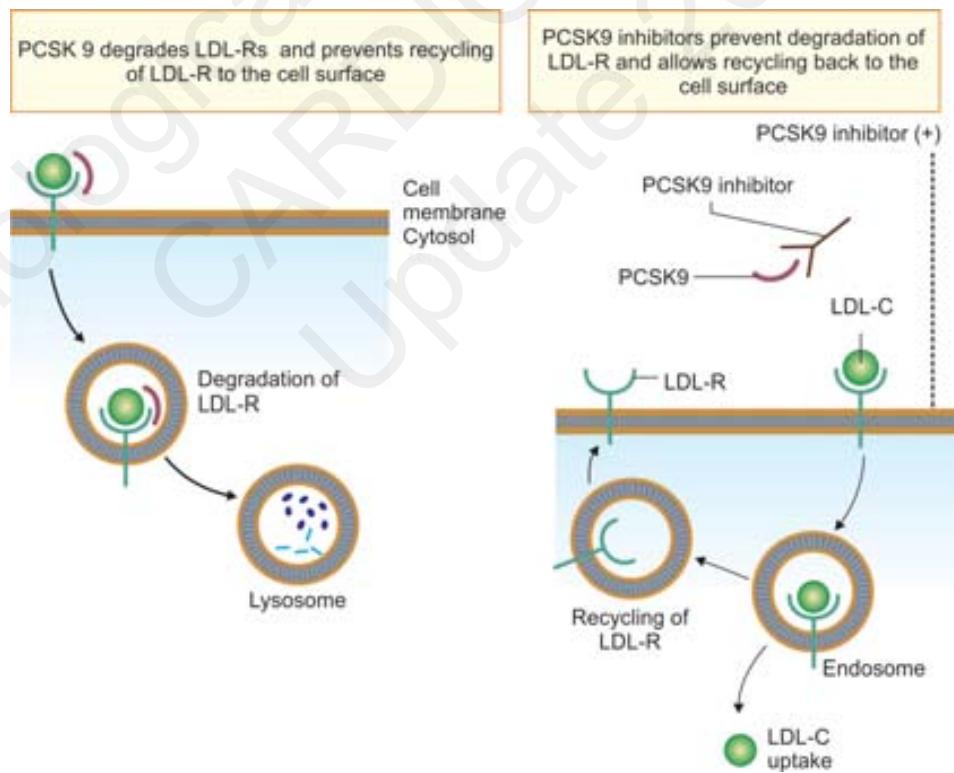

PROPROTEIN CONVERTASE SUBTILISIN/KEXIN TYPE 9 INHIBITORS

Proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors are a critical addition to the LDL-lowering armamentarium. In 2015, two of these agents, namely alirocumab and evolocumab, were approved in the USA and Europe for clinical use. Evolocumab received approval for HoFH, whereas both drugs were approved for heterozygous FH (HeFH) and clinical ASCVD. Bococizumab was studied in two randomized trials comparing it with placebo.⁹ Bococizumab had no benefit with respect to major adverse CV events involving lower-risk patients but did have a significant benefit in the trial involving higher-risk patients. Bococizumab is not a fully humanized monoclonal antibody (mAb) and its further development has currently been given up.

They are mAbs against PCSK9 and act by binding to it, thereby increasing the number of LDL receptors available to clear circulating LDL as shown in figure 1.

FOURIER trial¹⁰ a randomized, controlled study involved 27,564 patients with ASCVD and LDL cholesterol levels of 70 mg% or more on statin therapy. They were randomized to receive evolocumab or placebo. The primary efficacy endpoint was the composite of CV death, MI, stroke, hospitalization for UA, or coronary revascularization. The secondary efficacy endpoint was the composite of CV death, MI, or stroke. The patients were followed up for a median duration of 2.2 years. Evolocumab added to statin therapy lowered LDL cholesterol levels to a median of 30 mg% and reduced the risk of CV events. The study concluded that patients with ASCVD benefit from lowering of LDL cholesterol levels below currently recommended targets. ODYSSEY trial¹¹ enrolled 18,924 patients with recent ACS (1–12 months prior to randomization), on high-intensity statin therapy, but with LDL-C more than or equal to 70 mg%, non-HDL-C more than or equal to 100 mg%, or apoB more than or equal to 80 mg%. Patients were randomly assigned to alirocumab 75 mg subcutaneous (SQ) every 2 weeks or placebo, targeting LDL-C levels between 25 mg% and 50 mg%. After a median follow-up of 2.8 years, alirocumab reduced major adverse cardiovascular events, MI, and ischemic stroke. Alirocumab was also associated with a lower rate of all-cause death.

LAGOV study,¹² a randomized control trial looked at the effects of PCSK9 inhibition with evolocumab on coronary atherosclerosis in statin-treated patients 968 patients who

PCSK9, proprotein convertase subtilisin/kexin type 9; LDL-R, low-density lipoprotein receptor; LDL-C, low-density lipoprotein cholesterol.

FIG. 1: Mechanism of action of PCSK 9 inhibitors.

Source: Ahn CH, Choi SH. New drugs for treating dyslipidemia: beyond statins. Diabetes Metab J. 2015;39(2):87-94.

underwent coronary angiography. Among patients with angiographic coronary disease treated with statins, addition of evolocumab, compared with placebo, resulted in a greater decrease in percent atheroma volume (PAV) after 76 weeks of treatment, based on the findings of serial intravascular ultrasound (IVUS).

In the following group of patients, use of PCSK9 inhibitors is recommended by the European Society of Cardiology/European Atherosclerosis Society (ESC/EAS) task force:¹³

- Patients with ASCVD, who are at very high-risk, who have substantially elevated LDL-C levels despite maximally tolerated statin with or without ezetimibe therapy, and thus are considered at particularly high risk of an adverse prognosis
- Patients with ASCVD and at very high-risk who do not tolerate appropriate doses of at least three statins and thus have elevated LDL-C levels
- Familial hypercholesterolemia patients without clinically diagnosed ASCVD, at high or very high CV risk, and with substantially elevated LDL-C levels despite maximally tolerated statin plus ezetimibe therapy.

Dosage and Administration

Alirocumab

Initiate 75 mg SQ every 2 weeks. If more LDL reduction needed, may increase dose to 150 mg every 2 weeks. Alternative starting dose is 300 mg SQ every 4 weeks.

Evolocumab

In primary hypercholesterolemia with established clinical ASCVD or HeFH, give 140 mg SQ every 2 weeks or 420 mg SQ once monthly in abdomen, thigh, or upper arm. In HoFH, give 420 mg SQ once monthly. To administer 420 mg, give three (140 mg) injections consecutively within 30 minutes.

Drug Interaction with Statins

Proprotein convertase subtilisin/kexin type 9 inhibitors have an interesting and beneficial drug interaction with statins. Statins reduce synthesis of cholesterol. This leads to setting up of a counterregulatory process wherein sterol regulatory element-binding protein-2 (SREBP-2), a membrane-bound transcription factor that regulates cholesterol homeostasis in cells. SREBP-2 increases LDL-receptor density, and at the same time it stimulates the secretion PCSK9. If PCSK9 inhibitors are administered along with statins, it will counteract the action of PCSK9 and increases LDL receptors recycling (Fig. 2).

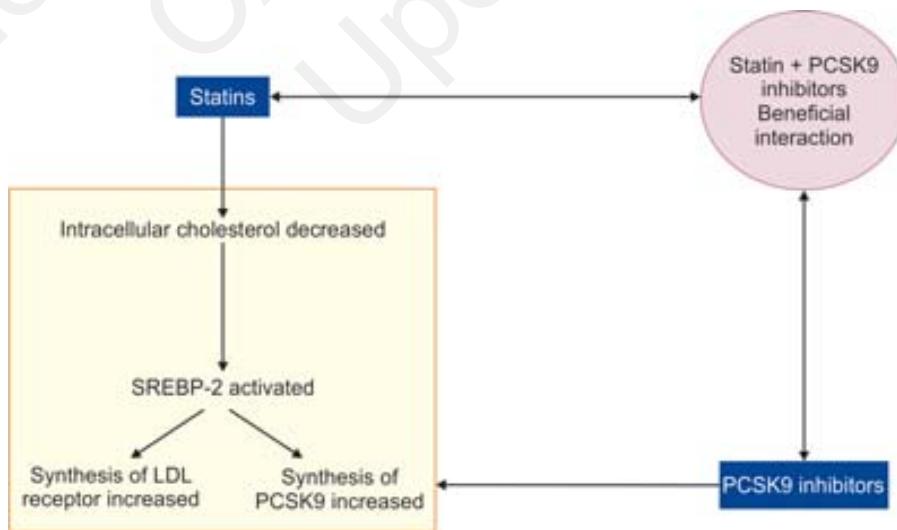

INCLISIRAN

Inclisiran is a chemically synthesized short interfering RNA molecule that produces sustained hepatocyte-specific, PCSK9-specific RNA silencing, thereby decreasing translation of the PCSK9 protein. In a phase II trial, ORION-1, inclisiran was found to lower PCSK9 and LDL cholesterol levels among patients at high CV risk who had elevated LDL cholesterol levels.¹⁴

In a prespecified analysis of secondary endpoints from the ORION-1 phase II study which was presented at the 86th European Atherosclerosis Society Congress (EAS, 2018), inclisiran showed effects beyond LDL-C and showed that it also reduces other atherogenic lipoproteins—non-HDL-C, apoB, very-low-density lipoprotein cholesterol (VLDL-C) and lipoprotein(a) [Lp(a)]—significantly and in a sustained manner.¹⁵

ORION program is running about 15 studies in various clinical scenarios (e.g., ORION-9 in HeFH and ORION-10 in ASCVD) and the studies are actively enrolling the subjects.

Inclisiran appears quite a promising therapy for AD. It eliminates LDL-C variability, reduces injection burden with

SREBP-2, sterol regulatory element-binding protein 2; PCSK9, proprotein convertase subtilisin/kexin type 9; LDL, low-density lipoprotein.

FIG. 2: Synergistic action between statins and PCSK9 inhibitors.

consequent better adherence to treatment and so far has shown robust efficacy and no safety issues.

In the meanwhile, FDA has granted “Orphan Drug Designation” to inclisiran for the treatment of HoFH.

MICROSOMAL TRIGLYCERIDE TRANSFER PROTEIN INHIBITOR: LOMITAPIDE

Lomitapide has been approved to reduce LDL-C, TC, apoB, and non-HDL-C in patients HoFH. It is an oral inhibitor of the microsomal triglyceride transport protein (MTP).

Microsomal triglyceride transport protein is an intracellular lipid-transfer protein that plays an important role in transport of TGs, cholesterol esters and phospholipids to apoB molecules and synthesis of VLDL and chylomicrons in the hepatocytes and enterocytes, respectively. Hence its inhibition provides a therapeutic target. Clinical trials have shown efficacy of lomitapide in reducing LDL-C. In a multinational single-arm, open-label, 78-week, phase III trial, lomitapide reduced mean plasma LDL-C levels by 50% from baseline in 23 evaluable adults with HoFH over a 26 weeks treatment period. Reductions from baseline in LDL-C levels were sustained for up to 78 weeks with continued lomitapide treatment.¹⁶

The recommended starting dose is 5 mg once daily and the dose should be escalated gradually up to a maximum recommended dose of 60 mg. Adverse effects include nausea, flatulence, diarrhea and fecal urgency, increase of transaminases, and hepatic fat content. It is contraindicated in patients with moderate or severe hepatic impairment, and in patients with mild hepatic impairment, dose should not exceed 40 mg daily. Regular liver monitoring should be performed at baseline and on an annual basis using both imaging and biomarker evaluations.

ANTISENSE OLIGONUCLEOTIDE AGAINST APOLIPOPROTEIN B—MIPOMERSEN

Mipomersen, a second-generation antisense oligonucleotide (ASO), acts mainly in the liver where it binds to apoB mRNA causing its cleavage and prevents the synthesis of apoB-100 protein. It has been approved by the FDA for the treatment of HoFH. It has been shown to reduce LDL-C, Lp(a), and apoB (Fig. 3). It is administered SQ in a dose of 200 mg weekly. The most common adverse effect is injection site reactions, flu like symptoms, and increase in hepatic fat content.^{17,18}

BEMPEDOIC ACID

It is a once-daily, oral LDL-C lowering drug that significantly reduces elevated LDL-C levels.

In the liver, bempedoic acid is converted to a coenzyme A (CoA) derivative, or ETC-1002-CoA, which directly inhibits ATP citrate lyase (ACL), a key enzyme that supplies substrate for cholesterol and fatty acid synthesis in the liver. Inhibition of ACL by ETC-1002-CoA results in reduced cholesterol synthesis and upregulation of LDL receptor activity in the

liver. However, unlike statins, bempedoic acid does not inhibit the cholesterol biosynthesis pathway in skeletal muscle, so it is unlikely to lead to muscle-related side effects. Bempedoic acid is inactive until it enters the liver where it is converted to its active form by the enzyme, ACSVL1, an enzyme not found in skeletal muscle cells.

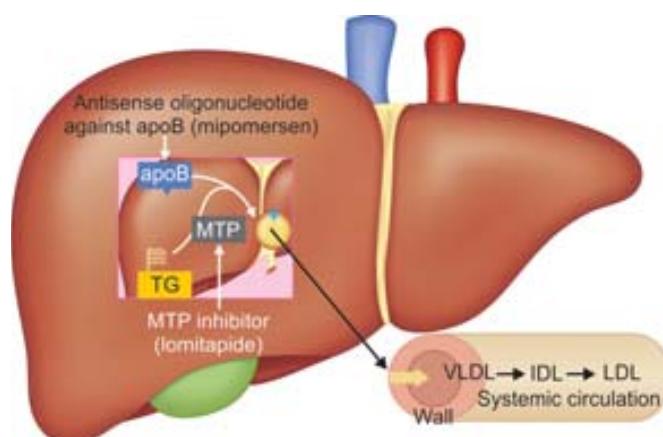

It has completed phase I and phase II clinical studies, which have demonstrated efficacy and safety of the drug. CLEAR Serenity is an ongoing phase III trial using this drug in patients with hypercholesterolemia, expected to be completed by July 2018.¹⁹

GEMCABENE

This is a novel drug which has multiple level targets that lower LDL-C, TG, and high sensitivity C-reactive protein (hsCRP) in plasma. It inhibits acetyl CoA carboxylase (ACC) and 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) synthase in the liver, thereby resulting in reduced production of cholesterol and TGs. Gemcabene has also been shown to enhance clearance of VLDL in the plasma by reduction of apoC-3 gene expression and thus plasma apoC-3 levels, which may facilitate the uptake of VLDL remnants via hepatic remnant receptors. Gemcabene's effects on hsCRP may be due to its effect on reduction of interleukin-6 expression.

Gemcabene was observed to be well tolerated in 895 subjects across 18 phase I and phase II trials both as monotherapy and in combination with statins.

In a phase II study in men and postmenopausal women more than 18 years old and less than 65 years of age with LDL-C 130 mg% or more while on low-intensity to high-intensity stable statin (the majority on moderate intensity) therapy. Sixty six patients were randomized 1:1:1 to gemcabene 300 mg, 900 mg, or placebo QD. It was concluded that gemcabene as add-on to stable statin therapy produces significant reductions in LDL-C of more than 20% and CRP more than 40% compared to placebo.²⁰

apoB, apolipoprotein B; MTP, microsomal triglyceride transfer protein; TG, triglycerides; LDL, low-density lipoprotein; VLDL, very low-density lipoprotein; IDL, intermediate-density lipoprotein.

FIG. 3: Mechanism of action of mipomersen and lomitapide.

CAT-2054

It is a novel oral product candidate designed to modulate SREBP in the liver. SREBP is a master regulator of lipid metabolism and controls the metabolism of both LDL-C and TGs, through effects on multiple downstream proteins including PCSK9 and HMG-CoA reductase. It is a conjugate of eicosapentaenoic acid and niacin by proprietary linkers that can be cleaved by the intracellular enzyme fatty acid amide hydrolase (FAAH). It has completed phase I trials and entering phase II studies.²¹

NOVEL DRUGS TARGETING HIGH-DENSITY LIPOPROTEIN CHOLESTEROL

Cholesteryl Ester Transfer Protein Inhibitors

Although it is well known that HDL-C plays a protective role against ASCVD, until recently there is no established data that raising HDL level is beneficial in terms of CV outcomes. Studies with niacin Atherosclerosis Intervention in Metabolic Syndrome With Low HDL/High Triglycerides (AIM-HIGH),²² The Heart Protection Study 2-Treatment of HDL to Reduce the Incidence of Vascular Events (HPS-2-THRIVE)²³ and CETP inhibitors dalcetrapib in DAL-OUTCOMES,²⁴ torcetrapib in Investigation of Lipid Level Management to Understand its Impact in Atherosclerotic Events (ILLUMINATE)²⁵ failed to show any CV benefit despite increasing HDL levels.

Cholesteryl ester transfer protein (CETP) transfers cholesterol from HDL-C to VLDL or LDL-C. Inhibition of this process results in higher HDL levels and reduces LDL levels.

However, the recently published Randomized Evaluation of the Effects of Anacetrapib Through Lipid-modification (REVEAL) trial, which was a randomized, double blind, placebo-controlled trial involving 30,449 adults with ASCVD on intensive atorvastatin therapy and who had a mean LDL cholesterol level of 61 mg/dL, a mean non-HDL-C level of 92 mg/dL and a mean HDL-C level of 40 mg/dL were randomized to receive 100 mg anacetrapib daily versus placebo. Follow-up period was 4.1 years. Primary outcome, which was first major coronary event, a composite of coronary death, MI, or coronary revascularization occurred in significantly fewer patients in the anacetrapib group than in the placebo group (10.8% vs. 11.8%, p = 0.004). It also demonstrated increase in mean HDL-C level and decrease in non HDL-C compared to placebo.²⁶ Despite this, the manufacturer felt that the clinical profile for anacetrapib does not support regulatory filings.

Upregulators of Apolipoprotein A-1 Transcription

Apolipoprotein A-1 (apo A-1) is the major and critical component of HDL particles and responsible for reverse cholesterol transport. Therefore enhancing the endogenous expression of apo A-1 forms a potential therapeutic target against atherosclerosis.

Overexpression of human apo A-1 in transgenic mice has elucidated that increased apo A-1 and HDL-C reduced atherosclerosis progression. On the basis of these observations, the development of new therapies targeting apo A-1 is ongoing. Several known drugs, like fenofibrate, pioglitazone, and 9-cis-retinoic acid, have been reported to regulate apo A-I gene transcription by activating peroxisome proliferator-activated receptor α (PPAR α) or retinoid X receptor (RXR), and retinoic acid receptor (RAR) heterodimer; however, they have not been as potent as expected, so identification of effective small molecules that raise the apo A-1 production by increasing its transcription is highly desired.²⁷

High-density Lipoprotein Cholesterol Infusion Therapy

Newly developed HDL infusions including reconstituted HDL (rHDL) are currently being tested in clinical trials to determine their effect on the amount and the composition of the plaque and the general state of inflammation. HDL infusions achieve stable levels rapidly in the plasma, making them most suitable in the post ACS stage when most ischemic events are likely to recur. rHDL has been shown to effectively induce cholesterol reflux and inhibit proinflammatory changes and platelet aggregation.²⁸ In the Effect of rHDL on Atherosclerosis-Safety and Efficacy (ERASE) trial, it was shown that short-term rHDL infusions can induce plaque regression within 4 weeks of treatment in ACS patients.²⁹

Triglyceride Reduction

Apolipoprotein C-3 Antisense Oligonucleotide-Volanesorsen

Apolipoprotein C-3 (apo C-3) is a multifaceted protein which plays a key role in TGs metabolism, but recent evidence also suggests that it also participates in the atherosclerotic lesion formation and several other pathological processes involved in atherosclerosis. Genetic observations have shown that loss-of-function mutations in the gene encoding apo C-3 leading to reduced TG levels are associated with decreased CVD risk.

Species-specific antisense suppression of apo C-3 has produced robust reduction in serum apo C-3 and TG and demonstrated good tolerance in various phase I and II trials.

Ongoing phase III trials about volanesorsen include the APPROACH (the APPROACH study: A Study of ISIS-APOCIIIRx in Patients with Familial Chylomicronemia Syndrome, NCT02211209), the COMPASS (the COMPASS study: A Study of Volanesorsen in Patients with Hypertriglyceridemia, NCT02300233), and the BROADEN (the BROADEN study: A Study of Volanesorsen in Patients with Partial Lipodystrophy, NCT02527343).³⁰ These studies aim to evaluate the efficacy and safety of 300 mg volanesorsen versus placebo. Thus to lower the apo C-3 levels in circulation via specific intervention seems to be an intriguing therapy for CV protection.

Angiopoietin-like Proteins Inhibitors

Angiopoietin-like proteins (ANGPTLs) are proteins that are related structurally to angiopoietins. Of these, ANGPTL 3 and 4 have recently been identified to play a role in regulating plasma lipid levels acting via lipoprotein lipase- and endothelial lipase-mediated hydrolysis of TGs and phospholipids, with more data available for ANGPTL 3 than 4. Loss-of-function variants in ANGPTL3 were associated with a reduced risk of coronary artery disease making it a potential therapeutic target to treat combined hyperlipidemia.

Inhibition of this protein has been shown to reduce plasma lipid levels in both animals and human studies. Strategies to inactivate ANGPTL3 include mAbs against it, namely evinacumab and selective antisense inhibition of ANGPTL3 expression in the liver.

In human volunteers, inhibition of ANGPTL3 with evinacumab was associated with dose-dependent reductions in LDL cholesterol (29%) and TG levels (76%).³¹

New PPAR α Agonists

Peroxisome proliferator-activated receptors are members of the nuclear receptor superfamily of ligand-activated transcription factors. PPARs contain three isotypes encoded by PPAR α (NR1C1), PPAR β/δ (NR1C2), and PPAR γ (NR1C3) genes. PPAR α plays a role in regulation of fatty acid transport as well as peroxisomal and mitochondrial β -oxidation in the liver. Fibrates are PPAR α -agonists. The next generation of PPAR α agonists is called "selective PPAR α modulators" (SPPARM α). They maximize the beneficial effects and minimize the adverse effects of fibrates.

Pemafibrate

It is the first of the SPPARM α to be developed, and has been shown to be safe and efficacious against dyslipidemia in a phase II study.³²

Pemafibrate to Reduce Cardiovascular Outcomes by Reducing Triglycerides IN patients With diabetes (PROMINENT) is ongoing study with the primary objective of the study being to determine whether pemafibrate administered twice daily will delay the time to first occurrence of any component of the clinical composite endpoint of nonfatal MI, nonfatal ischemic stroke hospitalization for UA requiring unplanned coronary revascularization, or CV death in diabetics with well-controlled sugars and LDL-C, but having raised TGs and low HDL-C.³³

Saroglitazar

Saroglitazar is novel first in class drug which acts as a dual PPAR α and γ agonist. Agonist action at PPAR α lowers high blood TGs, and agonist action on PPAR γ improves insulin resistance and consequently lowers blood sugar.³⁴

Saroglitazar is indicated for the treatment of diabetic dyslipidemia and hypertriglyceridemia with type 2 diabetes mellitus not controlled by statin therapy. It is approved for clinical use in India, though outcome data are awaited.

TABLE 1: Safety of PCSK 9 inhibitors, evolocumab¹⁰

Adverse event (AE)	Evolocumab (13,769 patients)	Placebo (3,756 patients)
Any AE	77	77
Serious AE	25	25
Reaction at injection site	2.1	3.6
Discontinuation of drug due to AE	1.6	1.5
Allergic reactions	3.1	2.9
Myalgia/myositis	5.0	4.8
New onset diabetes	8.1	7.7
Defective cognition	1.6	1.5

mellitus not controlled by statin therapy. It is approved for clinical use in India, though outcome data are awaited.

WHAT ARE THE RECOMMENDATIONS OF THE MEDICAL SOCIETIES ON NEW NONSTATIN MEDICATIONS?

2016 ACC Expert Consensus Statement³⁵

1. Ezetimibe is the first nonstatin medication that should be considered in most of the case scenarios, since it has established its safety and efficacy
2. Bile acid sequestrants may be considered as second-line therapy for patients in whom ezetimibe is not tolerated, but they should be avoided in patients with TGs greater than 300 mg/dL
3. Alirocumab and evolocumab may be considered if the goals of therapy have not been achieved on maximally tolerated statin and ezetimibe in higher-risk patients with clinical ASCVD or FH. They are not recommended for use in primary prevention patients in the absence of FH
4. For patients with HoFH, other options are use of lomitapide, mipomersen, and LDL apheresis as necessary.

2016 ESC/EAS Guidelines for the Management of Dyslipidemias³⁶

1. In the case of statin intolerance, ezetimibe, or BAS, or these combined, should be considered (IIa)
2. If the goal is not reached, statin combination with a cholesterol absorption inhibitor should be considered (IIa)
3. If the goal is not reached, statin combination with a BAS may be considered (IIb)
4. In patients at very high-risk, with persistent high LDL-C despite treatment with maximal tolerated statin dose, in combination with ezetimibe or in patients with statin intolerance, a PCSK9 inhibitor may be considered (IIb).

Lipid Association of India Expert Consensus Statement on Management of Dyslipidemia in Indians 2016: Part 1³⁷

Nonstatin drugs may be used in the following settings:

- As an alternative to statins when the patient is completely statin intolerant
- In combination with statins when the desired dose of statin cannot be used due to intolerance.

SAFETY OF VERY LOW LOW-DENSITY LIPOPROTEIN CHOLESTROL

There is a concern in the minds of many a clinicians and amongst general population about the safety of very low LDL-C. However, the evidence from the clinical trials to the contrary, is reassuring.

Further Cardiovascular Outcomes Research with PCSK9 Inhibition in Subjects with Elevated Risk (FOURIER)¹⁰ trial where median LDL-C achieved was 30 mg%, no difference was noted between the evolocumab group and the placebo group, except that injection site reactions were more common in the evolocumab group (Table 1). Even those patients who achieved LDL-C below 20 mg% showed no increased adverse effects, including neurocognitive functions as compared to the placebo.

In the Evaluating PCSK9 Binding Antibody Influence on Cognitive Health in High Cardiovascular Risk Subjects (EBBINGHAUS) study, a subgroup of patients from FOURIER trial, numbering 1,204 patients were followed for a median of 19 months. They were prospectively assessed for cognitive function more objectively, using the Cambridge Neuropsychological Test Automated Battery (CANTAB). The conclusion was that patients who received either evolocumab or placebo in addition to statin therapy, no significant difference in cognitive function between the groups was observed over a follow-up of a median of 19 months.³⁸

"HIGHEST RISK-HIGHEST BENEFIT STRATEGY"

Since PCSK9 inhibitors are pricey, "Highest Risk-Highest Benefit" Strategy" is a pragmatic, cost-effective approach to targeting use of PCSK9 inhibitor therapies. The addition of ezetimibe or PCSK9 mAbs to maximally tolerated statin therapy is expected to be cost-effective in very high-risk and high-risk patients. Clinical ASCVD in a diabetic with or without CKD, ASCVD with CKD, recent ACS (<3 months), coronary heart disease (CHD) with poorly controlled risk factors, CHD with peripheral vascular disease, CAD in patients more than 65 years old, stroke in a male subject, and FH fall into high or very high-risk for ASCVD.³⁹

CONCLUSION

Statins continue to stay as the first-line pharmacologic therapy for treating AD to reduce risk of ASCVD. However, there are situations when it becomes necessary to introduce

nonstatins in addition or as a substitute to statins. At present, approved newer agents are ezetimibe which is already available in our country and PCSK9 inhibitors which would be available shortly. Judicious use of these agents would effectively address the issue of residual cholesterol risk.

CARDIOLOGY
Update 2018

Choosing Between NOACS Wisely: Are They all the Same?

Sandeep Bansal, Anunay Gupta

INTRODUCTION

For over half a century, we have been using vitamin K-based drugs as oral anticoagulants. The vitamin K anticoagulants (VKAs) as oral anticoagulant (OAC) drugs act indirectly on the process of glutamic acid (Glu) carboxylation of the vitamin K-dependent coagulation factor proteins. They have been used for several indications like:

- Stroke prevention in atrial fibrillation (SPAF)
- Coronary artery disease (CAD)
- Prevention and treatment of deep vein thrombosis and pulmonary embolism in surgical or medical conditions
- Ischemic stroke
- Rare hypercoagulable states (e.g., factor-V Leiden or protein C and S deficiency).

They have been very successful in what they are meant for, i.e., anticoagulation and prevention of thrombosis. They reduce incidence of non-valvular atrial fibrillation (NVAF) by nearly two-thirds. However, they do have several shortcomings, viz. slow onset or offset, need for monitoring international normalized ratio (INR), significant drug and food interactions and high incidence of bleeding. This necessitated the development of non-vitamin K antagonist oral anticoagulants (NOACs) or directly-acting oral anticoagulants (DOACs).

Non-vitamin K antagonist oral anticoagulants have undergone phase three trials in prevention or treatment of venous thromboembolism following orthopedic surgeries, prevention or treatment of venous thromboembolism following general surgeries or medical conditions, prevention, and treatment of pulmonary embolism, SPAF and lately in treatment of CAD both with and without atrial fibrillation (AF). They are now widely being used for all these indications. However, the current discussion would largely be dedicated to choosing a NOAC in SPAF.

Currently, four NOACs are approved by the US Food and Drug Administration (FDA), i.e., Dabigatran [direct thrombin inhibitor (DTI)], apixaban, edoxaban, and rivaroxaban (factor-Xa inhibitors).

Although there is a lot of data available on these agents. But still clinicians find it difficult to choose most appropriate NOACs for their individual patient. Dienner HC et al. had recently reviewed this issue in two papers which are worth reading for every clinician prescribing NOACs for various indications.^{1,2} This review is intended to highlights practical points related to everyday use of NOACs in clinical practice. Several factors determine a physician's choice, viz:

- Medical conditions like kidney and liver functions
- Age of the patient
- Patient's profile, e.g., which is a greater consideration high risk of ischemic stroke or high-risk of bleeding
- Concomitant medications
- Adherence – likelihood of using once or twice daily regimen
- Cost
- Trial designs of phase three SPAF trials.

PHARMACOKINETICS AND PHARMACODYNAMICS DIFFERENCES

All NOACs differ from VKAs as a group and have many similarities. They have rapid onset of action, hence do not require bridging parenteral anticoagulation. They do not require monitoring.³ Their half-life is also similar (5–7 h). Table 1 highlights major difference among NOACs. As mentioned in the table dabigatran has a very low bioavailability 6–7% and its absorption depends on gastrointestinal (GI) pH and comes formulated with tartaric acid, which is considered responsible for GI side effects seen. Dabigatran capsules are hygroscopic, hence medication should be stored in bottles. Rivaroxaban bioavailability is high when taken with food (66–80%), hence it should be preferably taken with food. Although, drug interactions seen with NOACs are much less as compared to warfarin, there are few important interactions of which clinician should be aware of. All NOACs are impacted by permeability glycoprotein (P-glycoprotein) system. Similarly, cytochrome P450 metabolizes all NOACs except dabigatran. Hence, drugs which are inducers of

TABLE 1: General pharmacological characteristics of NOACs

Characteristics	Dabigatran	Rivaroxaban	Apixaban	Edoxaban
Bioavailability	pH dependent	Food dependent 60–80%	50%; food independent	62%; food independent
Renal clearance	80%	35%	25%	50%
CYP3A4 metabolism	No	Yes	Minor	Minor
P-glycoprotein	Yes	Yes	Yes	Yes

CYP3A4, cytochrome P450 3A4; NOACs, non-vitamin K antagonist oral anticoagulants; P-glycoprotein, permeability glycoprotein.

TABLE 2: Main characteristic features of four pivotal trials of NOACs*

	RE-LY		Rocket AF	Aristotle	Engage AF	
Drug	Dabigatran	Rivaroxaban	Apixaban	Edoxaban		
Patients	18,113	14,264	18,201	21,105		
Age (y)	71	73	70	72		
Mean CHADS ₂ Score	2.1	3.5	2.1	2.8		
Dose	110 mg BD	150 mg BD	20 mg OD	5 mg BD	60 mg OD	30 mg OD
Prior VKA(%)	50	62	57	58.8	59.2	
Mean TTR(%)	64	55	62	68.4		
RR of ischemic stroke	1.1	0.76	0.94	0.92	1.141	1.0
RR of stroke or systemic embolism	0.91	0.66	0.88	0.79	1.13	0.87
RR of major bleed	0.80	0.93	1.04	0.69	0.80	0.47
RR of hemorrhagic stroke	0.31	0.40	0.67	0.42	0.47	0.30
RR of GI bleed	1.09	1.49	1.47	0.88	1.23	0.67
RR of myocardial infarction	1.29	1.27	0.81	0.88	0.94	1.19
RR of death	0.91	0.88	0.85	0.89	0.92	0.87

*Modified and adapted from multiple sources.

AF, atrial fibrillation; GI, gastrointestinal; NOACs, non-vitamin K antagonist oral anticoagulants; RR, relative risk; TTR, time in therapeutic range; VKA, vitamin K anticoagulants.

P-glycoprotein should be used cautiously or not used with NOACs. Such drugs commonly used in clinical practice are antifungals, antituberculars, and antiepileptic drugs.

MAJOR DIFFERENCES IN TRIALS

To know the differences between the available NOACs, it is important to review the differences between those four major studies (Table 2). The Randomized Evaluation of Long-Term Anticoagulation Therapy (RE-LY study)⁴ was an open, blinded study that compared blinded doses of dabigatran 110 or 150 mg twice daily to open-label dose-adjusted warfarin. The other three trials were double-blinded, double-dummy trials comparing a once daily 20 mg dose of rivaroxaban (ROCKET AF),⁵ twice daily, 5 mg dose of apixaban (ARISTOTLE),⁶ and two doses (30 and 60 mg) of edoxaban, once daily (ENGAGE AF-TIMI),⁷ respectively, to warfarin.

One thing to always remember is that even though dabigatran 150 BD was superior to warfarin but confidence interval (CI) margin was just 0.98 means 24% relative reduction (RR) was with odds ratio (OR) 0.76 (0.60 – 0.98) and probability (p) value of 0.03. Hence, it can be said theoretically all NOACs were non inferior to warfarin, if

it comes to efficacy except high-dose dabigatran wherein a statistical significant superiority was noted. They were importantly superior over warfarin predominantly on the basis of improved safety margin.

Which NOACs to use?

It is difficult to directly compare NOACs from each other due to differences in the trial characteristics as summarized in Table 2. Table 3 summarizes individual patient group in which one NOACs can be used preferably over on the basis of multiple subgroup and post hoc analysis, and meta-analysis.⁸

Asian Patients

Asian patients are at high-risk of stroke due to increased prevalence of stroke risk factors. But they are also at increased risk of intracranial bleed, this fear leads to under treatment of AF patients with anticoagulation. In Asian patients, there was no excess bleeding when NOACs were used and superiority of NOACs to warfarin in reducing thromboembolism was maintained. Hence, NOACs are preferentially indicated in Asians in terms of both efficacy and safety.⁹

TABLE 3: Choosing the right NOACs for right patient

Factor	Features	NOACs
Patient compliance and preference	OD dosing	Rivaroxaban, edoxaban 60 mg
Renal dysfunction	Least renal clearance	Apixaban (preferred), rivaroxaban
Increased GI bleeding risk	Least incidence of GI bleeding	Apixaban, low-dose edoxaban
High-risk of bleeding (HAS-BLED >3)	Least bleeding risk	Dabigatran 110 BD and apixaban
Stable CAD	Evaluated in trial	Rivaroxaban low dose (not FDA approved)
Post PCI	Evaluated in trial	Rivaroxaban and dabigatran
Elderly (age >75 years)	Lesser risk of extracranial bleeding	Rivaroxaban or apixaban
High-risk of ischemic stroke, less risk of bleeding	Best reduction in ischemic stroke	Apixaban

CAD, coronary artery disease; FDA, Food and Drug Administration; NOACs, non-vitamin K antagonist oral anticoagulants; PCI, percutaneous coronary intervention.

Elderly Patients

Elderly patients (age >75 years) well participated in all the major NOAC trials. Meta-analysis of the trials in elderly population had shown that NOACs were more effective than conventional warfarin therapy in the prevention of stroke and systemic embolism, and they were not associated with any increase in major or clinically relevant bleeding events in patients over 75 years of age.¹⁰ However, in elderly patients intracranial bleeding risk was lower but extracranial bleeding risk was similar or higher with both doses of dabigatran compared with warfarin.¹¹ Hence, direct factor-Xa inhibitors should be preferably used in elderly.

Patient at High-risk of Bleed

The HAS-BLED (Hypertension, abnormal renal and liver function, stroke, bleeding, labile INR, elderly, drugs or alcohol) score can be used to predict patients at high risk of hemorrhage, with a score of 3 or greater signifying significant risk.¹² Low-dose Dabigatran (RR 0.80, 95%; CI 0.69–0.93; p = 0.003), apixaban (RR 0.69, 95%; CI 0.60–0.80; p <0.001) and edoxaban at high (RR 0.80, 95%; CI 0.70–0.91; p <0.001) and low-dose (RR 0.47, 95%; CI 0.41–0.55; p <0.001) have shown significantly reduced rates of major hemorrhage compared to warfarin as shown in table 2. However, there was no significant difference in the incidence of major bleeding in high-dose dabigatran (150 mg BD) and rivaroxaban versus warfarin (Table 2). Patients in ROCKET-AF trial who were in time in therapeutic range (TTR) were lower (only 55%), hence might have affected the rate of hemorrhage in warfarin arm. It should be remembered that rate of intracranial bleeding was significantly lower among all the doses tested of all NOACs. Hence, low-dose dabigatran, apixaban, and edoxaban may be used preferably in patients who are at high-risk of bleeding.

Increased Risk of Gastrointestinal Hemorrhage

Dabigatran 150 BD (RR 1.50) and rivaroxaban (3.2 vs. 2.2% p value <0.001) have higher risk of GI bleed, hence should be

avoided in patient at risk of GI bleed. All NOACs except low-dose edoxaban are associated with similar or increased risk of GI hemorrhage compared to warfarin. Apixaban and low-dose dabigatran have similar risk of GI bleed as compared to warfarin. Important point to remember is that GI bleeding, even in the setting of anticoagulation, does usually not cause death or permanent major disability and identifying and treating the cause is mandatory. Thus, the choice of OAC should be driven mainly by stroke prevention considerations. Hence, it would be suggested to use dabigatran 110 BD and apixaban 5 BD in such patients. Even though low-dose edoxaban was associated with low-risk of GI bleed but with reduced efficacy of stroke prevention.

Chronic Kidney Disease

Patients with renal impairment requires dose modification of all NOACs as they all are excreted by kidney (Table 4).

There are no clinical outcome data regarding the use of NOACs for patients with creatinine clearance (calculated by the Cockcroft-Gault equation) of less than 30 mL/min and also patients on hemodialysis. Hence, warfarin is the preferred anticoagulant for these patient subgroups.

TABLE 4: Summarizes dose modification criteria in patients with renal disease

Drugs	Criteria	Dose modification
Dabigatran	Creatinine clearance <50 mL/min <30 mL/min	110 mg BD as per ESC guidelines should not be used
Rivaroxaban	Creatinine clearance <50 mL/min	15 mg OD
Apixaban	Two of these factors: Age >80, creatinine >1.5, weight <60	2.5 BD
Edoxaban	Creatinine clearance <50 mL/min	30 OD

ESC, European Society of Cardiology.

Coronary Artery Disease Patients

Patients with stable CAD with AF is common and constituted up to 30% of patients in major NOACs trials. Incidence of CAD in more than 70 years of AF was 41%.¹³ Use of antiplatelet along with NOACs therapy is associated with increased risk of bleeding. Increased risk of myocardial infarction (MI) with dabigatran as was initially thought, was not supported by large FDA Medicare analysis.¹⁴ The COMPASS (Cardiovascular outcomes for people using anticoagulation strategies) trial evaluated role of rivaroxaban (low-dose) in stable CAD.¹⁵ Among patients with stable atherosclerotic vascular disease, patients who were randomized to rivaroxaban (2.5 mg twice daily) plus aspirin had better cardiovascular outcomes, but more major bleeding events versus those who were randomized to aspirin alone. Rivaroxaban (5 mg twice daily) dose alone did not result in better cardiovascular outcomes versus aspirin alone and resulted in more major bleeding events. Monotherapy with an NOAC is preferable for patients with AF and stable CAD. This suggestion is applicable to all NOACs.¹

Patient with AF undergoing percutaneous coronary intervention (PCI) and stenting need dual anti-platelet therapy (DAPT) for preventing stent thrombosis and Oral anticoagulation for preventing stroke. But it comes at the cost of increased risk of bleeding. In the PIONEER AF-PCI trial¹⁶ two rivaroxaban-based dual therapy (rivaroxaban 15/20 OD with P2Y12 inhibitor) treatment regimens significantly reduced bleeding complications compared to conventional triple therapy (DAPT plus oral anticoagulation) without increasing embolic or ischemic complications following PCI. Dual therapy with rivaroxaban and clopidogrel appeared to provide an optimal risk-benefit ratio.¹⁷ Similarly in the RE-DUAL PCI trial¹⁸ dual therapy with dabigatran (110 BD/150 BD) also reduced bleeding complications compared to conventional triple therapy in patients with AF undergoing PCI.

Single Risk Factor (CHA₂DS₂-VASC Score of 1 in Males or 2 in Females)

Patient with single-stroke risk factor increased risk of stroke varies from 0.5 to 3 %, but risk is lower compared to those with multiple risk factors. The CHA₂DS₂-VASC 2 score is used to assess risk of stroke in AF patients. The risk of embolization attributable to the individual risk factors (that might lead to a score of 1) is not equal. Female sex and vascular disease carry a lower risk than diabetes, hypertension, or age of 65-74 years.¹⁹

Women with a CHA₂DS₂-VASC score of 1 (or 0 for males) are at low-risk, and no antithrombotic therapy is recommended.²⁰ Anticoagulation should be considered for patients with AF and one or more additional stroke risk factors (i.e., men with a CHA₂DS₂-VASC score of ≥ 1 or women with a score of ≥ 2).²¹ There has been no randomized controlled trial (RCT) with NOACs with only one risk factor as event rates will be very low. In the ROCKET AF trial, the proportion of enrolled patients with CHADS₂ scores of 2 was capped at 10%. Mean CHADS₂ score was 3.5 in ROCKET-AF and 2.8 in ENGAGE-AF. Only

dabigatran and apixaban have been studied in such patients and hence should be preferably used.

COMPLIANCE

Once daily dosing has been shown to improve compliance and adherence over medications requiring multiple daily dosing. To promote adherence rivaroxaban or edoxaban should be considered due to their convenient OD dosing.³

CONCLUSION

We would like to suggest a patient-centered, individualized approach to manage thromboembolic risk in patients with AF. With the availability of several NOAC drugs now available, we can fit the drug to the patient profile. As discussed above, there are no head-to-head trials available for comparing NOACs. However, as summarized above we can carefully choose one NOACs over the other depending on the patient specific factors and shared decision making.

CARDIOLOGY
Update 2018

Newer Antihyperkalemic Drugs

AK Pancholia

INTRODUCTION

Hyperkalemia is the common electrolyte imbalance in clinical practice. Moderate-to-severe hyperkalemia leads to potentially fatal cardiac conduction abnormalities or arrhythmias. Risk factors for hyperkalemia include excess intake or supplementation of potassium, type 2 diabetes, liver cirrhosis, congestive heart failure (CHF), and chronic kidney disease (CKD). Ninety to ninety-five percent of ingested potassium is excreted through kidneys while rest excreted through gut. Normal kidneys take 6–12 hours to excrete an acute potassium load. Thus when kidney function decreases, risk for hyperkalemia increases.¹ Hyperkalemia has been observed in 26% of patients with CKD stages 3–5 [glomerular filtration rate (GFR) <60 mL/min].² Renin-angiotensin-aldosterone system (RAAS) inhibitors, including angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), and aldosterone antagonists are associated with hyperkalemia. Though RAAS blockers can play an important role in the management of CKD and cardiovascular disease (CVD), the development of hyperkalemia leads to a dose reduction or discontinuation of these medications, limiting their therapeutic benefit. Nonpharmacological therapeutic options for treatment of hyperkalemia are limited. In addition to reducing or discontinuing related medications, strategies include use of diuretics (as appropriate), treatment of metabolic acidosis, and dietary restrictions (i.e., limiting high-potassium foods).¹ Even pharmacologically, there has been no better option for correcting hyperkalemia.

Recent approval of the new heart failure (HF) medication entresto (LCZ696; sacubitril or valsartan) has further enhanced an interest by the healthcare community to optimize treatment regimens that include life-saving therapies such as ACEIs and ARBs. These agents are known in some patients to increase serum potassium to dangerously high levels that can lead to life-threatening arrhythmias. Patients who have CKD, advanced age, HF, and/or diabetes mellitus are particularly prone to developing hyperkalemia.

In the nephrology community, hyperkalemia has been reported in over half of all CKD patients. Thus monitoring and control of hyperkalemia is of paramount importance.

For last several years sodium polystyrene sulfonate (SPS), the US FDA-approved drug, is being used in treatment for hyperkalemia. Because of the variability in its time to onset of effect and high-sodium content make it a poor choice in acute hyperkalemia and sodium-restricted patient populations.³ To overcome these limitations the newer drugs patiromer sorbitex calcium (patiromer) and sodium zirconium cyclosilicate (ZS-9) have been developed.^{4,5}

CLINICAL MANIFESTATIONS OF HYPERKALEMIA

Increase in plasma potassium concentration has a several adverse clinical effects which may be magnified in the critically ill patient.

Cardiac Effects

Depolarization of cell membrane and decrease in duration of action potential due to hyperkalemia lead to some classical ECG changes (Fig. 1).⁶

Hospitalized patients with hyperkalemia have a higher mortality rate than those without hyperkalemia.^{7,8} The first cardiac manifestation of hyperkalemia may be ventricular fibrillation.⁹

Neuromuscular Effects

Hyperkalemia causes muscle weakness progressing to a flaccid paralysis and paresthesia. Deep tendon reflexes are depressed or absent, sensory changes are minimal.^{10,11}

Metabolic Effects

Hyperkalemia may produce a mild hyperchloremic metabolic acidosis,¹² and will limit the kidney's ability to excrete an acid load and thus prevent correction of a metabolic acidosis.¹³

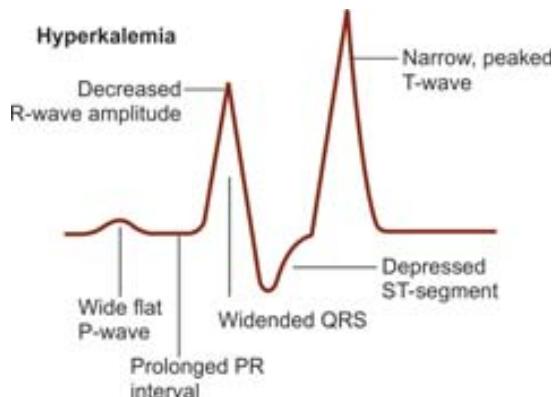

FIG. 1: Electrocardiography changes of hyperkalemia.

TABLE 1: Old drugs for hyperkalemia and their mechanism of action

Therapy	Start	Mechanism
Calcium gluconate	Fast	Antagonize excitation of membrane
Insulin and dextrose	Intermediate	Moves potassium inside the cell
Beta-adrenergic antagonists	Intermediate	Moves potassium inside the cell
Sodium bicarbonate	Intermediate	Moves potassium inside the cell
Diuretics	Late	Increases potassium urine excretion
Resins	Late	Increases potassium gastrointestinal excretion
Dialysis	Late	Potassium extracorporeal elimination

THERAPY FOR HYPERKALEMIA

Older Drugs for Hyperkalemia

Old drugs for hyperkalemia and their mechanism of action are shown in table 1.

Newer Drugs for Hyperkalemia

Limitations of the old therapy for hyperkalemia have paved the way for newer, effective, and safe drugs.

Sodium Polystyrene Sulfonate

Sodium polystyrene sulfonate, an organic enteral potassium-sodium exchange resin, nonselectively binds potassium and other cations, is commonly given with sorbitol, which results in diarrhea.¹⁴ Diarrhea lowers potassium via colonic epithelial cells that upregulate their ability to facilitate luminal losses of potassium in CKD, but it is a potentially dangerous side effect for hospitalized patients who are at risk for volume loss. It is also associated with frequent adverse effects and carries the risk of acute bowel necrosis as both an oral solution and as a retention enema, particularly in critically ill and postsurgical

patients. It also causes hypernatremia.¹⁵ Thus, SPS is not routinely prescribed as an outpatient, chronic oral therapy because of diarrhea and concerns about its unknown efficacy and poor tolerability.

Sodium Zirconium Cyclosilicate

It is a new oral agent used in the management of hyperkalemia. ZS-9 binds the potassium selectively. It is taken as an oral powder in liquid which is insoluble and not absorbed by the gut. Zirconium is a trace element, biologically inert, used in dental and medical processes, including as part of renal dialysis to remove ammonium. As a crystalline lattice, ZS-9 has many micropores with a specific size and negatively charged selectivity filter (Fig. 2).

The dietary potassium incorporates through micropores, with counter ions of sodium and hydrogen exchanged from within the latticework, with excretion of potassium-rich compound rather than absorbed. The pores are selective for potassium over both sodium ions and divalent ions like calcium and magnesium.¹⁶ ZS-9 has a low-risk of toxic effects because of lack of absorption. Its insolubility also prevents water absorption, which has led to constipation in polystyrene-based resins. ZS-9 is approved for clinical use in Europe but has not yet been approved by the FDA in the US.

Mechanism of Action

Figure 3 shows the mechanism of action of sodium zirconium cyclosilicate.

Clinical Trial with Sodium Zirconium Cyclosilicate

The HARMONIZE study (Fig. 4) was a phase 3, multicenter, double-blind, randomized controlled trial in hyperkalemic patients in outpatients for 28 days.¹⁷ Total 258 patients were given 10 g of ZS-9 with meals three times a day for 48 hours, then the 237 subjects who achieved normokalemia were randomized into receiving 28 days of a once-daily preparation of different doses (5 g, 10 g, 15 g) or placebo in each of the treatment groups patients maintain normokalemia ($K^+ < 5.1 \text{ mmol/L}$) at 28 days with comparable adverse effects with placebo.

Patiromer Sorbitex Calcium

Patiromer is a nonabsorbed potassium-binding polymer, available in powder form to be taken orally as suspension in water, and a calcium-sorbitol counter ion that binds potassium in the gastrointestinal lumen and increases fecal potassium excretion, leading to removal of potassium from the body and lowering of serum potassium levels.

Preclinical Studies

In balance studies¹⁸ in dogs given C13-patiromer, 99.9% of the administered dose was found in the feces with less than 0.1% in the urine and 0.002% in the plasma.

Phase I Studies

In these studies patiromer was found to increase the fecal contents of sodium and magnesium, reduced the fecal content of calcium in a dose-dependent manner.¹⁹ In the

Source: van der Meer P, van Veldhuisen DJ. To bind or not to bind: potassium-lowering drugs in heart failure. Eur Heart J. 2011;32(7):791-2.

phase I clinical study,²⁰ subjects with established CKD and HF, and with serum potassium levels in the range of 4.3–5.1 mmol/L were given either patiromer (30 g/day) or a placebo. Patiromer significantly reduced serum potassium; this was also demonstrated in patients with CKD.²¹ Patiromer was administered in a dose of 8.4 g twice daily for 2 days (at 0, 10, 24, and 34 hours). After 7 hours there was a significant reduction in the mean serum potassium level. Twenty-four hours after the first dose, 80% of subjects had a serum potassium level of less than 5.6 mmol/L in the mild hyperkalemia range. When the fourth and last dose was given after 34 hours, the mean serum potassium was 5.27 mmol/L.

The mean serum potassium level continued to decline for 7–10 hours after this last dose.

Phase II and III Studies—The AMETHYST-DN Trial

In this phase II trial,²² a study was made of the effect of different doses of patiromer on serum potassium levels. All subjects had type 2 diabetes, CKD [estimated GFR (eGFR) 15– <60 mL/min/1.73 m²] and were taking a RAAS inhibitor (RAASI) before and during the trial. Subjects were stratified into two groups; those with mild hyperkalemia with serum potassium levels 5–5.5 mmol/L and those with moderate hyperkalemia with serum potassium levels 5.6–5.9 mmol/L.

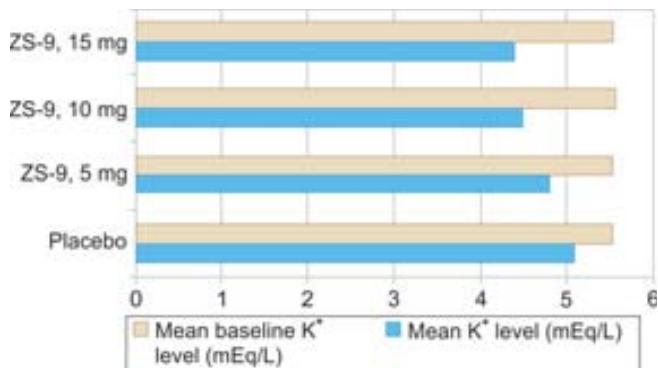

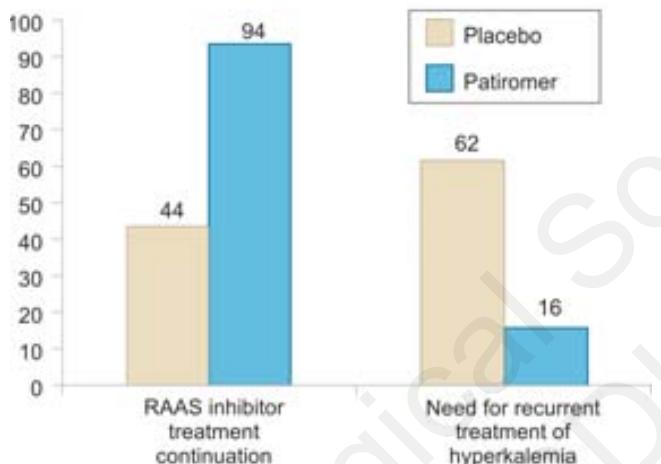

FIG. 4: HARMONIZE trial.

Effect of patiromer on RAAS inhibitors continuation and recurrent hyperkalemia treatment in patients with CKD

CKD, chronic kidney disease; RAAS, renin–angiotensin–aldosterone system.

FIG. 5: The OPAL-K trial.

Subjects received one of three dosage schedules for 8 weeks. All doses used caused significant reductions in serum potassium levels after 28 days on patiromer. On the basis of these findings the lowest starting doses were chosen. Those with mild hyperkalemia were to receive 8.4 g/day (which caused a fall in serum potassium of 0.35 mmol/L in the first phase) and those with moderate hyperkalemia were to receive 16.8 g/day (which caused a fall in serum potassium of 0.87 mmol/L in the first phase) as starting doses. Subjects then continued on patiromer for a further 44 weeks for a total of 52 weeks on patiromer. From week 4 to week 52, significant ($p < 0.001$) mean decreases from baseline in serum potassium were found at each monthly time point in subjects with mild or moderate hyperkalemia.

The OPAL-K Trials (Fig. 5)

In the OPAL-K study^{23,24} the effects of patiromer were studied in patients with CKD. Eligible subjects for the study had to have stage 3 or 4 CKD (eGFR 15– <60 mL/min/1.73 m²), have a serum potassium level of 5.1–6.4 mmol/L and have been on at least one RAASI for at least 28 days. There were two parts to the OPAL-K study. In the first, a study was made of

the effects of patiromer in subjects with CKD.²³ In the second part of the study, the effects of patiromer were examined in subjects with both CKD and HF.²⁴ In the initial 4-week phase of the OPAL-K study of subjects with CKD,²³ those with mild hyperkalemia (serum potassium, 5.1–6.4 mmol/L) received patiromer 8.4 g/day, while those with moderate-to-severe hyperkalemia (serum potassium, 5.5–6.4 mmol/L) received patiromer 16.8 g/day; these doses were increased if the target potassium level had not been reached or maintained. The mean daily doses actually taken were 12.8 g/day and 21.4 g/day in the mild and moderate hyperkalemia groups. At the end of the initial treatment phase after 4 weeks, the mean potassium level had fallen by 0.65 ± 0.05 mmol/L in the mild hyperkalemia group, and by 1.23 ± 0.04 mmol/L in the moderate hyperkalemia group. After only 2 days, patiromer had caused a fall in serum potassium. After 4 weeks 74% of those in the mild and 77% of those in the moderate-to-severe hyperkalemia groups were in the target serum potassium range (3.8–5 mmol/L).²³ Furthermore, 94% of subjects who continued on patiromer were able to continue taking a RAASI compared to 74% of subjects on a placebo.

In the second OPAL-HK trial (Fig. 6),²⁴ subjects were studied in two groups in the withdrawal phase; those with HF and those without HF. After the initial phase, subjects were eligible to continue to the randomized withdrawal phase if they had had moderate-to-severe hyperkalemia at baseline (>5.5 mmol/L at baseline), and if they now had a normal serum potassium level (3.8–5.0 mmol/L) after the initial 4 weeks on patiromer, and were still taking an RAASI and had HF. Subjects meeting these criteria were randomly assigned to receive either placebo or to carry on taking patiromer at the same dose as in the previous 4 weeks. At the start of this new phase, the mean serum potassium levels did not differ in these two groups. Subjects continuing on placebo had a mean increase of 0.74 mmol/L in their serum potassium levels, whereas those on patiromer had a mean increase of 0.10 mmol/L in their potassium levels. Those on patiromer were markedly less likely to redevelop hyperkalemia (serum

 - Constipation (7.2%)
 - Hypomagnesemia (5.3%)
 - Diarrhea (4.8%)
 - Nausea (2.3%)
- Common laboratory abnormalities:
 - Hypomagnesemia <1.4 mg/dL (9%)
 - Hypokalemia <3.5 mEq/L (4.7%)

potassium >5.5 mmol/L) as only 8% had at least one episode of mild or moderate hyperkalemia compared to 52% of those on placebo.

The PEARL-HF Trial

In the PEARL-HF trial,^{25,26} the effects of patiromer were studied in subjects with a history of chronic HF. To enter the trial, subjects had to have CKD (eGFR <60 mL/min/1.73 m²) and be on one or more therapies for HF, or had to have a history of hyperkalemia that had led to the stopping of therapy for HF within the last 6 months. Subjects were randomly assigned to receive either placebo or patiromer (30 g/day). All subjects were also started on spironolactone (25 mg/day). After 14 days the dose of spironolactone was raised to 50 mg/day if their serum potassium level was 3.5–5.0 mmol/L. After 14 days the dose of spironolactone was left unchanged if the potassium level was 5.1–5.5 mmol/L, but spironolactone was stopped if the level was less than 3.5 or more than 5.5 mmol/L. At the start of the trial the mean serum potassium levels of the two groups did not differ significantly. The two groups differed significantly after 48 hours with the serum potassium level being lower in the group receiving patiromer; the difference remained significant thereafter until the end of the trial. After 2 weeks of treatment the group receiving patiromer had a mean serum potassium level that was 0.45 mmol/L lower than those on placebo and this was also the difference after 4 weeks.

Adverse Effects of Patiromer

Box 1 shows adverse effects of patiromer.

Dosage and Administration

The recommended starting dose of patiromer is 8.4 g once daily, monitor the serum potassium level and dose can be increased to maximum up to 25.2 g once daily. It should not be used in emergency life-threatening situation because of slow onset of action. It can be taken with food but food should not be heated. It should not be taken in dry form.

CONCLUSION

Management of CKD, HF, and acute kidney disease is complicated by both acute and chronic hyperkalemia. Use of RAASi in these conditions further aggravate the problem and is challenging. Newer drugs like polymer patiromer sorbitex calcium and ZS-9 showed promise in both as acute

remedies and as adjunctive therapies for hyperkalemia, and may allow greater use of ACEIs, ARBs, and mineralocorticoid receptor antagonists in the vulnerable populations who have an especially great need for neurohormonal blockade.

Drug Interactions in Cardiology

Arunangshu Ganguly

INTRODUCTION

With increasingly more drugs, supplements, alternative therapies thronging the armamentarium of medical treatment the interactions between various forms of therapy are gaining increasing importance in field of medicine of which cardiovascular pharmacotherapeutics form an inseparable part. The interactions may potentiate or suppress the various drug effects, can cause harmful consequences or lead to a therapy being ineffective. So, a ready knowledge would be very comforting in choosing the drugs for use in different setting.

When two or more drugs interact to alter the effectiveness or toxicity of one or more drugs, drug-drug interactions (DDI) may be observed.¹⁻⁴ In patients receiving multidrug therapy, DDI is a major concern as it leads to an increased risk of hospitalization. Healthcare costs also rise considerably.⁵ Besides DDI, food-drug interaction is also an important component of drug interactions. They are caused by food nutrient supplements interacting with drug, such that body is unable to utilize the food or drug. The lack of knowledge about the active ingredients is the most common cause besides inadvertent usage. Alcohol, commonly used herbs and fruits may change the effects of drug causing serious health effects.

INCIDENCE

Actual incidence of DDI is around 1.3%.^{6,7} According to few other studies, the incidence is up to 11%. They constitute 2.8% patients admitted to hospital.^{8,9} Increased healthcare availability has increased DDI.¹⁰ In a recent study, it was reported that 1% of all the admission to the hospital is caused by DDIs. Adverse drug reactions (ADR), account for 0.6% admissions in hospital, 0.05% of visits to emergency department, and 0.1 % of rehospitalizations.^{11,12}

The incidence of cardiovascular disease (CVD) has already reached the top of the charts among all diseases. So, CV drugs are one of the most popularly prescribed drugs

in medicine. The drug interactions with CV drugs is more common as the patients are aged, have multiple ailments requiring treatment, hence, polypharmacy is the rule than exception. There is paucity of Indian data as to the incidence of this innocuous yet important happening. However, Mateti et al. reported that clinically important DDI in cardiology patients who have been admitted is 14.66%. Another study in the same setting reported DDI incidence to be 30%.¹³ Higher incidence of DDIs was reported in women and elderly men above 60 years. This was supported by others also.^{5,14,15}

The maximum DDIs were noted with antiplatelet and anticoagulant drugs around 76.13% and 72.72%, respectively. Drug pairs which are responsible for most DDIs were between heparin and aspirin (37.54%), clopidogrel and heparin (12.5%), clopidogrel and torsemide (12.5%), and heparin and warfarin (9.09%). Bleeding was the most common complication.¹⁶ In a separate study by Sharma et al. from Western Nepal a DDI of 21.3% was noted. Of the drugs that caused most of the interactions were clopidogrel, warfarin, atorvastatin, digoxin, furosemide and enalapril. Most interactions were of moderately severe category.

MECHANISM OF DRUG-DRUG INTERACTION

- Pharmacokinetic interaction—How body treats the drugs
- Pharmacodynamic interaction—What the drug does to your body
- Effect of genetic polymorphism—How the pharmacokinetics vary with it.

Pharmacokinetic Interactions

It depends on drug absorption, drug distribution, and drug metabolism.

- *Drug absorption:* Occurs in mucous membrane of gastrointestinal (GI) tract. Most mechanism leads to decreased absorption. However, one must remain more

concerned with rate of absorption. In drugs like oral anticoagulants if the total absorbed dose remains less affected it matters little if the rate of absorption slows down. But in drugs that require instant action the rate of absorption is important. Changes in gastric pH, adsorption and chelation, gastric motility, inhibition of drug transporter proteins, and malabsorption are the important mechanisms associated with drug absorption. Digoxin is metabolized by P-glycoprotein (the most characterized transporter protein). Hence the drugs that induce P-glycoprotein like rifampicin, may decrease the bioavailability of digoxin. Digoxin absorption is also affected by binding agents like cholestyramine. The tricyclic antidepressants increase the absorption of dicoumarol by decreasing gastric motility.

- **Drug distribution:** Drug distribution interactions occur mainly through two principles—
 - Protein-binding interactions and
 - Induction or inhibition of drug transport proteins.

Following absorption there is rapid distribution through circulation which may be in plasma dissolved state or bound to plasma proteins. In protein bound state, the degree of displacement, clearance, and excretion ratio determine the augmentation or decrease in drug effects. The importance of this interaction mechanism has been grossly overemphasized.¹⁰ As many drugs which are displaced in *in vitro* interactions are effectively buffered when the same happens *in vivo*. The distribution of drugs into the organs like brain, testis, etc. is limited by actions of P-glycoprotein like drug transporter proteins. Evidence is accumulating that DDI occurs due to interference with the activity of P-glycoprotein. P-glycoproteins are found in some cell membranes. They are responsible in expelling drugs and metabolites from cells. This has an impact on absorption, distribution, and elimination of drugs. The drugs inhibiting the transporters can therefore modify the actions of drugs according to which process the transporter is involved with the drug. For example, if the transporter acts by expelling some already absorbed drugs then its inhibition will increase the quantum of absorption of drugs leading to increased effects. Similarly, drugs like rifampicin which induces the activity of glycoprotein transporter causes vigorous expulsion of drugs like digoxin reducing the serum levels of digoxin in DDI with rifampicin¹⁷⁻¹⁹

- **Drug metabolism:** Though some drugs are cleared from the body by direct elimination by kidneys, most are metabolized to less lipid soluble entities which are easily eliminated by the kidneys. This chemical change is called “metabolism”, “biotransformation”, “biochemical degradation”, or sometimes “detoxification”. Some drug metabolism occurs in serum, kidneys, and skin; however, the major degradation occurs in liver microsomal enzymes. Drug metabolism entails two major reactions:
 - Phase I reactions (which involves oxidation, reduction, hydrolysis), turn drugs into more polar compounds, while

- Phase II reactions which involve coupling of drugs with some other substances (e.g., glucuronic acid, known as glucuronidation) to make usually inactive compounds.

Most phase 1 oxidation reactions are done by cytochrome P450, a heme-containing enzyme, which comprise of around 30 isoenzymes of which a few specific ISO enzymes of the family is of practical importance being involved in around 90% of the reactions. The most important isoenzymes are: cytochrome P (CYP)1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4. Other enzymes involved in phase I metabolism include monoamine oxidases and epoxide hydrolases. Less is known about the enzymes responsible for phase II conjugation reactions. However, UDP-glucuronyltransferases (UGT), methyltransferases, and N-acetyltransferases (NAT) are examples. Although metabolism is very important in the body removing drugs, it is increasingly recognized that drugs can be adsorbed, distributed, or eliminated by transporters, the most well understood at present being “P-glycoprotein.” So, the drug metabolism acts through changes in first-pass metabolism, enzyme induction, enzyme inhibition, and genetic factors like polymorphism. Changes in first-pass metabolism occur by regulating porto hepatic blood flow and/or induction of first-pass metabolism. Polymorphism explains the difference in metabolism of the same drug in different individuals²⁰⁻²⁵

- **Drug excretion interaction:** Drugs are mostly excreted in bile or urine. In renal circulation, the smaller molecules like salts water and some drugs get filtered through the pore of the glomerular membrane into the lumen of the tubules. The larger molecules like plasma proteins, blood cells are retained. The blood then passes through the remaining parts of the kidney where active energy transport mechanism removes drugs and their metabolites from the blood and secretes them into tubular filtrate (Fig. 1).

The drug interactions occur by means of changes in renal blood flow, changes in urinary pH, changes in tubular secretion, and changes in enterohepatic circulation.^{26,27}

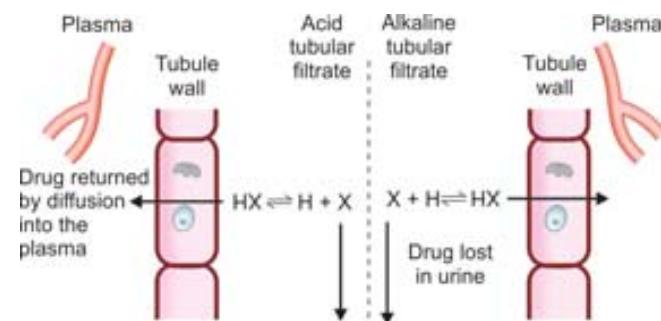

FIG. 1: An excretion interaction. If the tubular filtrate is acidified, most of the molecules of weak acid drugs (HX) exist in a unionized lipid-soluble form and are able to return through the lipid membranes of the tubule cells by simple diffusion. Thus, they are retained. In alkaline urine most of the drug molecules exist in an ionized nonlipid soluble form (X). In this form the molecules are unable to diffuse freely through these membranes and are therefore lost in the urine.

Pharmacodynamic Interactions

When the effects of one drug are changed by the presence of another drug at its site of action, the interaction is called dynamic interaction. Sometimes the drug directly competes for particular receptors (e.g., β_2 agonists). At other times it is indirect involving physiological processes. These interactions are much less easy to classify neatly than those of a pharmacokinetic type. They are basically of these types: synergistic (additive); antagonistic (opposing); drug or neurotransmitter uptake interactions (Tables 1 and 2).

- Synergistic:** When drugs with same effect are given together the result is additive. This can occur with main as well as adverse effects. Sometimes effects are solely toxic like—ototoxicity, nephrotoxicity, QT interval prolongation
- Antagonistic or opposing reactions:** Certain pairs of drugs have activities that are opposed to one another. For example, the coumarins prolong the prothrombin time by

competitively inhibiting the effects of dietary vitamin K. If the intake of vitamin K is increased, the effects of the oral anticoagulant are opposed, and the prothrombin time does not increase to produce therapeutic benefits

- Drug or neurotransmitter uptake reactions:** Presence of other drugs to prevent drugs acting on adrenergic neurons to reach the required sites of action. The tricyclic antidepressants prevent the reuptake of noradrenaline into peripheral adrenergic neurons. Thus, patients taking tricyclics and given parenteral noradrenaline have a markedly increased response (hypertension, tachycardia); similarly, the uptake of guanethidine (and related drugs guanoclor, betanidine, debrisoquine, etc.) is blocked by “chlorpromazine, haloperidol, and thiothixene”, a number of “amphetamine-like drugs”, so that the antihypertensive effect is prevented. The antihypertensive effects of clonidine are also prevented

TABLE 1: Additive, synergistic, or summation reactions

Drugs	Result of interaction
Antipsychotics + antimuscarinics	Increased antimuscarinic effects; heat stroke in hot and humid Conditions, adynamic ileus, toxic psychoses
Antihypertensives + drugs that cause hypotension (e.g., phenothiazines, and sildenafil)	Increased antihypertensive effects; orthostasis
Beta-agonist bronchodilators + potassium-depleting drugs	Hypokalemia
CNS depressants + CNS depressants Alcohol + antihistamines benzodiazepines + anaesthetics, general opioids + benzodiazepines	Impaired psychomotor skills, reduced alertness, drowsiness, stupor, respiratory depression, coma, and death
Drugs that prolong the QT interval + other drugs that prolong the QT interval Amiodarone + disopyramide	Additive prolongation of QT interval, increased risk of torsade de pointes
Methotrexate + co-trimoxazole	Bone marrow megaloblastosis due to folic acid antagonism
Nephrotoxic drugs + nephrotoxic drugs (e.g., aminoglycosides, ciclosporin, cisplatin, and vancomycin)	Increased nephrotoxicity
Neuromuscular blockers + drugs with neuromuscular blocking effects (e.g., aminoglycosides)	Increased neuromuscular blockade; delayed recovery, prolonged apnea
Potassium supplements + potassium-sparing drugs (e.g., ACE inhibitors, angiotensin II receptor antagonists, potassium-sparing diuretics)	Hyperkalemia

ACE, angiotensin-converting enzyme; CNS, central nervous system.

TABLE 2: Antagonistic or opposing interactions

Drug affected	Interacting drugs	Results of interaction
ACE inhibitors or loop diuretics	NSAIDs	Antihypertensive effects opposed
Anticoagulants	Vitamin K	Anticoagulant effects opposed
Antidiabetics	Glucocorticoids	Blood glucose-lowering effects opposed
Antineoplastics	Megestrol	Antineoplastic effects possibly opposed
Levodopa	Antipsychotics (those with dopamine antagonist effects)	Antiparkinsonian effects opposed
Levodopa	Tacrine	Antiparkinsonian effects opposed

ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

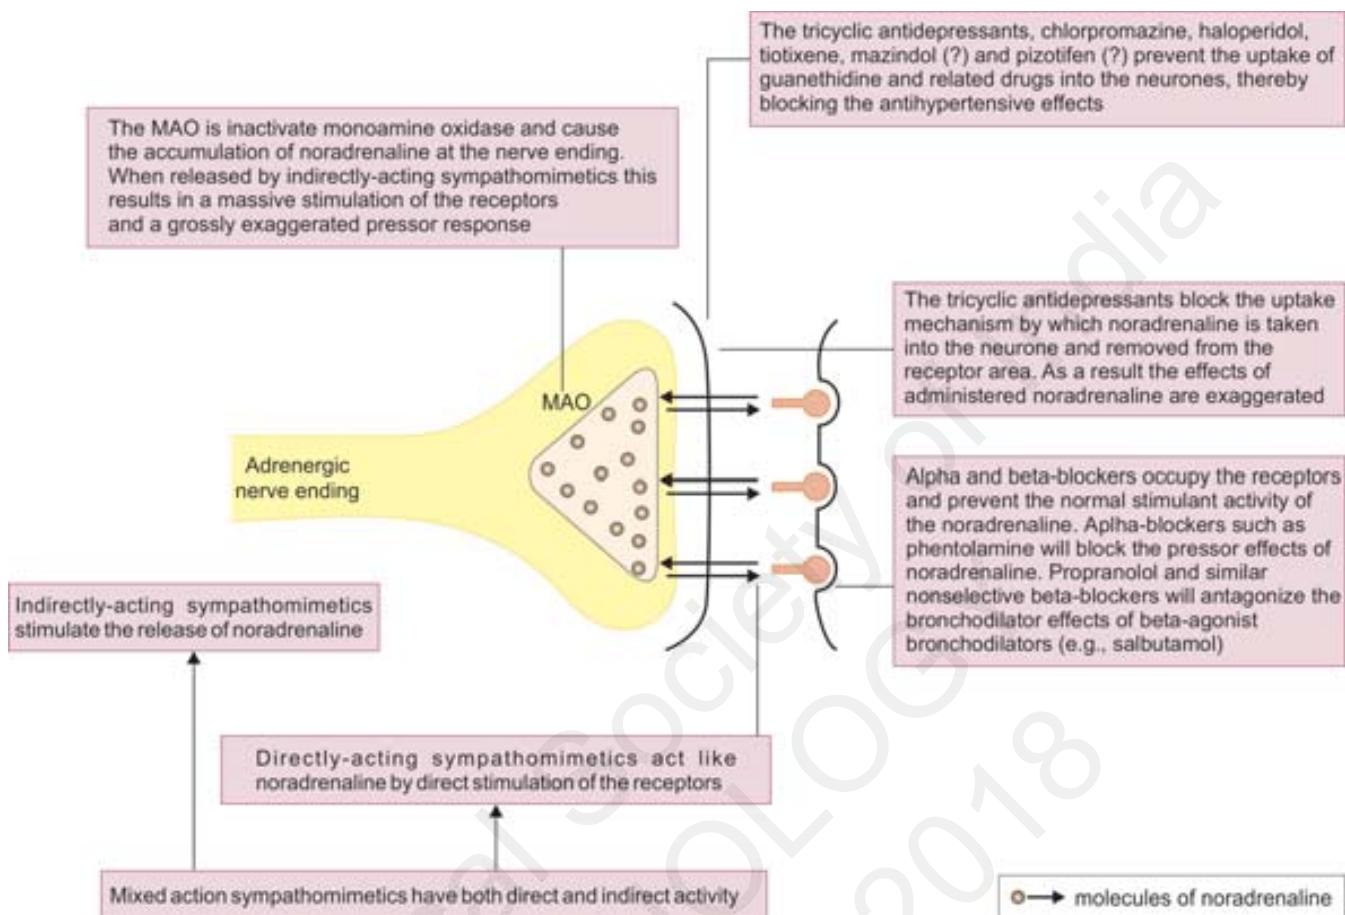

FIG. 2: Interactions at adrenergic neurons.

by the tricyclic antidepressants, one possible reason being that the uptake of clonidine within the central nervous system is blocked. Some of these interactions at adrenergic neurons are illustrated in figure 2.

Some Common Drug–Drug Interactions

Drugs commonly used in cardiology:

- **Antihypertensive:** Angiotensin receptor blockers (ARBs), calcium channel blockers (CCBs), angiotensin-converting enzyme inhibitors (ACEIs), and diuretics
- **Antidyslipidemic:** Statin, nicotinic acid
- **Antiplatelet drug:** Aspirin, glycoprotein IIb/IIIa antagonist
- **Anticoagulants:** Coumadin, heparin
- **Antiarrhythmic:** Amiodarone
- **Antiheart failure:** Beta-blocker, ACEI.

Angiotensin-converting enzyme inhibitor and ARB:

Usually do not have very significant interactions with other drugs. Aluminum hydroxide in antacids causes decreased absorption; however, H₂ blockers do not have synergistic effects of blood pressure reduction with CCBs and β-blockers. With aspirin; however, there is some controversy. Prostaglandin (PG) inhibition effects are not so prominent in patients who are euvolemic and normotensive. However, it affects the action of all antihypertensive drugs including ACEI in patients having hypertension. ACEI plays a vital role in

remodeling of heart and thereby decreases heart failure (HF). The use of aspirin and ACEI together in moderate-to-severe HF patients is detrimental as ACEI actions are suppressed (Hall et al., 2000). But this was countered by Latini et al. (2000). Low-dose aspirin (≤ 100 mg daily) appears to have little effect. It is not clear if aspirin really attenuates the benefits of ACE in HF. The likelihood of an interaction may depend on disease state and its severity. With diuretics some enhancements of first dose hypotension occur. However, chance of hypokalemia is not totally allied with concomitant use of ACEI and diuretics.

Alpha blockers: Selective α₁ blockers in cardiac use are mainly prazosin and doxazosin. With ACEI, β-blockers, and CCBs they have a propensity of accentuated postural hypotension symptoms which need to be explained properly to patients.

Antiarrhythmic: Two arrhythmic of same class are to be cautiously coadministered if obligatory otherwise to be avoided for risk of precipitation of adverse effects. Two class I antiarrhythmic drugs prolong QT to precipitate torsade. Similarly, two antiarrhythmic with effects on either sinoatrial node or atrioventricular (AV) node leads to symptomatic bradycardia or increased AV nodal delay leading to syncope.

The effects of adenosine is unduly accentuated if patient is on dipyridamole leading to cardiac arrest, whereas its

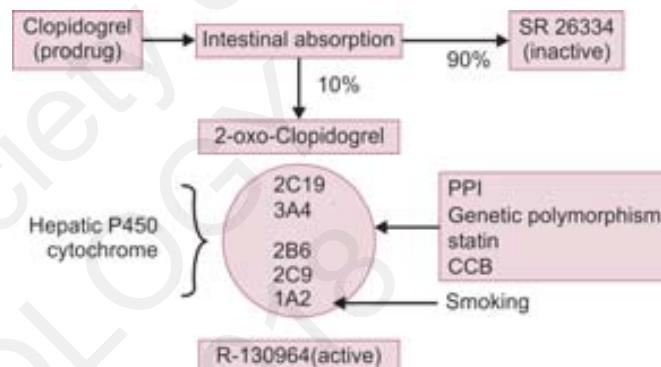

TABLE 3: Drug interactions of amiodarone

Drug	Result of interaction
Digoxin	Elevated digoxin plasma concentration
Warfarin	Elevated prothrombin time
Simvastatin	Increased incidence of myopathy when simvastatin dosage is higher than 20 mg per day
Sildenafil	Increased sildenafil plasma concentration
Cyclosporine	Increased cyclosporine plasma concentration
Antiarrhythmic drugs	Additive effects: possible elevated plasma concentrations of quinidine, disopyramide, flecainide, propafenone, and dofetilide
Quinolones	Additive QT effect: possible increased risk of proarrhythmia
Antidepressants	Increased plasma concentration of drugs metabolized in liver: possible increased risk of proarrhythmia

accentuations are diminished by simultaneous administration of xanthines. So while doing nuclear magnetic imaging studies one must be careful to discontinue xanthines for at least 24 hours prior to the test. Hypotension, bradycardia, ventricular fibrillation, and asystole have been seen in a few patients given amiodarone with propranolol, metoprolol or sotalol due to extreme QT prolongation. However, analysis of clinical trials suggests that the combination can be beneficial. Amiodarone may inhibit the metabolism of β -blockers metabolized by CYP2D6, such as metoprolol, which might be a factor in the interaction (Table 3). Verapamil and β -blockers often cause additive inhibitory action which however is helpful in controlling symptomatic atrial fibrillation with fast ventricular rate and left ventricular dysfunction.

Beta-blockers (especially propranolol and metoprolol) are generally metabolized by first-pass metabolism in liver. So drugs increasing this, like cimetidine and hydralazine, decrease effects of β -blockers.

Anticoagulants: The effects of acenocoumarol and warfarin are enhanced by amiodarone resulting in bleeding. It has been noted that although the maximal effects of interaction occur between 2 and 7 weeks, the effect may last long after withdrawal. Altered (usually enhanced) coumarin response has been reported with virtually every class of antibacterial. While some such as sulfamethoxazole, clearly have a pharmacokinetic interaction, for others there is no clear explanation for which an interaction might be expected. Theoretical mechanisms include reduction in production of vitamin K2 substances by intestinal bacteria or reduced enterohepatic recycling. Possible confounding mechanisms include a reduction in dietary vitamin K1 intake because of illness, or the effect of fever or infection on coagulation or drug metabolism. Cephalosporins and related β -lactams that have caused increases in prothrombin times when used alone, and might therefore be predicted to interact, include aztreonam, cefalotin, cefoperazone, ceftriaxone, and latamoxef. Other cephalosporins with a related side-chain include cefmenoxime, cefmetazole, cefminox, ceforanide, cefotetan, and cefpiramide. The macrolides, linezolid, chloramphenicol on the other hand have little interactions with coumarins. Penicillins and metronidazole report anecdotal cases whereas unpredictable response of increase

CCB, calcium channel blockers; PPI, proton pump inhibitors.

FIG. 3: Different clopidogrel interactions.

international normalized ratio (INR) may be observed with Quinolones. Rifamycins on the other hand reduce the effects of coumarins and the dose of coumarins may be required to increase 2–5-fold to maintain the INR. Most antidiabetic drugs do not have significant interactions except that older generation sulfonylurea actions are potentiated by coumarins causing hypoglycemia although the same has been rarely reported with newer generation sulfonylureas. Low-dose aspirin (75–325 mg daily) increases the risk of bleeding when given with warfarin by about 1.5–2.5-fold, although, in most studies the absolute risks have been small. The overall benefits of concurrent use outweigh the risks in certain patient groups; however, for some warfarin indications, there is not enough data to assess this. In addition to increased bleeding, high doses of aspirin (4 g daily or more) can increase prothrombin times. Therefore, aspirin is not considered a suitable analgesic or anti-inflammatory drug for those taking oral anticoagulants. However, clopidogrel, ticlopidine, and cilostazol do not have significant interactions with coumarins (Fig. 3). With antifungals, fluconazole and miconazole significantly potentiate actions of coumarins however with itraconazole and voriconazole the incidents are few. Griseofulvin decreases the effects of coumarins. Fibrates enhance the action of coumarins leading to bleeding complications whereas ezetimibe is neutral in interaction. Heparin may prolong the prothrombin time; therefore

a sufficient time interval should be allowed after the last heparin dose in a patient taking a coumarin to obtain a valid prothrombin time. Combined use of nonsteroidal anti-inflammatory drugs (NSAIDs) and coumarin anticoagulants increases the risk of GI hemorrhage. Care is needed with the combination. Some individual NSAIDs also alter the pharmacokinetics of warfarin like benzydamine and coxibs. Studies have suggested that fluvastatin and rosuvastatin can increase warfarin levels and/or effects. Other studies with atorvastatin, lovastatin, pravastatin, and simvastatin suggest that they do not usually significantly alter the effects of warfarin, although cases of bleeding have been seen when these statins were given with coumarins and fluindione. Neither aspirin nor piroxicam altered the pharmacokinetics of fondaparinux, and there was no significant change in bleeding time during concurrent use. In a pharmacodynamic study, the dose of heparin did not need changing when clopidogrel was also given, and the antiplatelet effects of clopidogrel were unaltered. Nevertheless, concurrent use of heparin or low-molecular weight heparins (LMWH) and antiplatelet drugs like clopidogrel and ticlopidine has the potential to increase bleeding risk and increased monitoring would be prudent. The combined use of aspirin with heparin or LMWH slightly increases the risk of hemorrhage. Combined use may be a contributing factor to the very rare complication of epidural or spinal hematoma. The bleeding time was prolonged by the concurrent use of dalteparin and ketorolac in healthy subjects, but not using heparin and ketorolac. Parecoxib did not alter the effect of heparin on activated partial thromboplastin time (aPTT). In a small clinical study, intramuscular ketorolac and subcutaneous enoxaparin appeared not to increase measures of postoperative bleeding when compared with opioids. Cases of spinal hematomas have been reported with concurrent use of heparin or LMWH and NSAIDs. Note that ketorolac may possibly cause serious GI bleeding and in the UK it is considered to be contraindicated in patients taking anticoagulants.

Aspirin: When aspirin and NSAIDs are given together, the effect of aspirin decreases, so, one should use analgesic with caution in HF patients.

Aspirin and ACEI are often coprescribed. Aspirin acts by inhibiting the production of thromboxane A2 (TXA2) and thus prevent the PG activity. The problem is aspirin acts by inhibiting PG production while ACEI needs PGs for its optimal action.

Effect of inhibition of PG is not so pronounced in normotensive and euvolemic subjects. In hypertensive subjects, inhibition of PG hampers the effect of nearly every antihypertensive drug including ACEI. As ACEI is immensely effective in controlling remodeling of heart and thus reduce the HF, concurrent use of aspirin and ACEI in moderate-to-high degree of HF patient will reduce the effect of ACEI (Hall et al., 2000), though it was countered by Latini et al. (2000).

Studies like SOLVD (Studies of Left Ventricular Dysfunction) and CONSENSUS II (the Cooperative New Scandinavian Enalapril Survival Study II) suggested that ACEI response was

Lovastatin	51	40	<ul style="list-style-type: none"> • Cyclosporine (12) • Macrolide antibiotics (2) • Azole antifungals (6) • Fibrates (5) <ul style="list-style-type: none"> • Digoxin (2) • Nefazodone (2) • Niacin (1) • Warfarin (1)

attenuated when used simultaneously with aspirin. So low-dose aspirin or short-term aspirin, other antiplatelet agents like clopidogrel, etc. were suggested by Peterson and Laurer (2011) as methods to prevent this conflict.

Statins: Commonly exert their lipid lowering action by decreasing the functions of HMG-CoA (3-hydroxy-3-methyl-glutaryl-coenzyme A) reductase enzyme which modulates a principal rate-limiting step in cholesterol biosynthesis.

How statin problems supposedly occur:

- Statins are transported to liver via the enzyme organic anion-transporter polypeptide 1 B1 (OATP1B1) which is encoded by the gene *SLCO1B1* (solute carrier organic anion transporter family, member 1B1). Now even if there is a single nucleotide polymorphism in the encoding gene stain transport to liver is hampered leading to increased statins in blood causing rhabdomyolysis
- The CYP isoenzymes in liver metabolize most of the statins like simvastatin, atorvastatin, mevastatin and lovastatin. The statins like fluvastatin and rosuvastatin are metabolized by CYP2C19 and CYP2C9. Pravastatin is the only statin metabolized through non-CYP pathway. When CYP3A4 inhibitor is used simultaneously with simvastatin rhabdomyolysis occurs (Rowan et al., 2010) (Tables 4 and 5). Although, in case of other statins using the same pathway there is no data however the same caution should be maintained for atorvastatin, lovastatin, and mevastatin.

Measures to be taken:

- To rule out statin toxicity, genetic testing is usually not required
- If one has to us CYP3A4 inhibitor statin therapy should stop. If statins are required to be used then rosuvastatin or pravastatin should be used.

Clopidogrel: Only 10% of total infused clopidogrel is absorbed in system and then they are metabolized into active form by several P450 group of enzymes, e.g., CYP2C19, CYP1A2, CYP2B6, and CYP3A4. Worsening of pharmacokinetic response of clopidogrel is a common problem. The various postulations to predict:

- Poor metabolism of clopidogrel may be due to polymorphism in CYP219 enzyme. This is accepted in epidemiological studies. A single nucleotide polymorphisms (SNP) CYP2C19*2 (or 681 G>A) can cause an increased risk of major adverse cardiovascular events (MACE) in the follow up [relative risk (RR): 1.96 (1.14–3.37); p = 0.02]. In the studies where stent thrombosis was evaluated (n = 4, total patients = 4,975), there was increased risk where the variant allele was present. [RR: 3.82 (2.23–6.54); p = 0.0001] (Sofi et al., 2011)
- Clopidogrel uses CYP3A4 enzyme for its metabolism. Stains and CCBs compete with clopidogrel for metabolism by the same enzyme. Hence, they reduce the activity of both statins and CCBs (Clarke et al., 2003; Jolanta et al., 2008). However, epidemiological studies by Mukherjee et al. in 2005; Saw et al. in 2007; and Schmidt et al. in 2011 show that there is no competitive interaction between clopidogrel and statin
- There was a remarkable interaction with smoking. Smoking increases the activity of CYP1A2 and hence

increases the metabolism of clopidogrel. Since clopidogrel is a prodrug, the increased metabolism increases the utility of clopidogrel. Although some epidemiological studies by Jae Kean Ryu, 2010 and Berger et al., 2009, agree to this hypothesis but there are other studies like Sibbald et al. in 2010 which contradict it

- The interaction of proton pump inhibitors (PPI) and clopidogrel is a bit elaborate. PPI gets metabolized through CYP3A4 whereas clopidogrel uses CYP2C19. So as such they do not interact with each other. However, when they are taken with grapefruit juice, the juice uses CYP3A4 for its metabolism and displaces PPI to be metabolized by CYP2C19. This diminishes the clopidogrel response. Similarly, when St John's Wort is taken it induces both the enzymes—CYP3A4 and CYP2C19 and so when PPI's, clopidogrel and St John's Wort are taken together significant drug interactions occur.
- Measures to be taken:
- Due to significant interactions on concomitant usage, grapefruit juice and St John's wort should not be taken along with clopidogrel and PPI
 - Similarly as there is no definite data to support statin and clopidogrel interaction; they can be coadministered. However, in high-risk patients one may avoid this. In that case a non-CYP statin like pravastatin or a different antiplatelet like prasugrel may be used instead
 - When CCBs and clopidogrel are simultaneously administered their response should be closely monitored and in case there is a possible interaction ongoing, any alternative molecule may be used.

Drug Food Interactions

Interaction between cardiac drugs and food occur mainly with grapefruit juice, monoamine oxidase inhibitors, antihypertensive and warfarin/acetrom, i.e., coumarin derivatives (Table 6).

TABLE 6: Food-drug interaction

Drug	Food	Interactions
Warfarin	High protein diet	Decrease INR raising serum albumin
	Green leafy vegetables	Decrease INR
	Vegetables containing vitamin K	Decrease INR
	Charbroiled	Decrease INR
	Cooked onions	Increase INR
	Cranberry juice	Increase INR without bleeding in elderly
Propranolol	Rich protein food	Increase serum levels
Celiprolol	Orange juice	Intestinal absorption inhibited
ACEIs	Empty stomach	Increase absorption
CCBs	Grapefruit juice	Increase bioavailability

ACEIs, angiotensin-converting enzyme inhibitors; CCB, calcium channel blockers; INR, international normalized ratio.

Unsuspected Drug Toxicity in Cardiology Practice

Ashish Tiwari, Sharad Chandra

INTRODUCTION

Cardiotoxicity is the occurrence of damage of myocardium cell leading to cardiac dysfunction. The heart becomes weaker and less efficient in pumping and therefore circulating blood to different part of body. Cardiotoxicity may be caused by chemotherapy and other drug treatment, complications from anorexia nervosa, adverse effects of heavy metals intake, or an incorrectly administered drug such as bupivacaine. Cardiotoxicity, if severe, leads to cardiomyopathy which is a serious disease in which the heart muscle becomes inflamed and lead to dysfunction of same.

CARDIOTOXICITY OF CYTOTOXIC DRUGS

Cardiotoxicity is a side effect of several cytotoxic drugs, mainly of the anthracyclines, can lead to long-term morbidity. The mechanism of toxicity in case of anthracyclines seems to involve the formation of free radicals leading to oxidative stress. This may cause apoptosis of cardiac cells or immunologic reactions. Cardiac protection can be achieved by limitation of the cumulative dose. Cytotoxic drugs causing cardiotoxicity includes anthracyclines, trastuzumab and HER2 agents, cyclophosphamide, bleomycin, vinca alkaloids, 5-fluorouracil, interferons, interleukins, paclitaxel, bortezomib and other cytotoxic drugs are associated with cardiotoxicity as well although little is known about the possible mechanisms.

Among all cytotoxic drugs, anthracyclines has a prominent role in treating many malignancies. All anthracyclines are cardiotoxic though their relative cardiotoxicity varies with different drugs (Doxorubicin > epirubicin > idarubicin > liposomal doxorubicin in that order).

There are three mechanisms which are involved in the cytotoxic action of anthracyclines—(1) high affinity binding to DNA (via nucleic intercalation causing inhibition of DNA and RNA synthesis and cleavage of DNA strands by alterations of topoisomerase II); (2) binding to the cell membrane which alters its normal fluidity and transport of ions semiquinonic;

and (3) oxygen free radical production (via reduction of enzymatic reaction).

Incidence of anthracycline cardiotoxicity ranges from 5 to 65% of treated cases, in relation to the total dose of drugs administered and over the duration of follow-up. Pathophysiological mechanism of drug toxicity includes formation of oxygen free radicals, calcium overload in myocytes, deficiency of antioxidant systems as catalase and superoxide dismutase and possible immunological reaction induced by the drug.¹

Clinical feature of anthracycline cardiotoxicity manifests as congestive heart failure (CHF) which includes pulmonary edema, fluid overload and dyspnea on exertion. Patient can be minimally symptomatic in form of tachypnea to severely symptomatic like in pulmonary edema.

Apart from cardiomyopathy, other cardiovascular (CV) complications of cancer therapy include systemic hypertension, pulmonary hypertension, pericardial disease, thromboembolism, QT prolongation and dysrhythmias. In fact, hypertension is commonest CV comorbidity seen in cancer registry. Anticancer drugs causing hypertension are mainly vascular endothelial growth factor (VEGF) inhibitors (bevacizumab, sorafenib and sunitinib) and proteasome inhibitors (carfilzomib). Dasatinib, which is used for chronic myeloid leukemia, causes pulmonary hypertension in estimated 0.45% of cases. Drugs associated with pericardial disease include cyclophosphamide, anthracyclines, cytarabine, imatinib, dasatinib, interferon- α , docetaxel and 5-fluorouracil. Chemotherapy causing thromboembolism includes thalidomide and lenalidomide, cisplatin, bevacizumab and everolimus (Tables 1 and 2).

Types of Cardiotoxicity

Acute or Subacute Cardiotoxicity

Alteration of ventricular repolarization phase, duration of QT, arrhythmias, acute heart failure (HF), myocarditis-pericarditis like syndrome.

TABLE 1: Anticancer agents associated with hypertension

Chemotherapy agents	Frequency	Incidence (%)	Comments of Use
Monoclonal antibody-based tyrosine kinase inhibitors			Pretreatment risk assessment
Bevacizumab	+++	4–35	
Ado-trastuzumab emtansine	+	5.1	BP goal <140/90 mm Hg
Monoclonal antibodies			
Alemtuzumab	+	14	Weekly BP monitoring in 1 st cycle
Ibritumomab	NA	7	Every 2–3 weeks BP monitoring for duration of therapy
Ofatumumab	+	5–8	
Rituximab	+++	6–12	
mTOR inhibitors			
Everolimus	++++	4–13	Initiate BP treatment when diastolic BP increases by 20 mm Hg
Temsirolimus	++	7	
Small molecule tyrosine kinase inhibitors			
Pazopanib	++++	42	More than 1 anti-HTN medication may be needed
Ponatinib	+	68	
Sorafenib	++++	7–43	Avoid diltiazem and verapamil with sorafenib
Sunitinib	++++	5–24	
Axitinib	++++	4	
Cabozantinib	NA	33–61	Hold chemotherapy as the last resort
Ibrutinib	++++	17	
Nilotinib	++++	10–11	Hold bevacizumab if systolic BP >160 mm Hg or diastolic
Ramucirumab	+	16	
Regorafenib	++++	30–59	BP >100 mm Hg
Trametinib	++++	15	
Vandetanib	NA	33	Early consultation with cardiologist
Ziv-aflibercept	+	41	
Proteasome inhibitors			
Bortezomib	++	6	
Carfilzomib	++	11–17	
Antimetabolites			
Decitabine	++	6	

Frequency of use was determined using inpatient and outpatient doses dispensed at MD Anderson Cancer Center during the time period of January 1, 2014 through December 21, 2014.

Key: + = <1,000 doses dispensed; ++ = 1,000–5,000 doses dispensed; +++ = 5,000–10,000 doses dispensed

BP, blood pressure; HTN, hypertension; mTOR, mammalian target of rapamycin.

Chronic Cardiotoxicity

Asymptomatic left ventricular dysfunction (LVD), systolic and/or diastolic dysfunction, severe form of dilated cardiomyopathy, cardiac death.

Symptoms of Cardiac Toxicity

Symptoms of cardiotoxicity includes feature of HF like shortness of breath on exertion, worsening to shortness of breath at rest, discomfort lying on your back, swelling of the ankles and fatigue. As the disease progresses, condition

deteriorates and can lead to pulmonary edema and shock. Cardiomyopathy has a high mortality and morbidity.

Prevention of Cardiac Toxicity

Heart problems may be prevented by altering the amount of drug administered (dose), method of administration and type of anthracycline. Also, some medications that can prevent damage from doxorubicin have been developed. Cardiac toxicity can often be prevented by giving less of the cancer drug or the schedule of the drug can be changed

TABLE 2: Anticancer agents associated with QT prolongation

Chemotherapy agents	Frequency	Incidence (%)	Comments of use
Histone deacetylase inhibitors	+	4–11	Tangent method of QT measurement
Belinostat	++++	3.5–6.0	–
Vorinostat	–	–	Fridericia correction formula
Chemicals Arsenic trioxide	++	26–93	–
Small molecule tyrosine kinase	Inhibitors	–	–
Dabrafenib	++++	2–13	Correct low K or Mg
Dasatinib	++++	<1–3	–
Lapatinib	++++	10–16	Remove QTc prolonging medications
Nilotinib	++++	<1–10	QTc >500 ms or >60 ms above baseline associated with TdP
Vandetanib	++++	8–14	–
BRAF inhibitor	–	–	–
Vemurafenib	++++	3	TdP reported for arsenic trioxide, sunitinib, pazopanib, vandetanib, and vemurafenib

See table 1 for frequency of use description.

K, potassium; Mg, magnesium; QTc, corrected QT interval; TdP, torsades de pointes.

so that you get lower doses more often (rather than larger doses less often). There are also forms of drugs that may be less toxic, for example, liposomal anthracyclines might have less cardiac toxicity than regular anthracyclines. Various agents and strategies have been tried over the years for cardioprotection which includes antioxidants, free radical scavenger, cardioselective β-blocker, statins, and modified anthracycline preparation (liposomal doxorubicin). Some of these are effective like modified anthracycline preparation, dexrazoxane, enalapril, candesartan, and β-blocker, while others like N-acetylcysteine and calcium antagonist did not show any improvement in trials.

Unsuspected Drugs Causing Cardiotoxicity (Other than Cytotoxic Drugs)

Analgesics

Nonsteroidal anti-inflammatory drugs (NSAIDs) are among the most commonly prescribed over-the-counter (OTC) medicine prescribed all over world. Traditional NSAIDs have the potential to trigger HF through sodium and water retention, increased systemic vascular resistance and blunted response to diuretics. Observational studies suggest an association between traditional NSAIDs use and HF precipitation and exacerbation. In an evaluation of 7,277 long-term NSAID users over 72 months, the Rotterdam study results found a trend to an increased risk of HF.^{2–5}

Anesthetic Medications

Inhalational or volatile anesthetics (desflurane, enflurane, halothane, isoflurane, and sevoflurane) can cause myocardial depression, peripheral vasodilation, and attenuated sympathetic activity with immediate effect. Intravenous anesthetics like ketamine and propofol are associated with negative

inotrope effect, while Dexmedetomidine is associated with alpha-2 adrenergic agonist action.⁶

Diabetes Mellitus Medication

As diabetes mellitus remains a major problem in most of the world and commonly associated with coronary artery disease (CAD) patients, side effects of these medications sometimes lead to adverse cardiac effects. Thiazolidinediones are associated with possible calcium channel blocker (CCB), metformin is associated with elevated lactic acid level and increased anaerobic metabolism. Recently dipeptidyl peptidase-4 inhibitors are also associated with HF.⁶

Cardiac Effects of Glitazones

Nissen et al. published meta-analysis in 2007 suggested 64% increase in death from CV cause and 43% increase in myocardial infarction (MI) after use of rosiglitazone. This meta-analysis has led to box warning and restricted access to rosiglitazone in the United States.⁷ However, later on further meta RECORD (Rosiglitazone Evaluated for Cardiovascular Outcomes and Regulation of Glycemia in Diabetes) trial and later on Food and Drug Administration stated that was not associated with excess CV risk. Recent data suggests that glitazones are relatively safe.⁸

Antiarrhythmic Medication

Antiarrhythmic medication can itself have cardiotoxic effects. Class I antiarrhythmics have negative inotropic and proarrhythmic effects. Sotalol, which is a class III agent, has proarrhythmic property and β-blocker property.⁶

Antihypertensive Medications

Among antihypertensive drugs, calcium channel blockers have negative inotropic effect while α₁ blockers can stimulate β₁ receptors with increase in renin and aldosterone.⁶

TABLE 3: Drugs causing prolong QT

Antipsychotics	Antiarrhythmics	Tricyclic antidepressants	Other antidepressants	Antihistamines	Others
Chlorpromazine	Quinidine	Amitriptyline	Mianserin	Diphenhydramine	Quinine
Haloperidol	Procainamide	Doxepin	Citalopram	Astemizole	Chloroquine
Droperidol	Disopyramide	Imipramine	Escitalopram	Loratadine	Hydroxychloroquine
Quetiapine	Flecainide	Nortriptyline	Venlafaxine	Terfenadine	Erythromycin
Olanzapine	Encainide	Desipramine	Bupropion	–	Ranolazine
Amisulpride	Sotalol	–	Moclobemide	–	–
Thioridazine	Amiodarone	–	–	–	–

Antifungal Medicines

Itraconazole, a commonly used antifungal medicine has negative inotropic action and should be cautiously used in patient with LVD. Amphotericin B can cause LVD on prolonged use but function generally improves after discontinuation of drugs.⁶

Hematological Medication

Anagrelide can cause inhibition of phosphodiesterase-4 while cilostazol causes inhibition of phosphodiesterase-3 resulting in arrhythmias. Cilostazol is contraindicated in HF patient.

Neurological and Antipsychiatry Medication

Among the antiepileptics, carbamazepine has negative inotropic and chronotropic action. It also depresses phase 2 repolarization and suppresses sinus node automaticity and atrioventricular conduction. Pregabalin causes L-type CCB which leads to negative inotropic action.

In antidepressant group of medication, citalopram causes dose-dependent QT prolongation, while tricyclic antidepressants have negative inotropic and proarrhythmic properties. Antimigraine medicines like ergotamine and methysergide causes valvular damage due to excessive serotonin activity. Lithium which is commonly used in bipolar disorders can cause direct myofibril degeneration and adrenergic stimulation.⁶

Urological Agents

Urological agents like tamsulosin, doxazosin, and prazosin causes beta-1 receptor stimulation with increase in renin and aldosterone.

Cardiac Effects of Antiretroviral Drugs

Premature atherosclerosis is a known complication of highly active antiretroviral therapy (HAART) mainly related to use of protease inhibitor component. HAART therapy can lead to dyslipidemia, insulin resistance and risk of diabetes, Lipodystrophy and increased risk of MI. Among all deaths in HIV patients, CV death attributes to more than 10% and this further increases if exposure to HAART prolongs. Large studies showed that protease inhibitors are associated with increased risk of MI while nucleoside reverse transcriptase inhibitors (NRTI) and non-nucleoside reverse transcriptase

inhibitor (NNRTI) are not. Despite all these effects of HAART, CV events can be controlled up to certain extent by tight control of metabolic derangement. So comprehensive evaluation of the absolute coronary risk of HIV patients before starting antiretroviral therapy is strongly advisable.⁹

Drugs Causing Prolong QT

These are listed in table 3.

CONCLUSION

Cardiotoxicity is a well-known side effect of many drugs including cytotoxic drugs. Apart from cytotoxic drugs where cardiotoxicity is common, drugs like analgesic, anesthetics, antiarrhythmics, antifungal medicines, hematological and neurological medicines can also cause cardiotoxicity. Cardiotoxicity presentation may vary from entirely asymptomatic patient to severely symptomatic HF. Hence, all cardiotoxic drugs should be judiciously used for the indicated purpose.

SECTION 13

Heart Failure

Heart Failure in India

Sandeep Seth, Karishma Landge

HEART FAILURE IN INDIA IS REACHING EPIDEMIC PROPORTIONS

Heart failure (HF) affects 26 million people worldwide and the burden of HF in India is about 1% of the population which comes to about 5–10 million patients. The rural community could have a lower burden and an actual survey found the HF prevalence about 1.2 per 1,000 adult population. The mortality is also high with almost one-third patients getting readmitted or dying soon after an acute HF event. Indian patients are younger, sicker and get less medication as compared to what is recommended by the guidelines.^{1–12}

CAUSES

Estimates suggest that the causes of HF contributing to this large number include rheumatic heart disease (13–52%), ischemic heart disease (27–55%), hypertension (6–23%), dilated cardiomyopathy (10%) and congenital heart disease (6%).^{13–15} A study from a rural community which screened for symptomatic HF,¹⁴ shortness of breath with or without pedal edema, found a prevalence of 1.2 per 1,000 population after screening an adult population of about 10,000 villagers and the causes were uncontrolled hypertension or ischemic heart disease.¹⁴ Hospital registries show a higher number of rheumatic heart disease. About 20% of the patients coming to cardiology outpatient departments (OPDs) have HF and the causes are more equally distributed between rheumatic heart disease and ischemic heart disease.^{13–23}

SEVERITY OF DISEASE

The mortality is 20–30% over 6 months^{24–26} (after an episode of acute decompensation) and use of guideline-based medical therapy is only 25–50%.^{16,25}

In the Trivandrum Heart Failure Registry,^{15,16} one of three HF patients died within 1 year of follow-up. They had taken patients of two groups, one with ejection fraction (EF) less than

45% and the other with EF more than 45% with most common etiology being ischemic heart disease, hypertension, chronic kidney disease (CKD), diabetes mellitus (DM), and stroke. Among 1,103 participants, 269 patients were readmitted once, 64 of them were readmitted more than once, and 75 of them underwent invasive procedure. One out of every three HF patients died and the cause of death was determined by verbal autopsy, i.e., patient who died prior to reach hospital and the patients who died within 24 hours of hospital admission were considered to be sudden cardiac death. And the participants who died in hospital after 24 hours of admission with required inotropic support were considered to have died with cardiogenic shock. The increased mortality in India is due to lack of optimal guideline-based medical treatment and increased hospital readmissions. According to the data 30% HF with reduced EF (HFrEF) patients received appropriate medication i.e., angiotensin-converting enzyme inhibitor or angiotensin receptor blocker (ACEI/ARB) and beta-blockers. (These medications are underused in India despite having scientific evidence which shows reduction in hospitalization and mortality in HF patients, due to lack of postdischarge transitional care and also due to lack of electronic medical records, nonexistent outpatient record keeping, and also difficulty in engaging physicians due to a hectic schedule.

The International Congestive Heart Failure (INTER-CHF)²⁶ study enrolled patients from rural parts of India, with history of hypertension 29%, DM 8%, CKD and 50% participants of left ventricular ejection fraction (LVEF) less than 40% and the cause of HF was ischemia 39%, hypertension 17%, idiopathic dilated cardiomyopathy 12% and primary valve disease 11% out of which 66% patients were from outpatient and 34% were inpatient. Of the 858 deaths within 1 year, the cardiac deaths were 46%, noncardiac deaths were 16% and unknown causes 38%. The all-cause mortality within 1 year was 16.5% with a mean age of 59 years. The study done in 16 different countries with total number of patients

being 5,823 and overall mortality was Africa 34%, India 23%, Southeast Asia 15%, Middle East 9%, and China 7%. The highest mortality was seen in Africa and India.

In the Acute Failure Registry (AFAR) study from All India Institute of Medical Sciences (AIIMS),²⁵ almost one-third of the patients died during the hospital admission and after discharge, over the next 3–6 months, another one-third either died or got readmitted. From this, we developed the Rule of Three, i.e., in acute HF, one-third die in hospital, at discharge one-third will have an event within 3 months. This study reports a higher in-hospital and follow-up mortality rates in acute decompensated heart failure (ADHF) patients of a younger age when compared to the western world. Total number of patients enrolled were 90 with left ventricular (LV) systolic dysfunction and leading cause being ischemic cardiomyopathy (53.9%), idiopathic cardiomyopathy (18.5%), and rheumatic heart disease (10.8%). Hospital care was given according the HF guideline-based treatment. During the 6 months period of study 1-month mortality rate was 15.8%, 3-month mortality was 26.3%, and 6-month mortality was 26.3%. At the end of 6-month 42 patients survived and 6-month rehospitalization ratio in patients were 39.5%. The overall in-hospital mortality was 30.8%.

Therefore, the target for interventions in acute HF has to be from the time of intervention to the first 3 months of discharge.

Some of the interventions that we suggest for reducing the high mortality of acute HF in India are as follows:

- At admission appropriate use of high-dose diuretics and avoidance of excess inotropes to manage acute HF. Taking care of precipitating factors like anemia and infections, correcting causes like ischemia
- Appropriate addition of vasodilators like ACEI or ARB or hydralazine-nitrate combinations and titration
- Addition of beta-blockers or ivabradine for rate control
- Adequate decongestant before discharge and addition of spironolactone or eplerenone
- Adequate discharge planning and OPD visit planning on day 3 or 7 depending on patient condition at discharge
- Creating HF clinics or disease management programs to manage such patients.

TACKLING THE PROBLEM IN INDIA

Heart failure is a problem which needs to be tackled at multiple levels starting from primary prevention, to controlling the risk factors like diabetes, hypertension, and all the risk factors for coronary artery disease. We need to focus strongly on ensuring prescription of guideline-based medication comprising of ACEI, beta-blockers and mineralocorticoid receptor inhibitors to all patients. Patients with indications for anticoagulation (atrial fibrillation) and resynchronization therapy [left bundle branch block (LBBB)] should be appropriately advised. End-stage HF patients should be advised and guided to centers doing LV assist device implants and heart transplants. Creating a cadre of HF nurses, HF management programs and HF clinics will help organize some of these efforts.²⁷⁻³³

Some of the efforts made in this direction by various centers in India include the use of checklists, smartphone apps developed in India and doing small workshops focusing on training doctors on the better use of guideline-based therapy for HF. More efforts are needed for this.

At AIIMS, we are regularly using all these to help the HF patients. There is a HF clinic. The heart transplant program started on 3rd August 1994 and Prof P Venugopal and his team did the first successful heart transplant in India on that day. Till date we have done 66 heart transplants. In India about 500 heart transplants have been done in the past 25 years. We also started the LV assist device program in India starting initially with the HeartMate first-generation devices which were implanted and then patients switched to a transplant and now the third-generation devices which can be used to bridge to a transplant or as destination therapy. We are currently using the HeartWare device.

India-specific guidelines are available and were published in 2015 and recently updated and are summarized here:²⁷⁻³³

- All patients of HF should be advised diet modification with salt and water restriction
- All patients should be taught how to monitor their weight and how to respond to water accumulation by increasing their diuretics and restricting water
- All patients should receive influenza and pneumococcal vaccine
- Simple innovative techniques like checklists have been developed like the Dhadkan app available on Google Play Store and Hriday card checklist which are being used at AIIMS and are available on request (Fig. 1)
- Heart failure clinics and management programs are being set-up all over India and the initial data coming in is already showing promise
- Vasodilators should be given to all. ACEI are preferred. ARBs are the alternative. If neither can be given then a combination of hydralazine-nitrate should be used. If the patients are still symptomatic on ACEI then the patients should be started on angiotensin receptor neprilysin inhibitor (ARNI). These are started after stopped ACE or ARB and at low doses which is especially important for Indian patients. The usual starting dose has been 50 mg twice daily, though in patients with borderline blood pressure it has been found that start with lower doses like half a tablet (half of 50 mg), i.e., 25 once a day and then gradually building up the dose is more tolerated (JPCS HF guidelines 2017)
- Beta-blockers should be given to all and uptitrated. These are not uptitrated in Indian patients. Ivabradine should be used if adequate heart rate control is not achieved
- Diuretics should be used in adequate doses to reduce shortness of breath and eliminate pedal edema. Torsemide and metolazone is sometimes more useful here since better diuresis and higher doses are achievable. Torsemide has better absorption and higher doses up to 100 mg are available. Spironolactone or eplerenone should be added to all patients

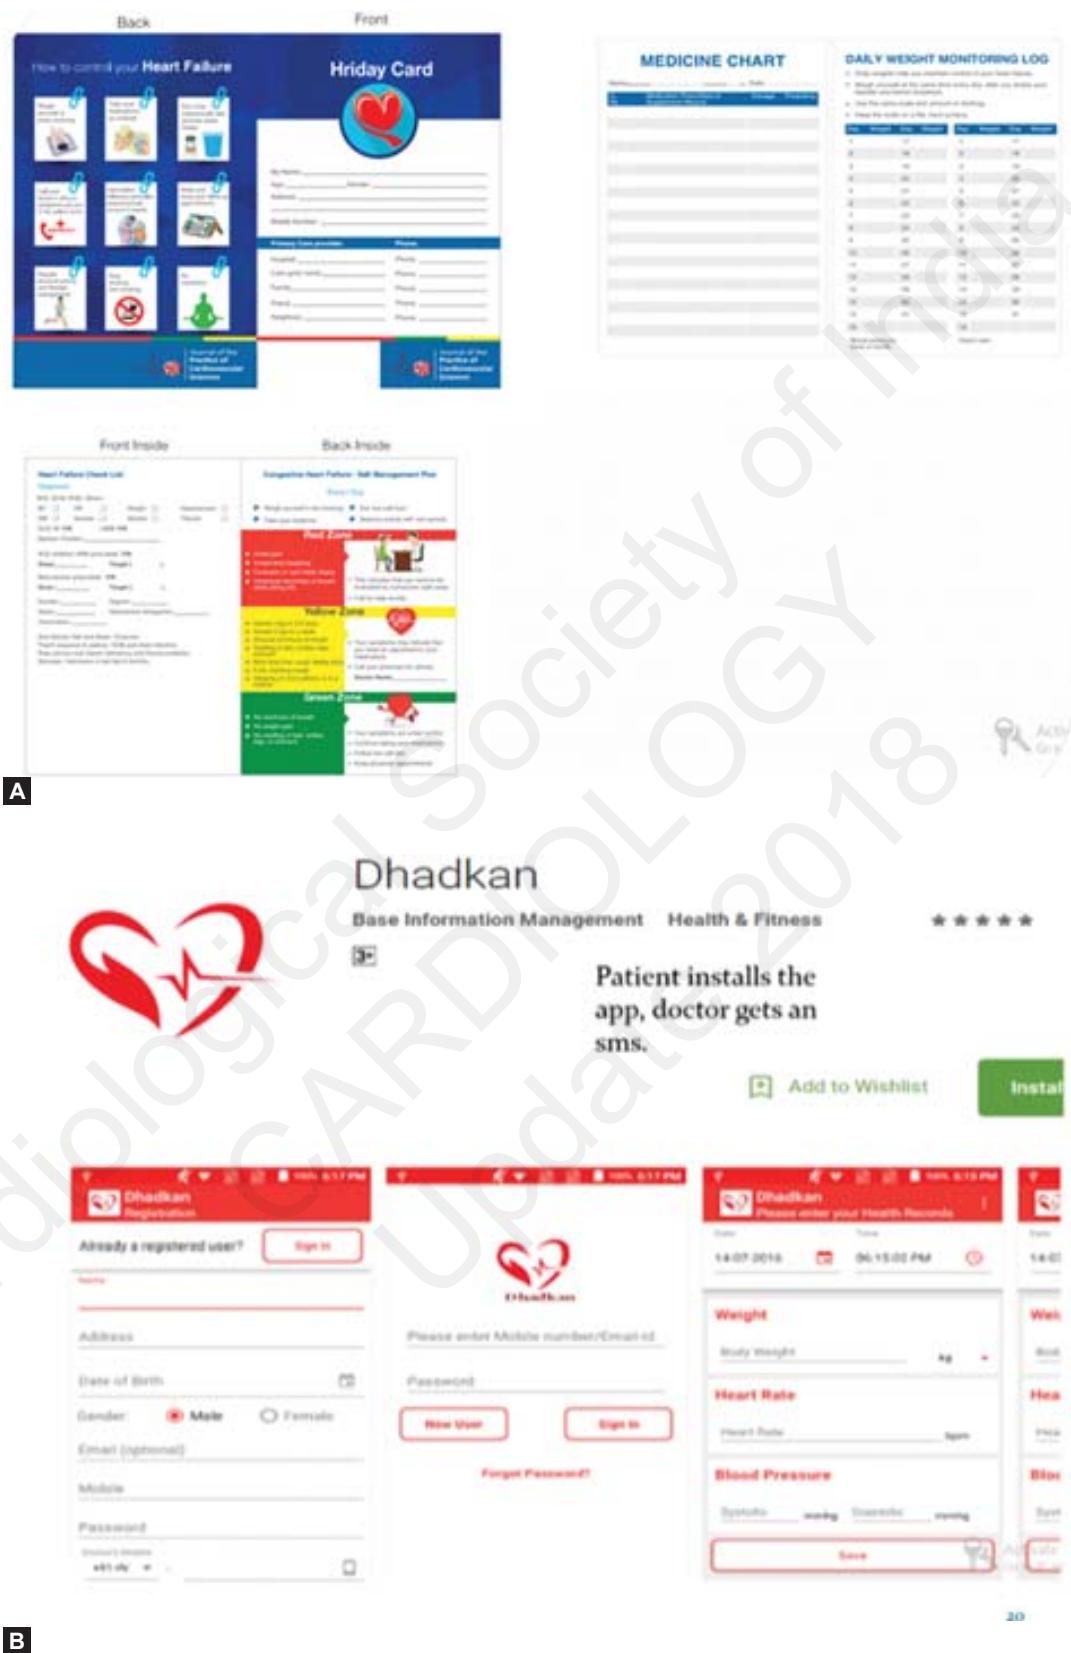

FIG. 1: A, The Hriday card; B, The Dhadkan app.

- Beyond drugs, patients should be assessed for need for devices in terms of implantable cardioverter defibrillators and cardiac resynchronization therapy in the presence of LBBB and an EF less than 35%
- In patients with multiple hospital admissions, end-stage HF therapy in the form of LV assist devices and heart transplant are practical options and should be offered. They are now available in most parts of India in both government and private hospitals with options of government aid also.

CONCLUSION

In conclusion, HF today can be treated and we are in a position to take failure out of HF.

Biomarkers for Heart Failure: Current Role and Relevance

Anunay Gupta, Ambuj Roy

CASE VIGNETTE

Mr AS, a 72-year-old man presents to the emergency with increasing cough and breathlessness. His pulse rate is 98 beats/min and blood pressure is 162/68 mm Hg. He is a known case of chronic obstructive airway disease (COAD), chronic kidney disease stage 3A and heart failure with preserved ejection fraction (HFpEF) on treatment. Important clinical decisions to be taken are whether it is heart failure (HF) or acute exacerbation of COAD. If its HF then how severe and what is the prognosis? Are there biomarkers to guide the management and discharge of the patient beyond usual clinical care?

INTRODUCTION

Heart failure burden has increased by many folds due to changing demographics, increasing burden of its risk factors like hypertension and diabetes and also better management coronary artery disease leading to higher number of its survivors but with impaired heart function. Despite improvements in therapy, the mortality rate in patients with HF has remained unacceptably high. However, the survival varies by countries and in the recent INTERCHF registry Indian patients had a very high mortality rate of 23% at one year which was lower than African countries but much higher than China and countries in Latin American and Middle East.¹

The diagnosis of HF has largely been a clinical diagnosis aided by investigations such as ECG, chest X-ray, and echocardiography. However, with increasing prevalence of multiple comorbidities as in the above case there has been a need for additional diagnostic aids for diagnosis of HF. In this respect many biomarkers of HF have been developed over the years, some of which have helped in improved diagnostic accuracy and also management of HF and have been mainstreamed in clinical care. There are others that have some varying promise and others which are in the pipeline. This review provides a focused update on current role and recent advances of biomarkers in HF.

What is an ideal biomarker?

An ideal biomarker of HF is that which will help in the diagnosis of HF, its prognosis, risk stratification, and guiding therapy. Therapy should alter its levels so as to be a marker of the state of HF in the individual patient.

NATRIURETIC PEPTIDES: B-TYPE NATRIURETIC PEPTIDE AND N-TERMINAL PROHORMONE B-TYPE NATRIURETIC PEPTIDE

Natriuretic peptide is the most widely tested and established biomarker in the management of HF. The natriuretic peptide system impacts salt and water handling and pressure regulation and may influence myocardial structure and function. B-type natriuretic peptide (BNP) is a natriuretic hormone initially identified in the brain but released primarily from the heart, particularly the ventricles. Cleavage of the prohormone proBNP produces biologically active 32 amino acid BNP as well as biologically inert 76 amino acid N-terminal proBNP (NT-proBNP). BNP have diuretic, natriuretic, and hypotensive effects. They inhibit the renin-angiotensin system, endothelin secretion, and systemic and renal sympathetic activity. Among patients with HF, increased secretion of BNP partially counteract the effects of norepinephrine, endothelin, and angiotensin II, limiting the degree of vasoconstriction and sodium retention.

In breathing not properly study, a plasma BNP more than 100 pg/mL diagnosed HF with a sensitivity, specificity, and predictive accuracy of 90%, 76%, and 83%, respectively.² NT-proBNP in the PRIDE study had similar sensitivity for excluding HF at cutoff of 300 pg/mL.³ NT-proBNPs have a varying sensitivity and specificity based on age, with age-related cutoffs of 450 pg/mL for less than 50 years, 900 pg/mL for 50–75 years, and 1,800 pg/mL for more than 75 years.⁴ Table 1 highlights the impact of other associated conditions on NT-proBNP levels. In a systematic review of 42 studies at a

TABLE 1: Impact of other conditions which can lead to variability in B-type natriuretic peptide (BNP) levels

Increased levels	Decreased levels
Increasing age	Obesity
Acute coronary syndrome	Flash pulmonary edema
Renal failure	Burnt out cardiomyopathy
Pulmonary hypertension	–
Pulmonary embolism	–
Atrial fibrillation	–
Anemia	–

threshold of 100 ng/L for BNP and 300 ng/L for NT-proBNP, the natriuretic peptides had sensitivities of 95% and 99%, and negative predictive values of 94% and 98%, respectively for a diagnosis of acute HF.⁵

Elevations in plasma BNP can establish the presence of HFpEF with similar accuracy to HF with reduced ejection fraction (HFrEF), though values are generally higher with HFrEF.⁶ However, the values do not adequately differentiate between HFrEF and HFpEF.⁷

It is important to note that not all patients with symptomatic HF have high plasma BNP concentrations and not all asymptomatic patients have low values. This was demonstrated in a review of 558 consecutive ambulatory patients with treated stable HF in a specialized outpatient HF clinic.⁸ In this study, 60 patients were considered asymptomatic, and their plasma BNP levels ranged from 5 pg/mL to 572 pg/mL (median, 147 pg/mL). Of the remaining 498 symptomatic (NYHA functional class II-III) patients, 106 (21.3%) had plasma BNP levels were normal (<100 pg/mL). These patients were more likely to be young and female and to have a nonischemic cardiomyopathy. While patients with raised levels without clinical HF may seem false positive cases, there is usually some pathophysiological cause for ventricular stress. Similarly, the other way round natriuretic levels may be normal in flash pulmonary edema at presentation but may rise subsequently over hours despite therapy. Another classical case of raised venous pressure without rise in natriuretic levels may be cardiac tamponade since it is not a ventricular failure.

There has been enthusiasm to use these biomarkers to guide therapy in HF patients so as to reduce clinical events and hospitalization. A patient-level meta-analysis of data from 2,431 patients from 11 trials showed a significant 38% reduction in all-cause mortality with natriuretic peptide-guided therapy compared with usual care.⁹ However, more recent Guide-IT trial using NT-proBNP-guided strategy failed to improve outcomes in HF with reduced ejection fraction. Patients with EF of 40% or less with elevated natriuretic peptide within 30 days of enrollment and history of a prior hospitalization for HF were recruited. The patients were assigned to a guided strategy in which HF therapy was titrated with the goal of NT-proBNP less than 1,000 pg/mL or to the usual guideline-directed care. There was no difference in the outcomes such as cardiovascular mortality, all-cause

mortality and time to first HF hospitalization at 15 months of follow up. There was no significant difference at 12 months in achieved NT-proBNP levels; the intervention group declined 53% to a median of 1,209 pg/mL and the control group declined 48% to a median of 1,397 pg/mL. The target of less than 1,000 pg/mL was achieved in 46% of the intervention group versus 40% of the control group ($p = 0.21$). This result highlights that when guideline-directed therapy is practiced, biomarkers-guided therapy do not make a difference and that guideline-directed care can lead to outcomes similar to biomarker-guided care if achieved.¹⁰ The difference between this study and other trials was the excellent management of the control group which probably negated the benefits of biomarker driven therapy.

In PARADIGM-HF trial, angiotensin receptor-neprilysin inhibitor (ARNI) showed improved outcomes compared to enalapril. ARNI inhibits the degradation of BNP resulting in elevated BNP levels. Thus, monitoring of chronic HF patients on sacubitril-valsartan treatment with BNP testing may be impaired. This is especially true in the first few weeks of ARNI therapy after which levels of BNP are stabilized and could be used in future management. The interpretation of NT-proBNP testing in HF appears to be unaffected by ARNI.¹¹ In a subset analysis it was seen that treatment with ARNI was nearly twice as likely as enalapril to reduce NT-proBNP to values less than or equal to 1,000 pg/mL and reduction in NT-proBNP levels was associated with reduced clinical events.¹²

Soluble ST2

Soluble ST2 (sST2) is a member of the interleukin (IL)-1 receptor-like family of proteins. It is expressed in response to mechanical stress on fibroblasts and cardiomyocytes. It is expressed in a transmembrane form (ST2L) and a soluble circulating form (sST2). Current assays measure sST2 and is the one in use in clinical studies.¹³ Soluble ST2 lacks disease specificity and, therefore, is not a valuable marker for the diagnosis of HF. Soluble ST2 is associated with adverse outcomes in HF, myocardial infarction, pulmonary disease, infection, and rheumatologic disorders. Higher levels of sST2 reflect increased inflammation, fibrosis, and wall stress and hence have the ability to be used as a composite marker like the “hemoglobin A1c (HbA1c)” for HF.¹³ The recommended cutoff for sST2 in chronic HF is 35 ng/mL. It is a prognostic marker for both HFpEF and HFrEF. In the PRIDE study, sST2 values were significantly higher in patients with HF and it was a powerful predictor of outcome. It has been shown that β -blockers can mitigate the risk associated with elevated sST2 in HF.⁸ Similarly, mineralocorticoid antagonist have been found to be beneficial in patients with elevated sST2.¹⁴ It is not known that whether sST2 can be used as a biomarker-guided strategy as seen with NT-proBNP.

High-sensitivity Troponin

The latest generation of high-sensitivity troponin (hsTn) assays are able to detect troponin in more than 50% of healthy subjects and ideally more than 95%.¹⁵ Recent American Heart Association/American College of Cardiology Foundation

guidelines endorse measuring troponin in acute HF to rule out acute coronary syndrome and risk stratification.¹⁶ Elevated hsTn is associated with increased in hospital mortality and can be used for risk stratification in HF.¹⁷ Serial measurements of hsTn during hospitalization for acute HF has shown to risk-stratify patients for 90-day mortality and readmission. It can also identify patients who are at high risk of developing clinical HF in the future in patients with stage A and B HF.¹⁸

NEWER BIOMARKERS

Even though natriuretic peptides have proven their usefulness in management of HF, limitations of natriuretic peptides measurement such as multiple comorbidities of HF patients that effect concentrations of BNP or NT-proBNP (e.g., sepsis, renal disease, and obesity), demand for other biomarkers.

Galectin 3

Galectin-3 (LGALS3) is a lectin expressed at low levels in body; however, upon injury or stress, its production is substantially increased. It is considered as a marker of myocardial fibrosis.¹⁹ In PRIDE study galectin-3 was a stronger prognostic marker for 60-day mortality compared to NT-proBNP. Moreover, the combination of galectin-3 with NT-proBNP was the best predictor for prognosis in subjects with acute HF.²⁰ Similarly in COACH study galectin-3 was associated with 18-month mortality and hospitalization rates.²¹ In a recent meta-analysis, pooled data from 8,419 patients with acute and chronic HF with a follow-up of 1-8.7 years, it was shown that an increase of 1% in circulating galectin-3 was associated with a 28% increased risk for all-cause mortality and a 59% increase in CV mortality, in fully adjusted models including estimated glomerular filtration rate and NT-proBNP.²² As with ST2, it is not known whether galectin-3 could have a role in guiding therapy. Similarly it is not known whether therapy targeting galectin-3 as an antifibrotic agent can be beneficial or not.

Procalcitonin

Procalcitonin (PCT) is a protein whose expression in parenchymal tissue is induced by bacterial infection, either by endotoxin or via cytokines (e.g., IL-6). It acts as a function of infection in patients presenting with acute dyspnea. Maisel et al. showed that patients with a diagnosis of acute HF and an elevated PCT concentration (>0.21 ng/mL) had a worse outcome if not treated with antibiotics ($p = 0.046$), while patients with low PCT values (<0.05 ng/mL) had a better outcome if they did not receive antibiotic therapy ($p = 0.049$). Therefore, PCT may aid in the decision to administer antibiotic therapy to patients presenting with acute HF in which clinical uncertainty exists regarding a superimposed bacterial infection.²³

Growth Differentiation Factor-15

Growth differentiation factor-15 (GDF-15) is a stress-response cytokine. In cardiomyocytes, it is produced and

released in the setting of oxidative stress or in response to stimulation with cytokines or angiotensin II.¹⁹ Increased levels are associated with worse outcomes in both acute HF and chronic HF.²⁴ GDF-15 offers additional prognostic value over and above natriuretic peptides.¹⁹

Mid-regional Proatrial Natriuretic Peptide

Mid-regional-proatrial natriuretic peptide (MR-proANP) provides both diagnostic and prognostic information that is additive to BNP or NT-proBNP, and has been shown in multiple HF studies.^{25,26}

CONCLUSION

Heart failure burden has rapidly increased and likely to worsen due to current demographic and disease patterns. Heart failure diagnosis and prognostication can be a challenge to clinicians. The biomarkers are envisioned to fill this void. Natriuretic peptides have become an integral part in the diagnosis and management of HF patients. Other biomarkers like sST2, hsTn, and PCT have also shown promise and are increasingly being used in HF patients in various settings. Role of newer biomarkers in the management of HF is still not well known and is evolving.

Practical Tips for using Beta-blockers, ACEI, ARBs, ARNI, Diuretics, Aldosterone Antagonists in Heart Failure

Vijay Kumar Chopra, Sanjay Mittal

INTRODUCTION

With the onset of heart failure (HF), there is activation of various neurohormonal systems as an adaptive response. However, over the course of time, this response becomes maladaptive and is responsible for perpetuation of HF. It follows, therefore, that the beneficial effects in terms of mortality and morbidity will occur with modification of neurohormonal systems and indeed, i.e., what has been shown in several HF trials. Beneficial as these agents are, for an optimal response it is important to use them in doses which have been shown to be beneficial in clinical trials

or at least to use the maximally tolerated doses. It is also important to use them judiciously while watching for their side effects and drug interactions. This brief review focuses on some practical tips for the appropriate use of these drugs in HF (Table 1).

BETA-BLOCKERS

Heart failure is characterized by sympathetic activation. Most of the deleterious effects are mediated by beta-blockers (BBs) and adrenergic receptors.¹ This results in tachycardia,

TABLE 1: Drugs for the prevention and treatment for chronic heart failure

Agent	Initiating daily dose	Maximal daily dose
Angiotensin-converting enzyme inhibitors		
Captopril	6.25 mg thrice	50 mg thrice
Enalapril	2.5 mg twice	10 mg twice
Lisinopril	2.5–5.0 mg once	20 mg once
Ramipril	1.25–2.5 mg once	10 mg once
Angiotensin receptor blockers		
Valsartan	40 mg twice	160 mg twice
Candesartan	4–8 mg once	32 mg once
Losartan	12.5–25 mg once	50 mg once
Beta-blockers		
Carvedilol	3.125 mg twice	25 mg twice (50 mg twice in patients weighing > 85 kg)
Carvedilol-CR	10 mg once	80 mg once
Bisoprolol	1.25 mg once	10 mg once
Metoprolol succinate CR	12.5–25 mg qd	200 mg once
Aldosterone antagonists		
Spironolactone	12.5–25 mg once	25–50 mg once
Eplerenone	25 mg once	50 mg once

fluid retention, and increased metabolic demands by the myocardium. Sympathetic activation also perpetuates remodeling of the ventricles resulting in hypertrophy and dilatation of ventricular cavities, which in turn places greater strain on the myocardium. By reducing heart rate (HR), BB when given in concert with angiotensin-converting enzyme inhibitor (ACEI), reverse this process, resulting in reverse remodeling, amelioration of symptoms, and prolongation of life. All patients of HF with ejection fraction (EF) less than 40%, whether symptomatic or not, should be on BB.

- Ensure that the patient does not have bronchial asthma, as it can get worse with BB. However, several patients of chronic bronchitis can tolerate BB and derive equal benefit. One has to watch for bronchospasm, however, which will necessitate withdrawal of BB
- Beta-blockers should not be started in grossly volume overloaded patients. Ideally a euvolemic status should be achieved before starting BB
- Initial dose should be relatively small depending upon the HR and blood pressure (BP). Uptitration should be done not earlier than 2 weeks depending upon the clinical status of the patient as each increment of dose may result in fluid retention. This can be managed by diuretics HR and BP in sitting and standing position should be checked at every visit and chest should be auscultated
- Recommended BB are carvedilol, metoprolol succinate, and bisoprolol with some evidence emerging for nebivolol. If the BP is on the lower side, one may like to avoid carvedilol as it is both alpha- and beta-blocker and may result in a greater drop in BP. As far as possible, BB should be started before discharge from the hospital. Nearly 85% of HF patients tolerate BB, including those with diabetes mellitus, peripheral vascular disease (PWD), and chronic obstructive pulmonary disease (COPD). Over a period of weeks and months, one after find a gradual increase in BP as a result of reverse remodeling allowing for further increase in the doses
- During acute decompensation, the dose of BB may have to be reduced at times² but not always, especially with gross fluid overload, bradycardia, and hypotension (Box 1). In case of fluid overload, the first attempt should be to identify and reverse any factors responsible for the same, i.e., hypertension, high salt intake, nonsteroidal anti-inflammatory drugs (NSAIDs), other fluid retaining drug or missing the dose of diuretics. Increase of diuretics dose may help in reversing fluid overload in most patients and reducing BB may not be necessary. In case of bradycardia, the first attempt should be to reduce or stop concomitant rate reducing agents like digoxin, amiodarone, or diltiazem. HR of 50 should be acceptable if hemodynamically stable. Dose of BB should be reduced if the HR falls below this level. Similar approach should be reduced in case of hypotension. Reducing diuretics or other concomitant antihypertensives like dihydropyridines should be the first step
- Symptoms of fatigue are common with BB, but generally resolve over time

BOX 1

Factors that may precipitate acute decompensation in patients with chronic heart failure

- Dietary indiscretion
- Inappropriate dose reduction/discontinuation of HF medications
- Myocardial ischemia/infarction
- Arrhythmias (tachycardia or bradycardia)
- Infection
- Anemia
- Initiation of medications that worsen the symptoms of HF
 - Calcium antagonists (verapamil and diltiazem)
 - Beta-blockers
 - NSAIDs
 - Thiazolidinediones
 - Antiarrhythmic agents [all class I agents, sotalol (class III)]
 - Anti-TNF antibodies
- Alcohol consumption
- Pregnancy
- Worsening hypertension
- Acute valvular insufficiency

HF, heart failure; NSAIDs, nonsteroidal anti-inflammatory drugs; TNF, tumor necrosis factor.

- Dose of BB should be decreased if HR is less than 50/min or if second or third degree heart block or hypotension develops.

ANGIOTENSIN-CONVERTING ENZYME INHIBITOR

In HF, activation of renin-angiotensin-aldosterone (RAS) axis has been well documented. This results in increase in peripheral resistance, salt and water retention, remodeling, endothelial dysfunction, and a host of other adverse hemodynamic and metabolic effects. Several ACEIs have been tried in landmark clinical trials³⁻⁵ with gratifying results and as a result they have established their place firmly as class I drugs in patients of symptomatic and asymptomatic HF. Enalapril, captopril, ramipril, and perindopril have all shown benefit in several studies. They relieve symptoms, prevent hospitalization, and prolong life.

Fluid retention can attenuate their effects. So it is preferable to optimize the dose of diuretics first (Table 2). There are certain precautions to be observed in their appropriate use:

- As with other vasoactive drugs, the initial dose should be relatively small depending upon the BP. The dose can be stepped up every 3–5 days depending upon the BP which should also be checked in standing position. Diuretics should be simultaneously reduced to prevent hypotension. BB can be started before the full dose of ACEI has been achieved
- Abrupt withdrawal of ACEI should be avoided in the absence of angioneurotic edema and hyperkalemia
- Majority of the adverse effects of ACEI are related to suppression of renin angiotensin system. Initial decrease

TABLE 2: Diuretics for treating fluid retention in chronic heart failure

Drug	Initial daily dose (s)	Maximum total daily dose	Duration of action
Loop diuretics			
Furosemide	20–40 mg once or twice	600 mg	6–8 h
Torsemide	10–20 mg once	200 mg	12–16 h
Thiazide diuretics			
Chlorthalidone	12.5–25 mg once	100 mg	24–72 h
Hydrochlorothiazide	25 mg once or twice	200 mg	6–12 h
Indapamide	2.5 mg once	5 mg	36 h
Metolazone	2.5–5.0 mg once	20 mg	12–24 h

in BP and mild azotemia seen during initiation of therapy is generally well tolerated, unless it becomes severe or symptomatic. While using ACEI, it is important to periodically monitor renal function test (RFT), as rise in creatinine and hyperkalemia may occur. A set of values should be obtained before starting these drugs and subsequently should be checked after 1–2 weeks at the time of stepping up the dose and every 2–3 months subsequently especially in patients of renal dysfunction, in those receiving aldosterone antagonists (AAs) and potassium sparing diuretics and in those with pre-existing hyponatremia, azotemia, and hypotension

- Precautionary measures should be taken to reduce the risk of worsening renal function which include avoiding concomitant nephrotoxic drugs (e.g., NSAIDs), evaluating and treating other causes of worsening renal function (e.g., intrinsic kidney disease), and avoiding volume depletion (i.e., if no congestion is present, reducing or suspending diuretic) at the time of ACEI initiation
- If serum creatinine increases by more than 50% above baseline or if serum creatinine is more than 3 mg/dL dose of ACEI should be decreased by one-half. Volume status should be evaluated the appropriateness of decreasing the diuretic dose should be considered tests. Serum creatinine, blood urea nitrogen (BUN), and serum potassium should be rechecked frequently (at least weekly) until levels have stabilized. After renal functions have stabilized, the appropriateness of uptitration ACEI dose should be assessed
- If serum creatinine is more than 3.5 mg/dL, ACEI should be stopped and volume status evaluated to determine the appropriateness of decreasing the diuretic dose. Serum creatinine, BUN, and serum potassium should be rechecked frequently (at least weekly) until levels have stabilized
- Caution should be taken in starting ACEI in patients with resting potassium levels above 5 mEq/L. The risk of hyperkalemia is increased if an AA is administered

concomitantly. On the other hand, concomitant potassium-wasting diuretic therapy can cause hypokalemia. It is advisable to check serum electrolytes and renal function at 1 week and at 1 month following increases in ACEI dose and then periodically (e.g. event 3–6 months), depending on the patient's stability and baseline renal function

- Cough and throat irritation occurs in about 10% of patients receiving ACEI. It is important to note that in patients receiving ACEI there may be other causes of cough such as bronchitis or HF. A careful history will establish the causality. If so suspected, ACEI should be discontinued and substituted with an angiotensin receptor blocker (ARB). Skin rash and itching also occurs in some patients due to elevated histamine levels
- Angioneurotic edema has been reported with ACEI, though it is uncommon (less than 1%).

ANGIOTENSIN RECEPTOR BLOCKERS

They should be used in symptomatic and asymptomatic patients with EF less than 40% in patients intolerant to ACEI due to cough, rash or angioneurotic edema but not in those with hyperkalemia. In ACEI intolerant patients, ARBs have shown improvement in outcomes.^{6–9} Like other drugs for HF, they too should be started in lower doses which should be gradually stepped up. The precautions in their use are identical to ACEI. An occasional patient can have cough or angioedema even with ARBs though the incidence is much less than with ACEI. ARBs approved for HF are losartan, valsartan and candesartan. Generally, ACEI and ARBs should not be combined except in certain specific situations. These will include difficult to control HF¹⁰ and heavy albuminuria. This decision is best left to the HF specialists and nephrologists.

ANGIOTENSIN RECEPTOR NEPRILYSIN INHIBITOR

This is a new class of drug which came into clinical use about 2 years ago after the remarkable success of the landmark PARADIGM (Prospective comparison of ARNI with ACEI to Determine Impact on Global Mortality and Morbidity) trial, which was prematurely stopped due to overwhelming superiority of the drug as compared to enalapril in treatment of chronic congestive HF. So strong was the evidence that on the basis of a single trial, both Food and Drug Administration (FDA) and the European Society of Cardiology (ESC) gave it a class I recommendation. The first in class drug is sacubitril/valsartan. This is a combination of an ARB valsartan and sacubitril, which is an inhibitor of neprilysin. Neprilysin is responsible for the breakdown of brain-type natriuretic peptide (BNP), other natriuretic peptides (NPs), and angiotensin II. Its inhibitor results in the elevation of NP levels, while valsartan blocks the effects angiotensin II despite at elevated levels. Following are some of the important tips for its use:

- American College of Cardiology/American Heart Association (ACC/AHA) recommend the use of angiotensin

receptor neprilysin inhibitor (ARNI) in patients with chronic congestive heart failure (CHF) even among those who are stable on ACEI or ARBs to improve cardiovascular outcomes, while ESC recommends the use of ARNI in patients who continue to be symptomatic or in HF despite adequate doses of ACEI/ARBs

- Patients on ARBs can be switched to ARNI straight away, if so required. Patients on ACEIs should have a gap of at least 36 hours between the last dose of ACEI and the first dose of ARNI to avoid angioneurotic edema. ARNI should never be combined with ACEI or other ARBs
- In ACEI/ARB naïve patients the starting dose of ARNI is 50 mg twice daily while patients already on a good dose of ARBs or ACEIs can be started on 100 mg twice daily if the BP is over 100 mm Hg. Clinical judgment should be exercised to avoid hypotension. The dose can be gradually stepped up every 2–4 weeks till 200 mg twice daily or a maximally tolerated dose has been achieved
- The ARNI should be started only if the BP is over 100 mm Hg systolic. If during the course of treatment the systolic BP falls to below 95 mm Hg then one should try to reduce other drugs which may be contributing to hypotension including reducing the dose of diuretics. If nothing else works, then the dose of ARNI can also be reduced. After correction of other factors, one should again try to increase the dose of ARNI if clinically possible.
- Reverse remodeling has been documented with ARNI. This means that after a few weeks or months of treatment the BP may actually come up with or without improvement in EF. This allows further uptitration of ARNI and BBs
- As with ACEI and ARBs, RFT should be monitored and the dose of diuretics should be gradually reduced to the minimum required to keep a patient euvolemic
- As with ACEI and ARBs, angioneurotic edema could occur and patients should be prewarned about it.

DIURETICS

In volume overloaded patients, diuretics play a critical role in improving symptoms of dyspnea and congestion. Depending upon the degree of congestion the starting dose could be oral or intravenous (IV). Loop diuretics, of which are extremely effective and fast acting. As HF improves, the dose of diuretics should be gradually reduced to the minimum required to maintain euvoolemia.

- In patients with acute dyspnea and fluid overload, IV loop diuretics are the drugs of choice. They can be given in doses of 20–40 mg 1–3 times a day, depending upon the clinical condition. The dose should be increased or decreased, depending upon the response of the patient. A commonly used method for dose titration in case of inadequate response is to double the dose till desired effect is achieved or the maximal dose is reached
- If diuresis is inadequate, one can use loop diuretics as an infusion, starting with 5 mg/hour and double the dose every 3–4 hours, depending upon the response. There is some evidence that this may be more effective than IV bolus doses, though some studies did not find any difference¹¹

- Loop diuretics can be combined with AAs or thiazide diuretics for enhancing the response.
- With IV diuretics, a close monitoring of BP, electrolytes and renal functions is needed. Hypokalemia, hyponatremia, azotemia, and hypomagnesemia are important. In patients receiving potassium sparing diuretics, hyperkalemia should be looked for especially in those receiving ACEI/ARBs and ARNI.¹² This is especially important in diabetics who may have occult renal dysfunction. Serum K levels between 4 mg/dL and 5 mg/dL are considered ideal administration of AA prevents low potassium. Hyperuricemia and metabolic alkalosis are the other complication of diuretics
- As euvoolemia is achieved, the doses should be reduced and changed to oral route. At each subsequent visit the need and the dose of diuretics should be evaluated. When euvoolemia is achieved, the patient in dry weight should be recorded. Subsequently patients should weigh themselves daily to maintain their ideal weight and to avoid fluid overload
- Bioavailability of frusemide is about 40–79% resulting in variable response. Bumetanide and torsemide have a better bioavailability
- Aggressive diuretic use can result in severe hyponatremia, especially in people with high RAS activation and high arginine vasopressin (AVP) levels and requires stringent water restriction
- Ototoxicity resulting in temporary or permanent hearing loss can be seen with rapid IV frusemide injections, it is much less with oral use
- Diuretics resistance refers to progressively diminishing response to diuretics and is associated with excessive salt intake, hypotension,¹³ advanced HF, and abrupt decline in cardiac or renal functions. One should enquire if any drugs are responsible, e.g., COX-2 inhibitors, NSAIDs, thiazolidinediones, trimethoprim, and other nephrotoxic drugs
- To treat diuretics resistance, one can add a proximal tubule diuretic or a distal collecting tubule diuretic, e.g., metolazone without reducing the loop diuretic
- Ultrafiltration should be considered if diuresis is inadequate despite all the measures.

ALDOSTERONE ANTAGONISTS

They are not only K-sparing diuretics, but have beneficial effects that are independent of their diuretic actions. They are recommended for New York Heart Association (NYHA) class II–IV patients with EF less than 35% who are receiving standard therapy with diuretics, ACEI, and BB.⁶ Spironolactone and eplerenone are the two AA available and have shown efficacy in clinical trials.¹⁴

- Start with a small dose and gradually increase
- Generally K supplementation should be stopped when starting AA
- Watch for hyperkalemia, especially in diabetics, and those receiving ACEI/ARBs/ARNI
- Check K and RFT after 3 days and 1 week after starting AA and subsequently once a month

- Aldosterone antagonists are not recommended in patients with serum creatinine more than 2.5 mg/dL or K more than 5.5 mEq/L
- Painful gynecomastia occurs in 10–15% of patients receiving spironolactone. These patients should be switched to eplerenone and gynecomastia usually resolves in 2–4 weeks.

HFpEF—How to Diagnose and Manage?

Sanjeev Sanghvi, Swati Mahajan

INTRODUCTION

Heart failure (HF) with preserved ejection fraction (HFpEF) accounts for up to 50% of all HF cases in the developed countries.¹ The prevalence of HFpEF ranges from 1% to 3%, and is expected to rise further with increasing life expectancy, better diagnostic awareness, and increasing prevalence of comorbidities like obesity, diabetes, hypertension, and atrial fibrillation (AF).¹ HFpEF was previously referred to as “diastolic” HF. This was in comparison to “systolic” HF, which corresponded to HF with reduced ejection fraction (HFrEF). However, diastolic dysfunction is not unique to HFpEF, as evidenced by presence of diastolic dysfunction in systolic HF also. The term “HF with normal ejection fraction” (HFnEF) was used briefly; however newer imaging techniques have confirmed that systolic function in HFpEF patients is not completely normal, with mildly reduced left ventricular (LV) systolic function by global longitudinal strain.² As the exact normal range of function is difficult to define and the LV function may not be entirely normal, the term “HFpEF” is now used.

In observational studies, rates of hospitalization and death among patients with HFpEF are similar to those among patients with HFrEF, but in clinical-trial populations, outcomes are better in patients who have HFpEF.³ Death from noncardiovascular causes is more common in patients who have HFpEF than in those with HFrEF.^{4,5} Long-term mortality trends in HFpEF is similar to HFrEF, with less than 50% 5-year survival in HFpEF cohorts.^{6,7} Outcomes following hospitalization for decompensated HFpEF are quite poor, with more than one-third of patients dead or rehospitalized within 60–90 days of discharge.⁸

PATHOPHYSIOLOGY OF HFpEF

Despite its burden, the pathophysiological mechanisms of HFpEF remain controversial and are likely to be multifactorial.⁹ The lack of a comprehensive paradigm applicable

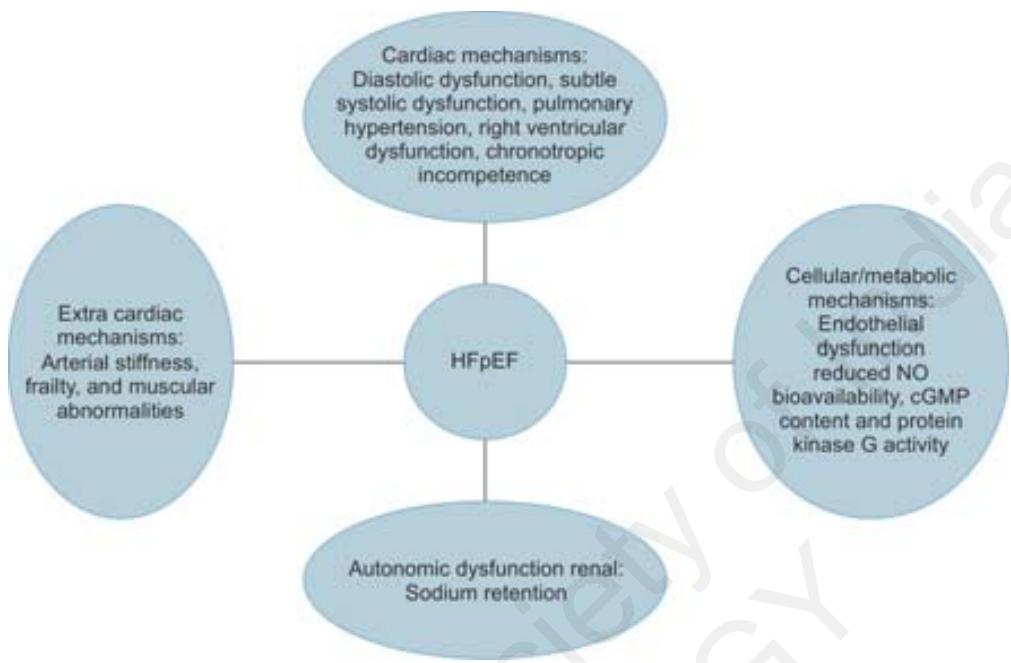

to all patients suggests that hemodynamic derangements responsible for this disorder may be quite heterogeneous. Hemodynamic features of HFpEF involve both cardiac and extracardiac mechanisms (Fig. 1).

DIAGNOSIS OF HFpEF

The diagnosis of HFpEF remains challenging due to the advanced age of the patient and concomitant multiple illnesses. In fact, multiple comorbidities are the rule in HFpEF rather than the exception,¹⁰ and significantly influence cardiovascular structure and function as well as long-term prognosis.¹¹ Depending upon the LV ejection fraction (LVEF), HF can be defined as those with normal LVEF (typically considered as ≥50%: HFpEF) and those with reduced LVEF (typically considered as <40%: HFrEF). Patients with an LVEF in the range of 40–49% represent a “grey area”, which is now defined as HF with midrange ejection fraction (HFmrEF).¹² Current guidelines advocate using LVEF as one component of a diagnostic algorithm for HFpEF, alongside detection of additional myocardial abnormalities to implicate a cardiac cause for symptoms (Table 1).^{12,13}

HISTORY AND CLINICAL EXAMINATION

A detailed history should always be obtained. At each visit, symptoms and signs of HF should be assessed, with particular attention to the evidence of congestion. Symptoms and signs for HF are usually nonspecific and hence may not discriminate well between HF and other clinical conditions. The diagnosis of chronic HFpEF, especially in elderly patients with comorbidities and no signs of central fluid overload, becomes difficult. In order to improve the specificity, the clinical diagnosis of HFpEF should be supported by objective measures of cardiac dysfunction at rest or during exercise. Symptoms and signs are important to monitor the response to the treatment.

cGMP: cyclic guanosine monophosphate; HFpEF: heart failure with preserved ejection fraction; NO: nitric.

INVESTIGATIONS

Electrocardiogram

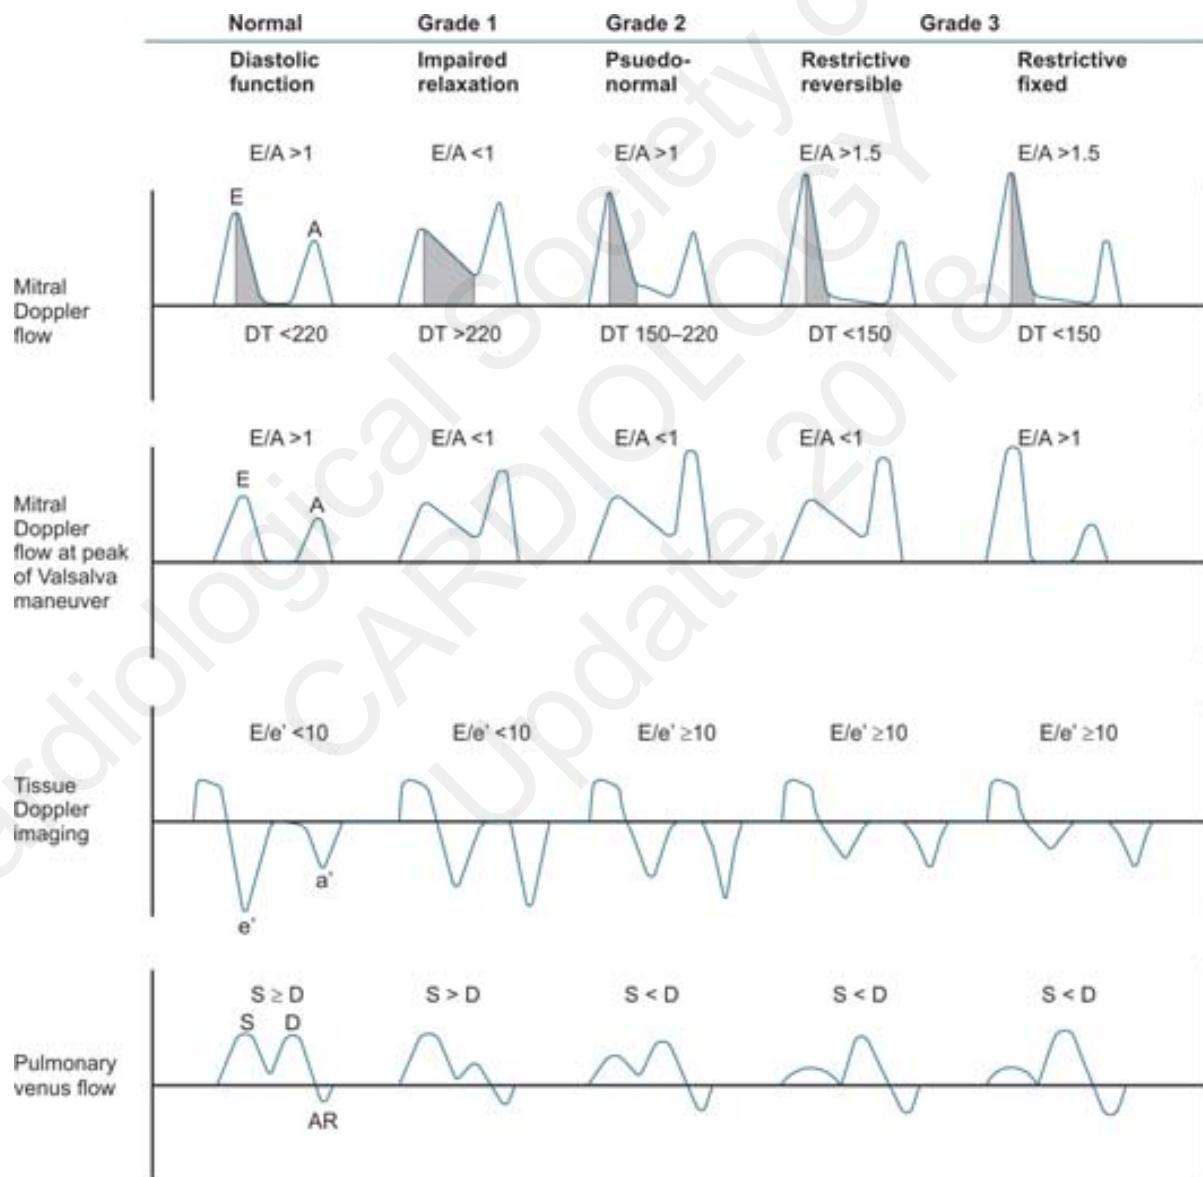

The electrocardiogram (ECG) may reveal abnormalities like repolarization abnormalities, AF, and LV hypertrophy.

Chest X-Ray

A chest X-ray is of limited use in the diagnosis of HFP EF. It is most useful in identifying an alternative explanation for a patient's symptoms and signs. The chest X-ray may show evidence of pulmonary venous congestion in a patient with HF, and is more helpful in the acute setting.

Echocardiography

Echocardiography has an important role in the diagnosis of HFP EF and is considered one of the most useful investigations in this setting. As diastolic dysfunction, which is graded from I to IV (Fig. 2), is the hallmark pathophysiological process in HFP EF, it is not surprising that echocardiography in HFP EF mainly focuses on markers of diastolic dysfunction. The key echocardiographic measurement in the assessment of diastolic dysfunction is E/e'. E represents the peak velocity of transmural flow in early diastole, whereas e' represents the tissue Doppler early diastolic septal or lateral lengthening peak velocity of the mitral annulus. E/e' is thought to be a

A: transmural flow velocity with atrial contraction; a': velocity of mitral annular motion with atrial contraction; AR: flow into pulmonary vein during atrial contraction; D: diastolic; E: early diastolic flow velocity; e': velocity of early diastolic mitral annular motion; S: systolic.

FIG. 2: Classification of diastolic dysfunction.

reflection of left atrial pressures and thus of LV end-diastolic pressure (LVEDP). To date, an elevated E/e' (reflecting filling pressures ≥ 13 mm Hg) has been incorporated in guidelines as sufficient evidence of diastolic dysfunction.¹² However, only 25% of HFpEF patients have an elevated E/e', thereby suggesting low specificity and sensitivity of this parameter, even in combination with additional echo markers of diastolic dysfunction. Therefore, absence of an elevated E/e' does not rule out the presence of diastolic dysfunction.

Biomarkers

Normal levels of brain natriuretic peptide (BNP) are reported in up to 30% of patients, despite clinical, echocardiographic, and invasive hemodynamic evidence of HFpEF.¹⁴ The absence of LV dilatation in HFpEF yields lower BNP concentrations and therefore less sensitive discrimination between the normal and HF state. Further ambiguity may be introduced by obesity, which is associated with lower plasma BNP concentrations, and by AF, which is associated with raised plasma BNP concentrations.¹⁵ Other biomarkers like galectin-3, ST2, tissue inhibitor of metalloproteinases (TIMPs), amino-terminal propeptide of type III procollagen (PIINP), homocysteine and resistin are particularly upregulated in HFpEF.¹⁶

Invasive Testing

Invasive hemodynamics at rest with assessment of filling pressures pulmonary capillary wedge pressure (PCWP) more than or equal to 15 mm Hg or LVEDP more than or equal to 16 mm Hg, followed by exercise hemodynamics if below these thresholds, with assessment of changes in filling pressures, pulmonary artery systolic pressure (PASP), stroke volume and cardiac output, can be performed.¹⁷

Diastolic Stress Testing

Exercise testing has been shown to enhance the diagnosis of HFpEF in patients with no overt signs of volume overload and normal filling pressures at rest and it holds promise for novel diagnostic strategies.¹⁷

One of the first studies addressing markedly elevated filling pressures during moderate exercise in patients with normal resting hemodynamics was by Borlaug et al.¹⁷ They showed that more than 50% of patients with dyspnea on exertion had increased LV filling pressures only during exercise. Different dynamic exercise protocols are available, with semisupine bicycle ergometry and echocardiography at rest and submaximal exercise being used most often.¹⁸ Exercise-induced increase in E/e' beyond diagnostic cut-offs (i.e. 13) and other indirect measures of systolic and diastolic function, such as longitudinal strain, are used.

Additional Role of Cardiac Magnetic Resonance Imaging

Over the last decade, attention has been given to the potential utility of cardiac magnetic resonance (CMR) and it is among the most promising noninvasive modalities. It provides good

spatial resolution, and helps in the assessment of global as well as regional cardiac anatomy. Furthermore, information on left atrial volume and function, blood flow velocities, as well as myocardial tissue characteristics can be obtained. T1-mapping is used to quantify the degree of diffuse myocardial fibrosis.¹⁹ In addition, CMR is considered the gold standard for the assessment of the right ventricle.²⁰ CMR may also be useful in the diagnosis of infiltrative cardiomyopathy (amyloidosis) or inflammatory cardiomyopathy (sarcoidosis).

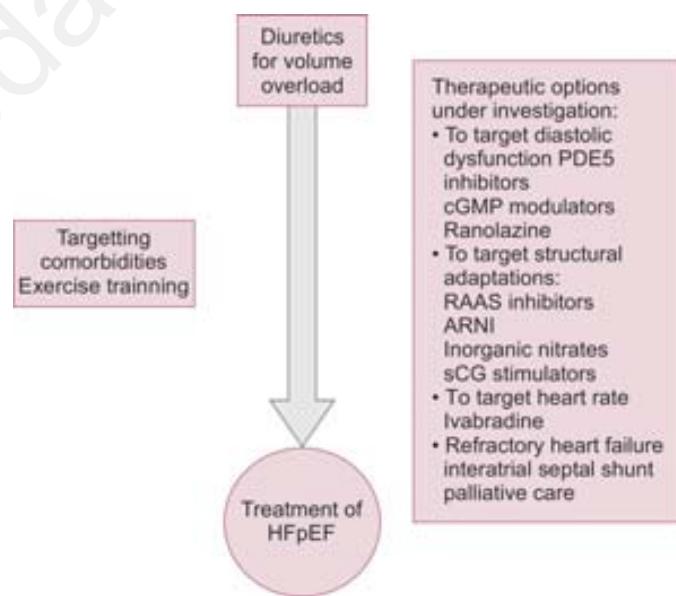

TREATMENT (FIG. 3)

Pharmacological Treatment

Neurohormonal Antagonists

Angiotensin-converting Enzyme Inhibitors/ Angiotensin Receptor Blockers

Various studies have evaluated the role of angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) for the treatment of HFpEF, including perindopril in elderly people with chronic HF (PEP-CHF),²¹ CHARM-Preserved,²² and irbesartan in patients with HF and preserved systolic function (I-Preserve).²³ No improvement was detected among patients randomized to the ACE-inhibitor or ARB in these trials, but the studies were limited by high crossover rates and, in part, insufficient power. Trials employing a low ejection fraction (EF) cut-off for HFpEF (e.g., >40% CHARM-Preserved, >45% I-Preserve) insufficiently represented symptomatic HFpEF, as defined by current guidelines.¹³ The recent American College of Cardiology/American Heart Association (ACC/AHA) 2013 HF guidelines recommend the use of ACE-inhibitors, ARBs, or beta-blockers in hypertensive patients with HFpEF with the goal of

ARNI, angiotensin receptor-neprilysin inhibitor; cGMP, cyclic guanosine monophosphate; HFpEF, heart failure with preserved ejection fraction; PDE5, phosphodiesterase-5; RAAS, renin-angiotensin-aldosterone system.

FIG. 3: Treatment of heart failure with preserved ejection fraction.

controlling blood pressure (class IIa recommendation, level of evidence C), but data on beneficial outcomes, beyond risk factor control are inadequate to recommend the use of these agents specifically for the treatment of HFpEF.¹³

Beta-blockers

The effect of beta-blockers in patients with HFpEF has not been evaluated in an adequately powered study. Randomized trial to determine the effect of nebivolol on mortality and cardiovascular hospital admission in elderly patients with HF (SENIORS)²⁴ concluded that nebivolol, a beta-blocker with vasodilating properties, is an effective and well-tolerated treatment for HF in the elderly, however recruiting few patients with EF more than or equal to 50%, SENIORS insufficiently represented symptomatic HFpEF, as defined by current guidelines.

Mineralocorticoid Receptor Antagonist

Animal studies showed that mineralocorticoid receptor antagonist (MRA) prevent collagen synthesis and remodeling.²⁵ Small studies in HFpEF patients showed improvement in diastolic dysfunction parameters after treatment with MRA.²⁶ The Aldosterone Receptor Blockade in Diastolic Heart Failure (Aldo-DHF) trial was conducted in patients with chronic HF, New York Heart Association (NYHA) class II or III. It was a randomized, double-blinded, placebo-controlled trial.²⁷ It was observed that the co-primary endpoint E/e' was significantly reduced in the spironolactone group. However, peak volume of oxygen (VO_2) was not affected by spironolactone. There was improvement in LVEF, with significant decrease in LV mass index (LVMI), and N-terminal pro B-type natriuretic peptide (NT-proBNP) from baseline in the spironolactone group. Treatment of preserved cardiac function HF with an aldosterone antagonist (TOPCAT), a phase-III trial found no reduction in the composite of cardiovascular death, aborted cardiac arrest, or HF hospitalization in patients with symptomatic HF and a LVEF 45% or more with the use of spironolactone, however, reduction in HF hospitalization was observed.²⁸

The Randomized aldosterone antagonism in HFpEF (RAAM-PEF) trial randomized HFpEF patients to 6 months of eplerenone versus placebo, and showed reductions in circulating markers of collagen turnover and modest improvement in diastolic function.²⁹

Angiotensin Receptor-Neprilysin Inhibitor

Sacubitril, a neprilysin inhibitor, increases the levels of peptides which promote natriuresis, vasodilation, and reduce extracellular fluid (ECF) volume via sodium excretion; eventually reducing preload and ventricular remodeling. Valsartan inhibits the effects of angiotensin-II by selectively blocking the receptor type-1 (AT₁), and concomitantly inhibits angiotensin-II-dependent aldosterone release. LCZ696 (sacubitril/valsartan) is a member of a new class of agents called angiotensin receptor-neprilysin inhibitor (ARNI), which combines a neprilysin inhibitor and an ARB. Prospective comparison of ARNI with ARB on examination of HFpEF (PARAMOUNT) trial randomized patients with LVEF more than or equal to 45%, signs and symptoms of HF, and

elevated NT-proBNP plasma levels to LCZ696 or valsartan for 12 weeks.³⁰ The primary endpoint was change in NT-proBNP levels from baseline to 12 weeks. There was significant decrease in NT-proBNP levels from the baseline in LCZ696 group compared to valsartan group. There was significant reduction in left atrial volumes and dimensions after 36 weeks in the LCZ696 group. PARAGON-HF (NCT01920711) is an ongoing trial to determine the efficacy of sacubitril/valsartan compared with valsartan in patients with chronic HFpEF.

Other Pharmacological Agents

Diuretics

Diuretics are used to relieve the symptoms of congestion in patients with HFpEF.

Phosphodiesterase-5 Inhibitors

Phosphodiesterase-5 (PDE5) inhibition leads to accumulation of intracellular cyclic guanosine monophosphate (cGMP)- and nitric oxide (NO) induced pulmonary vasodilation in patients with pulmonary arterial hypertension.³¹ PDE5 inhibition to improve clinical status and exercise capacity in HFpEF (RELAX) trial determined the effect of the PDE5 inhibitor sildenafil on exercise capacity and clinical status in HFpEF.³² Sildenafil (n = 113) or placebo (n = 103) was administered orally at 20 mg, 3 times daily for 12 weeks, followed by 60 mg, 3 times daily for 12 weeks. PDE5 inhibition with sildenafil, compared with placebo, did not result in significant improvement in exercise capacity or clinical status in patients with HFpEF.

Cyclic Guanylate Monophosphate Stimulators

Modulation of NO-cGMP-protein kinase G signaling pathway, by various pharmacological agents, may increase cGMP content and reduce myocardial stiffness in HFpEF.

Oral Soluble Guanylate Cyclase Stimulators

Acute hemodynamic effects of riociguat in patients with pulmonary hypertension associated with diastolic HF (DILATE-1) evaluated riociguat in patients with pulmonary hypertension with LV diastolic dysfunction. Improvement in hemodynamics was observed with the use of riociguat.³³

The SOCRATES-PRESERVED was a prospective, randomized, placebo-controlled double blind, phase 2b dose-finding study in patients with HFpEF (EF $\geq 45\%$), to determine tolerability and the optimal dose regimen of the soluble guanylate cyclase stimulator vericiguat in patients with chronic HF and preserved EF. Patients received vericiguat once daily at 1.25 or 2.5 mg fixed doses, or 5 or 10 mg titrated from a 2.5 mg starting dose or placebo for 12 weeks. Vericiguat was well tolerated, was associated with improvements in quality of life in patients with HFpEF but with no change in NT-proBNP at 12 weeks compared with placebo.³⁴

Others

Use of isosorbide mononitrate (ISMN) has not shown any improvement in HFpEF trials.³⁵ Nitrate's effect on activity tolerance in HFpEF (NEAT-HFpEF) trial demonstrated decrease in patient's activity with the use of ISMN, possibly because of excess hypotension.³⁵

Inorganic nitrate delivers NO during hypoxia and acidosis and avoids hypotension as seen with ISMN. Beetroot juice (dietary inorganic nitrate) has been evaluated in a phase II study where it led to improvement in exercise endurance in patients with HFpEF.³⁶ Presently, there are ongoing studies with inhaled nitrite preparation, to evaluate its benefits in HFpEF patients.

Ivabradine

Heart rate (HR) is one of the major determinant of diastolic function. Slow incomplete relaxation can be induced by increased afterload to such an extent that it leads to marked increase in filling pressures. Also the myocardium of HF patients may exhibit a flat or negative myocardial relaxation velocity to HR relationship, even at a lower range of HR, when compared to a normal heart. Hence, lowering the HR would prevent the clinical expression of this HR-dependent relaxation impairment. Reil et al. showed that ivabradine decreases arterial elastance by enhancing arterial compliance and reducing HR.³⁷ Effect of ivabradine in patients with HFpEF (EDIFY) trial showed that HR reduction with ivabradine did not improve outcomes.³⁸

Late Sodium (Na^+) Current Inhibition

Ranolazine inhibits the late Na^+ current, thereby minimizing intramyocyte Na^+ accumulation and the resultant Ca^{2+} overload. The ranolazine for the treatment of diastolic HF (RALI-DHF) study evaluated the effect of ranolazine versus placebo on hemodynamics, measures of diastolic dysfunction, and biomarkers in 20 patients with HFpEF and diastolic dysfunction.³⁹ After 30 minutes of infusion, significant decrease from baseline were observed in LVEDP and PCWP in the ranolazine group, but not in the placebo group. RAZE trial, is an ongoing trial to evaluate the effects of ranolazine compared with placebo on exercise capacity in patients with HFpEF [NCT01505179].

Other Novel Therapies

Functional Iron Deficiency and Anemia

In a small study, functional iron deficiency was present in almost 50% of HFpEF patients; however, it did not correlate with diastolic dysfunction or exercise capacity.⁴⁰ FAIR-HFpEF [NCT03074591] is an ongoing trial to see the effect of intravenous (IV) iron (ferric carboxymaltose) on exercise tolerance, symptoms, and quality of life in patients with HFpEF and iron deficiency with and without anemia.

Bendavia

Bendavia (mitochondrial enhancer) is being evaluated in Mito-HFpEF trial, an ongoing study.

Treatment of co-morbidities

Comorbidities, such as hypertension, AF, diabetes, renal or pulmonary disease, anemia, obesity, and deconditioning, may contribute to the HFpEF. Management of comorbidities in the patients with HFpEF is class IB or C according to AHA 2013 guidelines.¹³

Nonpharmacological Treatment

Exercise Training

To date, exercise training is the only intervention that has shown symptomatic benefit in relatively young patients with HFpEF. Exercise training in Diastolic HF Pilot study (Ex-DHF-P) evaluated the benefit of combined endurance or resistance exercise training compared with usual care in symptomatic (NYHA class II-III) HFpEF patients.⁴¹ There was significant improvement in peak VO_2 after 3 months in the training group. The ongoing phase II Ex-DHF study (ISRCTN 86879094) will evaluate the role of exercise training in patients with HFpEF.

Autonomic Modulation and Chronotropic Incompetence

Autonomic dysfunction is one of the factors implicated in the pathophysiology of HFpEF. Modulation of autonomic function, e.g., by baroreceptor activation, vagal nerve stimulation, and renal artery denervation, is under investigation for treating the patients with HFpEF.⁴²

Controlled Left to Right Interatrial Shunt

In patients with HF and EF more than or equal to 40% creation of an interatrial shunt with the interatrial shunt device (IASD) leads to unloading of left atrium and reduction in PCWP during exercise.

The REDUCE LAP-HF I was a phase II randomized, parallel-group, blinded multicenter trial. Patients were randomized (1:1) to the IASD versus a sham procedure. IASD treatment led to reduction in PCWP during exercise.⁴³

CONCLUSION

Patients who have signs and symptoms of HF but a preserved EF, objective evidence of abnormal cardiac structure and function should be confirmed. Natriuretic peptide levels may be normal in patients with HFpEF, particularly in obese patients. Medications that improve outcomes in patients with HFrEF have not shown to be of benefit in those who have HFpEF. Since, no therapy has been shown to improve outcomes in patients with HFpEF, current therapy mainly relies on the relief of volume overload (when present) and treatment of coexisting conditions. Certainly, our current knowledge base is still inadequate to the task of managing this increasing clinical problem.

Heart Failure with Midrange Ejection Fraction—What is This?

Arup Dasbiswas

INTRODUCTION

In heart failure (HF) cases, we find the ejection fraction (EF) as a continuum between reduced and preserved EF. Initially, studies were conducted mainly in HF with reduced EF (HFrEF) patients having a left ventricle ejection fraction (LVEF) less than 35–40%. Subsequently, focus was shifted to the cohort of patients having HF with preserved EF (HFpEF), i.e., on patients with HF symptoms, but with a LVEF exceeding 50%. The recent guidelines from the American Heart Association/American College of Cardiology Foundation (AHA/ACCF) and the European Society of Cardiology (ESC) have defined HFrEF as having symptoms and signs of HF with an LVEF less than 40%, whereas HFpEF is defined as HF with an LVEF more than or equal to 50%.^{1,2}

The OPTIMIZE-HF (Organized Program to Initiate Lifesaving Treatment in Hospitalized Patients with Heart Failure)³ and the ADHERE (Acute Decompensated Heart Failure Registry)⁴ studies started to explore the characteristics, treatment patterns, and outcomes of patients with mildly reduced LVEF, suggesting these patients might have notable differences from those patients with HFrEF and HFpEF. Therefore, in-between HFrEF and HFpEF a less studied and a less characterized cohort remains, which fills in the gap of EF continuum with HF. The 2013 ACCF/AHA guidelines classified this range of LVEF 41–49% as borderline HFpEF¹, whereas the 2016 ESC guidelines have identified patients with HF and an LVEF 40–49% as having heart failure with midrange ejection fraction (HFmrEF).²

Considered as a grey area, the HFmrEF is gaining increasing attention in recent studies. Though, it is known that the patients with HFmrEF have higher readmission rates than patients with HFpEF and mortality rates comparable to HFrEF and HFpEF.⁵ HFmrEF remains insufficiently characterized compared with the other groups. Therapy for patients with HFmrEF is also unclear, as clinical trials have not directly targeted this sizeable HF population. However, targeting this group to improve the outcome may lead to achieving success in a sizeable proportion of HF patients, because this

group forms a good chunk of the population having HF, as the prevalence of HFmrEF is estimated to be in the range of 10–20% of all HF patients.^{6,7}

CLINICAL CHARACTERISTICS

Four elements are simultaneously required for a positive diagnosis of HFmrEF: (1) symptoms with or without signs of HF, (2) LVEF of 40–49%, (3) elevated natriuretic peptides [B-type natriuretic peptide ≥ 35 pg/mL or N-terminal pro B-type natriuretic peptide (NT-proBNP) ≥ 125 pg/mL], and (4) relevant structural heart disease—left ventricle hypertrophy (left ventricular mass index ≥ 115 g/m² for males and ≥ 95 g/m² for females) or left atrial enlargement (>34 mL/m²) or diastolic dysfunction ($E/e' \geq 13$ and a mean e' septal and lateral wall <9 cm/s).²

Characteristics of patients with HFmrEF are largely intermediate between those of HFpEF and HFrEF.⁸ The exception to this statement is cases in which ischemia is an etiology or a precipitating factor for HF decompensation, which is at least as common in HFmrEF as HFrEF.^{9,10}

Outcome Data

Reported outcomes are variable, with some studies reporting similar long-term event rates, others reporting intermediate medium-term outcomes, and yet others reporting lower in-hospital mortality rates in HFmrEF.

Rickenbacher et al.¹¹ studied 622 patients with HF. The analysis was based on the Trial of Intensified versus standard Medical therapy in Elderly patients with Congestive Heart Failure (TIME-CHF) comprising a population with established HF including the whole spectrum of LVEF. Of the 622 patients, 108 (17%) were classified as having HFmrEF. During a median follow-up of 794 days, mortality was 39.7% without significant differences between groups. NT-proBNP-guided as compared with standard therapy resulted in improved survival free of HF hospitalizations in HFrEF and HFmrEF, but not in HFpEF.

Chioncel et al.¹² followed up 9,134 patients' data for 1 year. They found that The HFmrEF group resembled the HFrEF group in some features, including age, gender, and ischemic etiology, but had less left ventricular and atrial dilation. Mortality at 1 year differed significantly between HFrEF and HFpEF (8.8% vs. 6.3%); HFmrEF patients experienced intermediate rates (7.6%). Age, New York Heart Association (NYHA) class III/IV status, and chronic kidney disease (CKD) predicted mortality in all LVEF groups. Low systolic blood pressure and high heart rate were predictors for mortality in HFrEF and HFmrEF.

Kapoor et al.⁹ analyzed the factors potentially contributing to HF hospitalization among 99,825 HF admissions from 305 hospitals in the Get With The Guidelines-HF (GWTG-HF) database between January 2005 and September 2013 and assessed their association with length of stay and in-hospital mortality. In patients with borderline EF (EF, 40–49%), pneumonia was associated with longer hospital stay, whereas dietary and medication noncompliance were associated with reduced length of stay.

PREDICTORS AND OUTCOMES OF HEART FAILURE WITH MIDRANGE EJECTION FRACTION

The majority of aforementioned data have been taken from prevalent cases of HF. Whereas, Bhamhani et al.¹³ sought to examine clinical and biochemical predictors of incident HFmrEF in the community. They pooled data from four community-based longitudinal cohorts, with ascertainment of new HF classified into HFmrEF (EF 41–49%), HFpEF (EF ≥50%), and HFrEF (EF ≤40%). Predictors of incident HF subtypes were assessed using multivariable Cox models. Among 28,820 participants free of HF followed for a median of 12 years, there were 200 new HFmrEF cases, compared with 811 HFpEF and 1,048 HFrEF. Clinical predictors of HFmrEF included age, male sex, systolic blood pressure, diabetes mellitus, and prior myocardial infarction (multivariable adjusted $p \leq 0.003$ for all). Biomarkers that predicted HFmrEF included natriuretic peptides, cystatin-C, and high-sensitivity troponin ($p \leq 0.0004$ for all). Natriuretic peptides were stronger predictors of HFrEF [hazard ratio (HR) 2.00 per 1 standard deviation increase, 95% confidence interval (CI) 1.81–2.20] than of HFmrEF (HR 1.51, 95% CI 1.20–1.90, $p = 0.01$ for difference), and did not differ in their association with incident HFmrEF and HFpEF (HR 1.56, 95% CI 1.41–1.73, $p = 0.68$ for difference). All-cause mortality following the onset of HFmrEF was worse than that of HFpEF (50 vs. 39 events per 1,000 person-years, $p = 0.02$), but comparable to that of HFrEF (46 events per 1,000 person-years, $p = 0.78$). They found overlap in predictors of incident HFmrEF with other HF subtypes. In contrast, mortality risk after HFmrEF was worse than HFpEF, and similar to HFrEF.

Therapeutic Implications

Patients with LVEF between 40 and 50% were sometimes included in HFpEF trials, when the cut-off point for inclusion

was LVEF more than 45%, but the patients with HFmrEF were not studied as a separate entity. Therefore, specific therapeutic evidence for this group of patients with HFmrEF is lacking. As the patients with HFmrEF, have to some extent, been included in trials of HFpEF, rather than in HFrEF, the 2016 ESC guidelines for the diagnosis and treatment of acute and chronic heart failure² recommended that they should be treated as patients with HFpEF, until further evidence demonstrating a prognostic difference between these two categories emerge.

Comorbidity control should be the prime target for the management of HFmrEF. Both cardiovascular diseases (CVD) (atrial fibrillation, hypertension, coronary artery disease, and pulmonary hypertension) and noncardiovascular diseases [diabetes, CKD, anemia, iron deficiency, chronic obstructive pulmonary disease (COPD), and obesity] should be looked into and managed optimally.

Similarly, precipitating factors should be prevented and/or rapidly managed. In the GWTG-HF registry of patients hospitalized for HF the most common precipitants for hospitalization were pneumonia/respiratory process (28%), arrhythmia (22%), medication noncompliance (16%), worsening renal failure (15%), and uncontrolled hypertension (15%), regardless of the baseline EF group.⁵

Diuretics should be used only if signs or symptoms of congestion are present; they represent the hallmark of symptom relief therapy, but have no influence on mortality. There is no specific recommendation for diuretic usage depending on LVEF, but rather a clinical judgment, depending on symptoms.

As the HFmrEF patients often have comorbidities such as hypertension, atrial fibrillation or ischemic heart disease (IHD), they often receive β -blockers and angiotensin-converting enzyme (ACE) inhibitors or angiotensin-receptor blockers (ARBs), and rarely mineralocorticoid receptor antagonist (MRA), in different combinations.¹⁴ These are the drugs known to have prognostic impact on HFrEF, and same expectation is there while treating patients with HFmrEF. However, future studies on this subset of patients are needed.

In diabetes mellitus, sodium-glucose co-transporter type 2 (SGLT2) inhibitors modestly lower glycated hemoglobin A1c (HbA1c). But in EMPA-REG (10% HF at baseline), empagliflozin reduced HF hospitalization by 35%,¹⁵ and in CANVAS (14% HF at baseline), canagliflozin reduced HF hospitalization by 33%.¹⁶ This has generated considerable interest in SGLT2 and also SGLT2/1 inhibition in HF^{17,18} and several trial programs are underway¹⁹ to address whether SGLT2/1 inhibitors in combination with diuretics can improve outcomes in prevalent HF with HFrEF, HFmrEF, and/or HFpEF, in patients with and without diabetes.

Heart Failure with Recovered Ejection Fraction²⁰

For patients with HFrEF, improving left ventricular (LV) reverse remodeling is an important goal. This may be achieved via multiple measures, including neurohormonal blockade, revascularization, resynchronization therapy, and mechanical

unloading, etc. Not every patient responds to these measures in the same manner. Factors that are associated with better reverse remodeling include female sex, younger age, shorter HF duration, lack of a left bundle branch block, higher baseline BP, a nonischemic etiology, etc. These treatment responders may achieve improvement in the EF and reduced LV size. They may improve from HFrEF to HFmrEF and even normalized EF to more than or equal to 50%.

CONCLUSION²¹

The 2016 ESC guidelines introduced the term HFmrEF, corresponding to the previously denoted “grey area” EF 40–49%. But, one should remember EF is not the ideal marker to classify HF. EF also may change with time and treatment. Around 17–34% of patients with HF may improve to a higher category with appropriate management, more common in absence of IHD.²² Other modalities may better characterize HF, e.g., global longitudinal strain, but their impact and feasibility in routine clinical practice are yet to be seen. Utilizing multiple markers and personalized approaches to HF may improve characterization and classification in HF.

Heart failure with midrange EF is intermediate regarding certain characteristics, and it resembles HFrEF regarding age, preponderance of male sex, greater prevalence of IHD, and greater prognostic impact of CKD.

In an individual patient-level meta-analysis from RCTs, β -blockers were not effective in atrial fibrillation (AF), but in sinus rhythm, they reduced all-cause and CV mortality in HFrEF and HFmrEF but not HFpEF.²³ In a post-hoc analysis from CHARM (Candesartan in Heart failure: Assessment of Reduction in Mortality and Morbidity), candesartan reduced the composite of CV death and HF hospitalization in HFrEF (where 57% received concomitant ACE inhibitor), and HFmrEF (27% ACE inhibitor) but not HFpEF (16% ACE inhibitor).²⁴

Despite significant research done in the field of HFmrEF, further data collection and pragmatic and well-designed trials are needed to form appropriate guidelines.

Monitoring Therapy in Heart Failure with Reduced Ejection Fraction

Soura Mookerjee

INTRODUCTION

Once any difficulties regarding the diagnosis of heart failure (HF) have been overcome, the question of how best to manage patients in the long-term arises. Successful management includes monitoring in addition to treatment of HF.

Nothing can substitute for a careful history and physical examination. However, it necessitates adequate time available for well-trained health professionals and full examination of each patient's chest, jugular venous pressure (JVP), abdomen, and periphery as well as measurement of arterial pressure in the supine and standing positions. Especially useful are accurate examination of the JVP and auscultation for a third heart sound, both necessitating observer experience. A low blood pressure that falls further with upright posture indicates deterioration in left ventricular (LV) function and/or volume depletion, the latter necessitating reduction in diuretic dose or relaxation of restriction on dietary sodium intake. Uncontrolled hypertension, on the other hand, is one precipitant of hospital readmission for HF.

Body weight standardized to time of day and clothing, should preferably be recorded regularly by the patient at home as well as in the clinic. This can detect sodium and water retention (increased weight) and overdiuresis or cardiac cachexia (weight loss). Plasma electrolytes and renal function should be measured every few months and more frequently when there is clinical deterioration.

TRIALS OF BIOMARKER-GUIDED THERAPY FOR HEART FAILURE (TABLE 1)

Since 2000, several randomized controlled trials have reported the efficacy of serial measurements of plasma B-type peptides in titration of therapy for chronic HF.¹ Trials were heterogeneous with respect to design, patient characteristics duration of follow-up, end points, and target peptide concentrations. However, there was an overall consistency as supported by two meta-analyses.^{2,3}

The first of these was a pilot study from Christchurch, New Zealand reported in 2000 with 69 patients. Significantly, fewer deaths or admissions with newly decompensated HF were observed in the hormone-guided group. This small, but positive, study was the sole contribution to the field until 2007, when the French multicenter STARS-BNP was reported.⁴

The GUIDE-IT (Guiding Evidence Based Therapy Using Biomarker Intensified Treatment in Heart Failure) study⁵ was planned for 1,100 patients with ejection fraction (EF) of 40% or less, elevated natriuretic peptide and history of a prior HF event. Patients were assigned patients to a guided strategy in which HF therapy was titrated with the goal of N-terminal prohormone of brain natriuretic peptide (NT-proBNP) less than 1,000 pg/mL or to the usual guideline-directed care. The primary endpoint was a composite of time to first HF hospitalization or cardiovascular (CV) mortality.

The trial was stopped for futility by the data safety and monitoring board after 864 patients were enrolled due to a lack of benefit in the biomarker guided arm. As quoted from an editorial "Perhaps the most likely explanation for the outcomes observed in the GUIDE-IT trial is that when clinical care follows guidelines and addresses the key issues, biomarkers do not make a difference and that guideline-directed care, if achieved, is more efficient and can lead to outcomes similar to biomarker-guided care".

Thus the failure of the GUIDE-IT was a big blow to the biomarker-guided approach to tailor HF medications.

MULTIDISCIPLINARY CARE APPROACH TO THE MANAGEMENT OF HEART FAILURE PATIENTS

The multidisciplinary HF care approach includes:

- Standard care (i.e., in person follow-up visits) and
- Alternative approaches (regularly scheduled telephone contact between patient and health care specialist by electronic transfer of physiological data using remote

TABLE 1: Trials of biomarker-guided therapy for heart failure

Trials	Year	No. of patients	Follow up	Target proBNP	Primary endpoint	Result
New Zealand	2000	69	9 months	<1,700 pmol/L	Death + admissions	+
STARS-BNP	2006	220	15 months	<1,000 pg/mL	Death due to HF	+
					Death + hospitalizations	+
					All-cause mortality	-
TIME-CHF	2009	499	18 months	BNP level 2 times less ULN and NYHA to II	Event free survival and QoL	-
BATTLESCARRED	2009	364	3 years	NT-proBNP <1,300 pg/mL	Mortality	+ (for age <75 years)
PRIMA	2010	345	702 days	NT-proBNP <2,491 pg/mL	Days alive out of hospital	-
PROTECT	2010	151	10 months	NT-proBNP <1,000 pg/mL	Total cardiovascular events	+
SIGMA-HF	2010	252	9 months	NT-proBNP <800 male <1,000 female	Days alive, days out of hospital and symptom score	-
STARBRITE	2011	130	90 days	BNP level. Congestion score	Death/hospitalizations	-
GUIDE-IT	2017	864	15 months	NT-proBNP <1,000 pg/mL	Time to first HF hospitalization and CV mortality	(Halted)

BNP, brain natriuretic peptide; HF, heart failure; NYHA, New York Heart Association; QoL, quality of life; ULN, upper level of normal; NT-proBNP, N-terminal prohormone of brain natriuretic peptide; CV, cardiovascular.

access technology. These alternative approaches may decrease the number of office visits and increase the efficiency of treatment of HF).

REMOTE MONITORING OF HEART FAILURE: TOOLS AND RESULTS

Structured Transtelephonic Support and Telemonitoring of Heart Failure Patients

Inglis et al. analyzed 41 randomized clinical trials comparing structured telephone support (25 studies, 9,332 patients) and telemonitoring (18 studies, 3,860 patients) with standard care for HF.⁶ A significant reduction in all-cause mortality and HF hospitalizations was achieved with telemonitoring.

Telemonitoring involved an interactive voice-response system that transmitted daily information about symptoms and weight to the clinicians. Just over half of patients in the telemonitoring group actually used the system. Fourteen percent of patients never used the system.

However, the TIM-HF (Telemedical Interventional Monitoring in Heart Failure) study⁷ failed to show a benefit.

Thus telemonitoring for HF though promising has not yet conclusively proven to be of benefit.

Remote Monitoring with Implanted Therapeutic Devices

The number of HF patients with cardiac implantable electronic devices (CIEDs) has increased in recent decades. A substantial number of modern CIEDs are equipped with remote monitoring

capabilities. Remote monitoring of implantable cardioverter defibrillators (ICDs) and cardiac resynchronization therapy (CRT) devices allow wireless download and stored diagnostic information from device to an external transmitter and transfer to the manufacturer's database and available to the clinician through a specific interface.

Furthermore, technical features of the devices [anti-tachycardia pacing, direct current (DC) shock, ventricular pacing percentage] and so-called "HF diagnostic" parameters, such as thoracic impedance, heart rate variability, presence of arrhythmias, patients' activity level, mean heart rate at rest and exertion, can also be remotely monitored.

Remote monitoring may play an important role in the early diagnosis and management of system-related complications in patients with implanted CIEDs.⁸ The majority of which are lead-related complications (insulation defect or conductor disruption). The TRUST (The Lumos-T Safely RedUceS RouTine Office Device Follow-Up) trial⁹ and ECOST trial¹⁰ have shown the beneficial effect of remote monitoring. Spencker et al. in a retrospective cohort analysis of 54 patients with an ICD lead failure¹¹ have shown that in 91% of all lead-related ICD complications, the diagnosis could be established correctly by an alert from the remote monitoring system.

Detection of Hemodynamic Deterioration in Heart Failure Patients

Many commercially available CIEDs can measure intrathoracic impedance which changes with volume overload in the pulmonary circulation caused by an elevated LV filling pressure.

While Yu et al.¹² and Abraham et al.¹³ demonstrated the superiority of impedance monitoring, the SENSE-HF (Sensitivity of the InSync Sentry OptiVol feature for the prediction of Heart Failure) trial (501 patients) showed that an intracardiac impedance-derived fluid index had low sensitivity and positive predictive value.¹⁴ Similar disappointing results have been demonstrated in the DOT-HF (Diagnostic Outcome Trial in Heart Failure) study.¹⁵

The PARTNERS-HF (Program to Access and Review Trending Information and Evaluate Correlation to Symptoms in Patients With Heart Failure) trial¹⁶ showed that in patients with implanted CRT-Ds reduced impedance was the most sensitive parameter to predict HF hospitalizations. Cowie et al. developed and validated a dynamic HF score based on the following parameters monitored by implanted ICDs or CRTs: intrathoracic impedance, heart rate variability, arrhythmia burden, and patient activity.¹⁷ The IN-TIME (Implant-Based Multiparameter Telemonitoring of Patients with Heart Failure) trial¹⁸ also showed that composite clinical score and mortality were significantly lower in the telemonitoring group versus standard monitoring group. However, the world's largest remote monitoring study REM-HF (Remote Management of Heart Failure Using Implantable Electronic Devices) trial¹⁹ presented at the ESC Congress 2016 and the MORE-CARE (The MOnitoring Resynchronization dEvices and CARdiac patiEnts) trial with biventricular ICD²⁰ turned out to be negative trials.

A meta-analysis of the TRUST, ECOST, and INTIME trials²¹ demonstrated that remote monitoring with BIOTRONIK Home Monitoring was associated with a 38% reduction in all-cause mortality compared to conventional office follow-ups. The combined risk of all-cause mortality or

hospitalization for HF decompensation was 36% lower in the remote monitoring group.

The presented results demonstrate that significant differences exist between devices from different manufacturers which can have an impact on their effectiveness.

Detection of Sleep Disorders in Heart Failure by Remote Monitoring (Table 2)

Patients with HF often complain of sleep disorders such as sleep fragmentation or nonrestorative sleep, difficulties in initiating sleep, or waking up too early in the morning.²² Additionally, HF patients can have secondary insomnia due to HF itself or from the adverse effects of prescribed medications.²³ CIEDs with incorporated sleep apnea monitoring (SAM) system can detect, count, and report breathing disorders during the night.

Remote Monitoring by Implanted Monitoring-only Devices (Table 2)

Implanted monitoring-only devices are hemodynamic monitors measuring intracardiac or intravascular pressures. Examples are:

- Chronicle (Medtronic) studied in COMPASS-HF (Chronicle Offers Management to Patients with Advanced Signs and Symptoms of Heart Failure)²⁴
- Cardio-MEMS (St Jude Medical, acquired by Abbott) studied in CHAMPION (The CardioMEMS Heart Sensor Allows Monitoring of Pressure to Improve Outcomes in NYHA Class III Heart Failure Patients)²⁵
- HeartPOD device (St Jude Medical) studied in HOMEOSTASIS.²⁶

TABLE 2: Major studies demonstrating role of remote monitoring in heart failure

Study	No. of patients	Study protocol	Results
Structured transtelephonic support and telemonitoring of HF patients			
Tele-HF	1,653	Telemonitoring care vs. usual care	<ul style="list-style-type: none"> • Readmission rates – NS • Deaths – NS
TIM-HF	710	Telemedical care vs. usual care	Hospitalization rates – NS
Remote monitoring with implanted therapeutic devices—detection of heart rhythm disorders			
ASSERT	2,580	Patients with implanted CIEDs, 2.5 years of follow-up. Newly detected AF episodes (with >6 min of duration) were counted	Newly detected AF episode detected in 34.7%
TRENDS	1,368	Patients without history of AF enrolled. Newly detected AF episodes (with >5 min of duration) were counted	Newly detected AF episode detected in 30%
TRUST	1,339	Remote monitoring vs. standard care	AF detection earlier (5.5 days) in remote monitoring group vs. 40 days with standard care
CONNECT	1,997	ICD implanted patients	Patients with implanted ICDs were involved 3 vs. 24 days interval between AF episodes detection and clinical response in the remote monitoring vs. standard follow-up groups

Continued

Study	No. of patients	Study protocol	Results
COMPAS	538	Remote monitoring vs. standard care (18.3 months)	<ul style="list-style-type: none"> • 17.3% vs. 19.1% ($p < 0.01$ for noninferiority) patients experienced at least one major adverse event (all-cause death, hospitalizations for device-related or CV events) in remote monitoring standard care • Fewer hospitalizations for atrial arrhythmias (6 vs. 18) and strokes (2 vs. 8) ($p < 0.05$) • 56% less interim ambulatory visits in the remote monitoring vs. standard care group ($p < 0.001$)
Detection and management of system-related complications in patients with implanted CIEDs			
ECOST	40	Patients with high-voltage leads with 22 ± 4 months of follow-up	Lead failure registered in 7.5%
Detection of heart failure worsening in hemodynamics			
SENSE-HF	501	Intracardiac impedance-derived fluid index measurement	Low-sensitivity and positive predictive value in the early period after implantation (6 months), though sensitivity improved within the first 6 months after implantation
DOT-HF	335	Patients with implanted CIEDs. Randomized to have information available to physicians and patients as an audible alert in case of preset threshold crossings (access arm) or not (control arm)	Routine monitoring of intrathoracic impedance did not show better outcome and associated with more HF hospitalization
PARTNERS-HF	694	Patients with implanted CRT-Ds followed-up for 11.7 ± 2 months	Reduced impedance/increased fluid index was the most sensitive parameter to predict HF hospitalizations
IN-TIME	664	NYHA II and III patients with implanted ICDs and CRTDs randomized to standard vs. remote monitoring (in response to telemonitoring observations the investigators did a standardized telephone interview to confirm worsening of patient's overall condition or symptoms, or sudden increase in body weight (>2 kg in preceding 3 days) or scheduled visit to family doctor arms	<ul style="list-style-type: none"> • 63 patients (18.9%) with worsened composite clinical score in the telemonitoring group vs. 90 patients (27.2%) in the control group ($p = 0.013$) • Mortality lower in telemonitoring vs control group ($n = 10$ vs. 27) • No significant differences in hospitalization
REM-HF	1,650	Patients with implanted CIEDs (ICD, CRTP, and CRT-D) with remote monitoring facility randomized to usual care or remote monitoring, with follow-up of 2.8 years. Management of patients with remote monitoring was based on the data healthcare professional received on a weekly basis. Patients in usual care group had a usual care from heart failure service and remote monitoring of the device (once per 3–6 months)	No significant difference in the primary (death from any cause or unplanned CV hospitalization) and secondary (death from any cause, CV death) unplanned hospitalization end points
MORE-CARE	865	Patients with implanted CRT-Ds randomized into remote and standard follow-up arms	<ul style="list-style-type: none"> • No significant difference in the composite of death and hospitalization due to CV and device-related reasons between these two groups • Sign 38% reduction in healthcare resources use in the remote arm (2-year rates of CV hospital, CV emergency admissions, and CV in-office follow up) compared with the standard arm
Detection of sleep disorders: the potential implementation of remote monitoring			
DREAM	40	Patients with implanted CIEDs and incorporated sleep apnea monitoring (SAM) algorithm were enrolled. Sleep apnea diagnosis was confirmed by polysomnography as a gold standard diagnostic technique and compared with the respiratory disturbances index evaluated by the SAM algorithm	<ul style="list-style-type: none"> • 88.9% sensitivity (95% CI 65.3–98.6%) • 88.9% positive predictive value (95% CI 65.3–98.6%) • 84.6% specificity (95% CI 54.6–98.1%)

Continued

Continued

Study	No. of patients	Study protocol	Results
Remote monitoring with implanted monitoring-only devices			
COMPASS-HF	274	Patients were randomized into chronic device and standard groups	<ul style="list-style-type: none"> Reduction in HF admissions or urgent follow-up visits in chronic group by 21% ($p = 0.33$) ns Statistically significant 36% reduction in relative risk of time to first hospitalization
REDUCE-HF	1,300	Patients with an indication of ICD implantation evaluated (ICD implantation with an RV pressure monitoring)	<ul style="list-style-type: none"> The trial was prematurely terminated due to technical complications No benefit from hemomonitor
CHAMPION	550	NYHA Class III patients randomized into the CardioMEMs and usual monitoring groups	<ul style="list-style-type: none"> Statistically significant reduction in HF hospitalization (regardless of LV ejection fraction) by 28% and 37% in the CardioMEMS group over 6- and 15-month follow up respectively Non-HF-related hospitalizations were similar. CardioMEMS group had a significant reduction in the mean PAP and better QoL during the 6-month follow up (Minnesota Living with Heart Failure Questionnaire)
HOMEO-STASIS	40	NYHA class III-IV HF patients received a HeartPOD device to directly measure LA pressure The follow-up period was divided into the first blinded (3 months), the second titration (3 months) and the third stability periods (19 months)	<p>HeartPOD group had statistically significant:</p> <ul style="list-style-type: none"> Improved control of LA pressure Improved NYHA class More optimal neurohormonal antagonist dosing 59% reduction of clinical events in the titration and stability period vs. observation period

AF, atrial fibrillation; CIED, cardiac implantable electronic device; CI, confidence interval; CV, cardiovascular; CRTD, cardiac resynchronization therapy defibrillator; CRTP, cardiac resynchronization therapy pacemaker; HF, heart failure; ICD, implantable cardioverter defibrillator; LA, left atrial; NYHA, New York Heart Association; QoL, quality of life; RV, right ventricle.

Despite the theoretical advantage of implantable hemodynamic monitoring devices, the sensitivity for such approach needs to be validated in large randomized trials.

CONCLUSION

- Biomarker-guided therapy for HF is a new avenue to tailor HF medications
- Telemonitoring of HF patients can obviate the need for frequent physical examination of heart failure patients
- Remote monitoring through implanted devices can provide valuable information regarding hemodynamic parameters, sleep disorders, and implanted device-related complications
- None of the above approaches have till date unequivocally demonstrated their efficacy in randomized trials and presently do not supercede a meticulous clinical evaluation of heart failure patients.

Stepwise Approach to Acute Decompensated Heart Failure

BP Singh, Ravi V Prasad, Nirav Kumar

INTRODUCTION

Acute heart failure (AHF) is defined as new-onset or recurrence of sign and symptoms of heart failure (HF) requiring emergent therapy and hospitalization.¹ In most cases, it is due to deterioration of symptoms in previous HF. Acute coronary syndrome (ACS), myocarditis, acute valve regurgitation, and cardiac tamponade are some important causes of AHF diagnosed for the first time.² Many terms have been used to characterize AHF which include AHF syndromes, acute decompensated heart failure (ADHF), and acute decompensation of chronic HF requiring hospitalization. The term ADHF will be used in this review. Despite marked improvement in treatment and survival of chronic HF, outcomes of ADHF remain still poor with recurrent rehospitalization and 1-year mortality rates reaching 10–30%.³

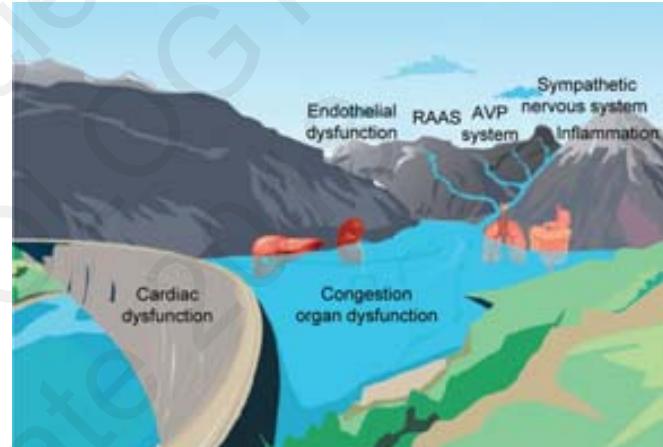

PATOPHYSIOLOGY

In ADHF patients, three neurohormonal pathways viz., sympathetic nervous system, renin–angiotensin–aldosterone system and arginine–vasopressin system, are activated to counteract the negative effects of HF. There is impaired excretion of sodium through the kidneys resulting in sodium and water retention (Fig. 1).⁴ Raised cardiac filling pressures and venous congestion are observed prior to the frank features of clinical decompensation.⁵

EVALUATION OF THE PATIENT WITH ACUTE DECOMPENSATED HEART FAILURE

Acute decompensated heart failure is a life-threatening condition and treatment should be initiated at the earliest after the hospitalization of these patients.⁶ The initial evaluation of ADHF includes:

- Establishing diagnosis as rapidly and effectively

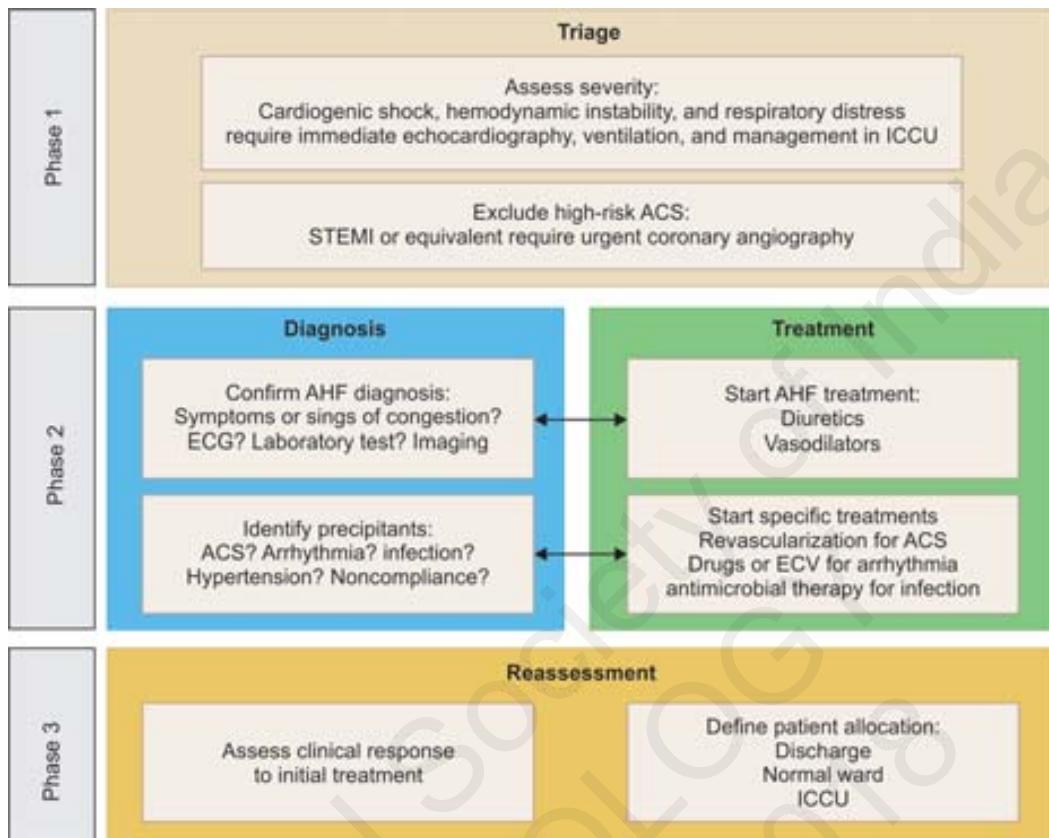

AVP, arginine-vasopressin; RAAS, renin–angiotensin–aldosterone system.

FIG. 1: Congestion in heart failure.

- Emergent treatment for potentially life-threatening conditions (e.g., circulatory failure, respiratory failure)
- Identifying any precipitating causes and their treatment (Box 1)
- Risk stratification for triage of patients (Fig. 2).

History and physical examination should primarily focus on the presence of congestion which is the typical feature of ADHF. Left-sided congestion may cause dyspnea, cough, orthopnea, paroxysmal nocturnal dyspnea, tachypnea, abnormal lung auscultation (rales, crackles, and wheezing) and finally, hypoxia.^{7,8} Right-sided congestion may cause bilateral peripheral edema, decreased urine output, abdominal pain, nausea, and vomiting, jugular vein distention or positive hepatojugular reflux, ascites, hepatomegaly and/or icterus.⁷ Hypotension, tachycardia, weak pulse, mental confusion, anxiety, fatigue, cold sweated extremities, and decreased urine output indicate signs and symptoms of hypoperfusion and thus, severity of the condition. Cardiogenic shock is the most severe form of ADHF characterized by reduced stroke volume, decreased systolic blood pressure (SBP), and clinical

ACS, acute coronary syndrome; ECV, electrical cardioversion; ECG, electrocardiograph; ICCU, intensive cardiac care unit; STEMI, ST-elevation myocardial infarction.

FIG. 2: Early management and triage of acute decompensated heart failure.

BOX 1 Factors triggering acute heart failure¹

- Acute coronary syndrome
 - Tachyarrhythmia
 - Excessive rise in blood pressure
 - Infection
 - Nonadherence with salt/fluid intake or medications
 - Brady arrhythmia toxic substances
 - Toxic substances
 - Drugs (NSAIDs, corticosteroids, negative isotropic substances, cardiotoxic, and chemotherapeutics)
 - Exacerbation of chronic obstructive pulmonary disease
 - Pulmonary embolism
 - Surgery and perioperative complications
 - Increased sympathetic drive, stress-related cardiomyopathy
 - Metabolic/hormonal derangements
 - Cerebrovascular insult
 - Acute mechanical cause: Myocardial rupture complicating acute coronary syndrome (free wall rupture, ventricular septal defect, acute native or prosthetic valve incompetence secondary to endocarditis, aortic dissection or thrombosis)
- NSAIDs, nonsteroidal anti-inflammatory drugs.

		No congestion (dry)	Congestion (wet)	
		Good perfusion (warm)	Warm and wet: PCWP elevated, CI normal	Diuretic: Furosemide bumetanide
Poor perfusion (cold)	Good perfusion (warm)	Warm and dry: PCWP normal, CI normal (compensated)		
	Poor perfusion (cold)	Cold and dry: PCWP low-normal, CI decreased	Cold and wet: PCWP elevated, CI decreased	Aquaretic/natriuretic: Tolvaptan nesiritide
		Inotrope: Dobutamine milrinone	Vasodilator: Nitroglycerine nitroprusside	

PCWP, pulmonary capillary wedge pressure; CI, cardiac index.

FIG. 3: Classification of patients presenting with acutely decompensated heart failure.

Based on presence/absence of congestion and hypoperfusion, patients are classified into four groups (Fig. 3).¹¹ They are “wet-warm” (congested but well perfused), “wet-cold” (congested and hypoperfused), “dry-cold” (not congested and hypoperfused) and lastly, “dry-warm” (decongested, well-perfused). This classification may help to guide initial therapy (mostly vasodilators and/or diuretics) and carries prognostic information.¹²

signs of hypoperfusion.⁹ This form of ADHF carries very high in-hospital mortality rate of about 40–50%.¹⁰

RELEVANT INVESTIGATIONS

- Chest X-ray:* It should be routinely done and provides useful information in the diagnosis of ADHF. Pulmonary venous congestion, pleural effusion, interstitial or alveolar edema, and cardiomegaly are the most important findings in ADHF patients. Chest X-ray is also useful to identify alternative noncardiac diseases i.e., pneumonia, pulmonary infections, etc.⁸
- Electrocardiogram (ECG):* It is rarely normal in ADHF. It is helpful in identifying underlying cardiac disease and potential precipitants (rapid atrial fibrillation and acute myocardial ischemia)¹³
- Echocardiography:* It is done immediately only in patients with hemodynamic instability (particularly in cardiogenic shock) and suspected life-threatening structural or functional cardiac abnormalities (mechanical complications, acute valvular regurgitation, and aortic dissection)¹
- Natriuretic peptides (NP):* Upon presentation, a plasma NP level [B-type natriuretic peptide (BNP), N-terminal pro-B-type natriuretic peptide (NT-proBNP)] should be measured in all patients for differentiating ADHF from noncardiac causes of acute dyspnea. NPs have high sensitivity and normal levels in suspected ADHF make the diagnosis unlikely (thresholds: BNP <100 pg/mL, NT-proBNP <300 pg/mL). Elevated levels of NPs do not always confirm the diagnosis of ADHF, as they may also be associated with a wide variety of cardiac and noncardiac causes¹⁴
- Other laboratory tests should be performed at admission on all patients with ADHF:* Cardiac troponin, blood urea nitrogen, creatinine, electrolytes, liver function tests, thyroid stimulating hormone, glucose, and complete blood count. D-dimer is indicated in patients with a suspicion of acute pulmonary embolism.¹

Routine arterial blood gas (ABG) is not needed and should be restricted to patients in whom oxygenation cannot be readily assessed by pulse oximetry.¹

Cardiac troponins measurement is useful for detection of ACS as the underlying cause of ADHF. However, elevated concentrations of cardiac troponins are detected in ADHF, even without obvious myocardial ischemia or an acute coronary event, suggesting ongoing myocyte injury or necrosis in these patients. Also in acute pulmonary embolism, elevated troponins are seen.¹⁵

Routine invasive hemodynamic evaluation with a pulmonary artery catheter is not indicated for the diagnosis of ADHF. It may be helpful in selected cases of hemodynamically unstable patients with an unknown mechanism of deterioration.¹

MANAGEMENT GOALS

All ADHF patients require rapid transfer to the nearest hospital preferably to a site with a cardiology department with intensive care unit. Early diagnosis is important in ADHF. All patients with suspected ADHF should have a diagnostic workup, appropriate pharmacological, and non-pharmacological treatment started promptly and in parallel.

Patients with respiratory distress/failure or hemodynamic compromise should be triaged to a location where immediate respiratory and cardiovascular support can be provided (Flowchart 1).

TREATMENT OF ACUTE HEART FAILURE

Oxygen and/or Ventilatory Support

In ADHF, oxygen should not be used routinely in nonhypoxemic patients, as it causes vasoconstriction and a reduction in cardiac output. It is only recommended when $\text{SpO}_2 <90\%$ or $\text{PaO}_2 <60 \text{ mm Hg}$ to correct hypoxemia.¹⁶ During oxygen therapy, ABG and SpO_2 should be monitored. Noninvasive positive pressure ventilation [continuous positive airway pressure (CPAP), bilevel positive airway pressure (BiPAP)] should be considered in patients with respiratory distress (respiratory rate >25 breaths/min, $\text{SpO}_2 <90\%$) and started as soon as possible to decrease respiratory distress and reduce the rate of mechanical endotracheal intubation. Noninvasive positive pressure ventilation can reduce blood pressure and should be used with caution in hypotensive patients. Intubation is recommended, if respiratory failure, leading to hypoxemia ($\text{PaO}_2 <60 \text{ mm Hg}$), hypercapnia ($\text{PaCO}_2 >50 \text{ mm Hg}$) and acidosis ($\text{pH} <7.35$), cannot be managed noninvasively.¹⁷

A management algorithm for patients with ADHF based on the clinical profile during an early phase is presented in flowchart 2.

Identification of Precipitants/Causes Leading to Decompensation that Needs Urgent Management¹

The next step should be the identification of major precipitants/causes leading to decompensation, which should be managed urgently to avoid further deterioration. These include the following:

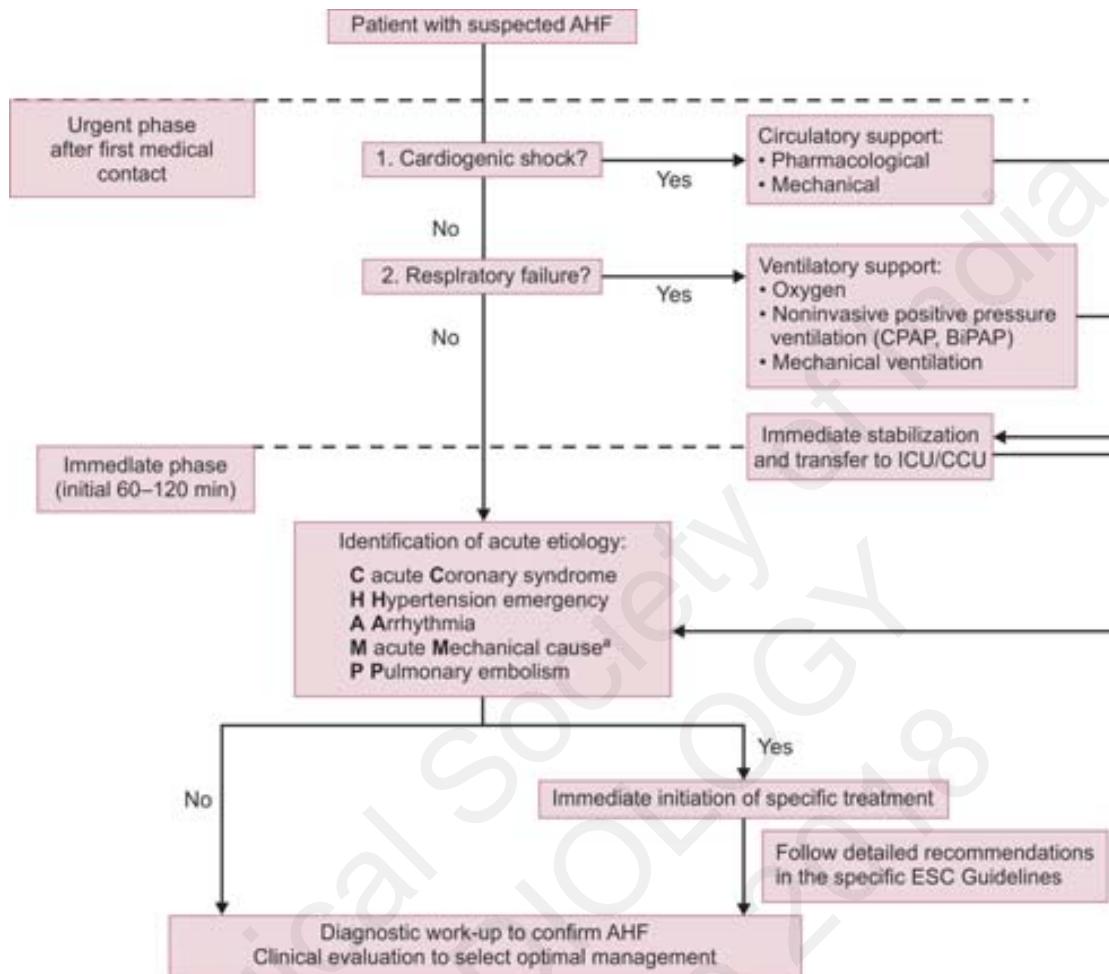

CHAMP, pulmonary infection, severe anemia, acute renal failure.¹

- Acute Coronary syndrome
- Hypertensive emergency
- Rapid Arrhythmias or severe bradycardia/conduction disturbance
- Acute Mechanical cause underlying HF
- Acute Pulmonary embolism
- Pulmonary infection
- Severe anemia
- Acute renal failure.

Pharmacological Therapy

Diuretics

Diuretics play important role in the treatment of ADHF especially with signs of fluid overload and congestion. Diuretics increase salt and water excretion. In patients with signs of hypoperfusion, diuretics should be avoided. Intravenous loop diuretics are recommended to improve symptoms rapidly.¹⁸ It

AHF, acute heart failure; BiPAP, bilevel positive airway pressure; CPAP, continuous positive airway pressure; CCU, coronary care unit; ESC, European Society of Cardiology; ICU, intensive care unit.

FLOWCHART 1: Overall management of a patient with acute heart failure.¹

is recommended to regularly monitor symptoms, urine output, renal function, and electrolytes during use of intravenous diuretics. Current evidence demonstrates that there is no significant difference in symptoms or changes in renal function when loop diuretics are administered as a bolus compared to continuous infusion or at a high dose compared to a low dose. Furthermore, no difference appears to exist in the safety and efficacy of bolus injection compared to continuous infusion of loop diuretics.¹⁹ Combination of loop diuretic with either thiazide-type diuretic or spironolactone may be considered in patients with resistant edema or insufficient symptomatic response.

Vasodilators

Intravenous vasodilators are the second most often used agents in ADHF for symptomatic relief. They have dual benefit by decreasing venous tone (to optimize preload) and arterial tone (decrease afterload). Consequently, they also increase stroke volume. Vasodilators are especially useful in patients with hypertensive ADHF, whereas in those with SBP

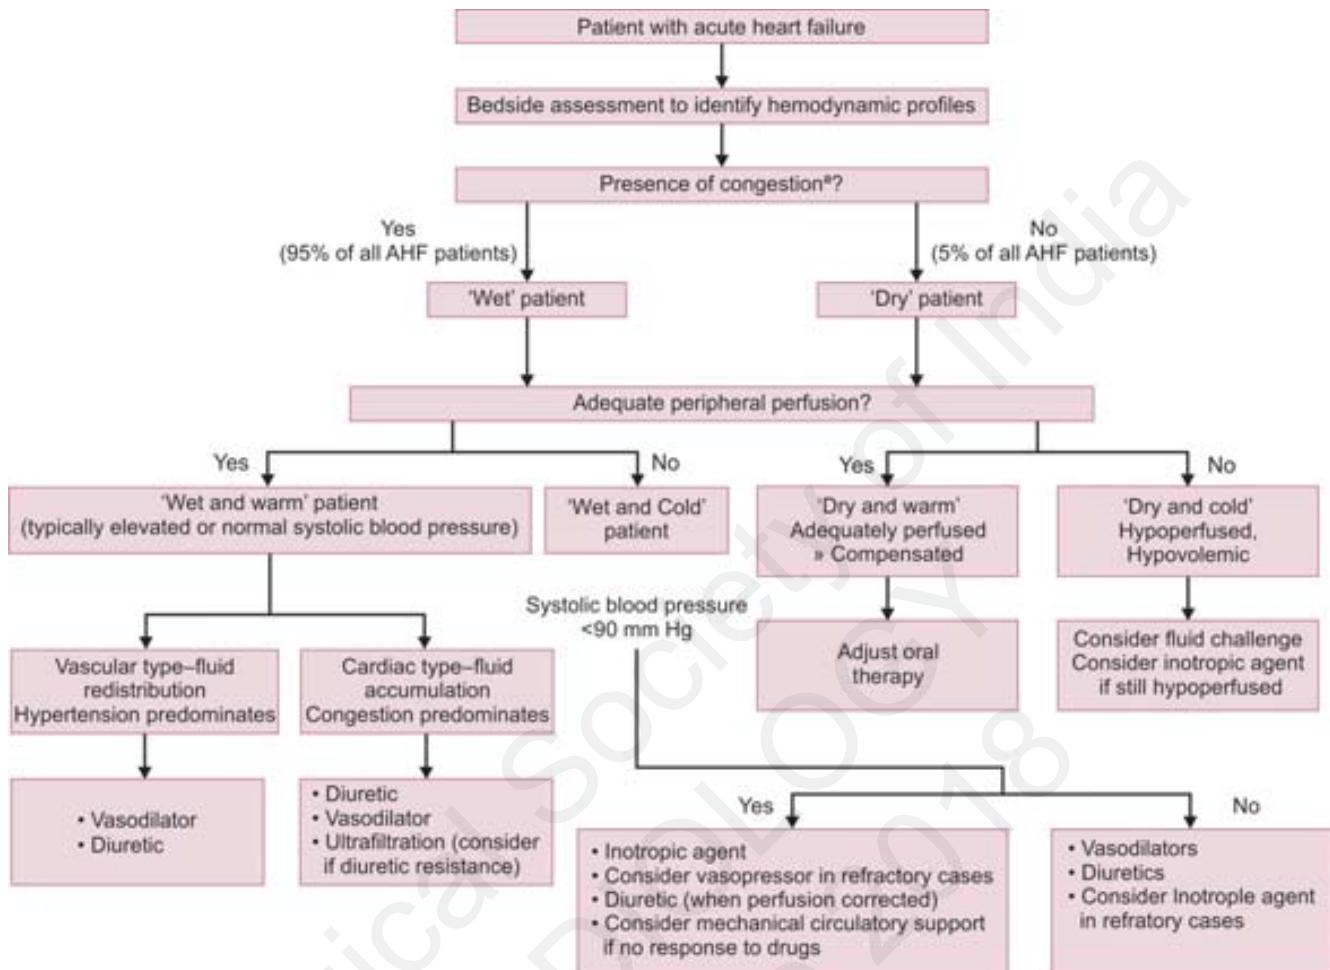

<90 mm Hg (or with symptomatic hypotension), they should be avoided. Dosing should be carefully controlled to avoid excessive decreases in blood pressure.^{20–22} They should be used with caution in patients with significant mitral or aortic stenosis (Table 1).

Inotropic Agents

Use of inotropes like dobutamine, dopamine, levosimendan, phosphodiesterase III (PDE III) inhibitors should be reserved for patients with a severe reduction in cardiac output resulting in compromised vital organ perfusion, which occurs most often in hypotensive ADHF.²³ Levosimendan is preferable over dobutamine to reverse the effect of beta-blockade if beta-blockade is thought to be contributing to hypoperfusion.²⁴ Inotropes, especially those with adrenergic mechanisms may cause myocardial ischemia and arrhythmias, thus, ECG monitoring is required. There is long-standing concern that they may increase mortality. In any case, inotropes must be used with caution starting from rather low doses and up-titrating with close monitoring (Table 2).²⁵

SECTION 13

Heart Failure

FLOWCHART 2: Management of patients with acute heart failure based on clinical profile during an early phase 1.

TABLE 1: Intravenous vasodilators used to treat acute decompensated heart failure (ADHF)¹

Vasodilator	Dosing	Main side effects	Other
Nitroglycerine	Start with 10–20 µg/min increase up to 200 µg/min	Hypotension, headache	Tolerance on continuous use
Isosorbide dinitrate	Start with 1 mg/h, increase up to 10 mg/h	Hypotension, headache	Tolerance on continuous use
Nitropusside	Start with 0.3 µg/kg/min, increase up to 5 µg/kg/min	Hypotension, isocyanate toxicity	Light sensitive
Nesiritide	Bolus 2 µg/kg + infusion 0.01 µg/kg/min	Hypotension	–

TABLE 2: Positive inotropes and/or vasopressors used to treat acute decompensated heart failure¹

Vasodilator	Bolus	Infusion rate
Dobutamine	No	2–20 µg/kg/min (β+)
Dopamine	No	3–5 µg/kg/min: inotropic (β+)
Milrinone	25–75 µg/kg over 10–20 min	0.375–0.75 µg/kg/min
Enoximone	0.5–1.0 mg/kg over 5–10 min	5–20 µg/kg/min
Levosimendan	12 µg/kg over 10 min(optical)	0.1 µg/kg/min which can be decreased to 0.05 or increased to 0.2 µg/kg/min
Norepinephrine	No	0.2–1.0 µg/kg/min
Epinephrine	Bolus: 1 mg can be given IV during resuscitation, repeated every 3–5 min	–

Vasopressors

Drugs with prominent peripheral arterial vasoconstrictor action such as norepinephrine or dopamine in higher doses (>5 mg/kg/min) are given to patients with marked hypotension. These agents raise blood pressure and redistribute blood to the vital organs at the expense of an increase in left ventricle (LV) afterload. Dopamine was compared with norepinephrine in the treatment of various shock patients.²⁶ A subgroup analysis suggested that norepinephrine would have fewer side effects and lower mortality. Epinephrine (adrenaline) should be restricted to patients with persistent hypotension despite adequate cardiac filling pressures and the use of other vasoactive agents, as well as for resuscitation protocols (Table 2).²⁷

Conventional Guideline-directed Medical Therapy

During admission, all previous guideline-directed medical therapy should be evaluated and adjusted based on patient presentation. If hypotension is present, holding beta-blockers and angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers may be beneficial to allow for adequate diuresis and ensure target organ perfusion. ACEI therapy should be started at low doses as early as possible during the index hospitalization in the absence of significant renal dysfunction or hypotension. Beta-blockers doses should also be started in low dose and titrated to achieve target doses. They are avoided in presence of hypotension, bronchospasm, or symptomatic bradycardia. Caution should be used when administering beta-blockers to patients who have required inotropic therapy during their index hospitalization and to patients with newly diagnosed HF.²⁸

Thromboembolism Prophylaxis

Thromboembolism prophylaxis is recommended to reduce the risk of deep venous thrombosis and pulmonary embolism.²⁹

Digoxin

It should be used in patients with AF and fast ventricular rate (>110 bpm) and can be given in boluses of 0.25–0.5 mg intravenous; if there is urgency, 0.0625–0.125 mg may be an adequate dose in patients with moderate-to-severe renal dysfunction.³⁰

Opiates/Anxiolytics and Sedatives

Opiates relieve dyspnea and anxiety. In ADHF, routine use of opiates is not recommended and only be cautiously considered in patients with severe dyspnea, mostly with pulmonary edema. Side effects include nausea, vomiting, hypotension, bradycardia, and respiratory depression may be observed with use of opiates. Anxiolytics or sedatives may be needed in a patient with agitation or delirium.³¹

Renal Replacement Therapy

Ultrafiltration involves the removal of plasma water across a semipermeable membrane in response to a transmembrane

pressure gradient.¹ Routine use of ultrafiltration is not recommended and should be confined to patients who fail to respond to diuretic based strategies.³² The following criteria may indicate the need for initiation of renal replacement therapy in patients with refractory volume overload: oliguria unresponsive to fluid resuscitation measures, severe hyperkalemia ($K^+ > 6.5$ mmol/L), severe acidemia (pH <7.2), serum urea level (>150 mg/dL), and serum creatinine (>3.4 mg/dL).³³

Mechanical Circulatory Support in Acute Heart Failure

To manage patients with ADHF with cardiogenic shock, short-term mechanical support systems like percutaneous cardiac support devices, extracorporeal life support (ECLS), and extracorporeal membrane oxygenation (ECMO) may be used to support patients with left or biventricular failure until cardiac and other organ function have recovered. Typically, the use of these devices is restricted to a few days to weeks. Evidence regarding the benefits of temporary percutaneous support system in patients not responding to standard therapy, including inotropes is limited.³⁴

Intra-aortic Balloon Pump

The indications for an intra-aortic balloon pump (IABP) are to support the circulation before surgical correction of specific acute mechanical problems like rupture of ventricular septum, acute regurgitation of mitral valve, severe acute myocarditis and in selected cases of acute myocardial ischemia or infarction before, during and after percutaneous or surgical revascularization.³⁵

Other Interventions

In patients with ADHF and pleural effusion, pleurocentesis may be considered to alleviate dyspnea. In patients with ascites, ascitic tapping may be considered to relieve symptoms. This procedure leads to reduction in intra-abdominal pressure, may partially normalize the transrenal pressure gradient, thus improving renal filtration.³⁶

MANAGEMENT OF PATIENTS WITH CARDIOGENIC SHOCK

In patients with suspected cardiogenic shock, immediate ECG, and echocardiography are recommended. These patients should be referred to a higher center with facility of cardiac catheterization Lab and a dedicated coronary care unit (CCU) with availability of mechanical circulatory support. In patients with cardiogenic shock complicating ACS, an immediate coronary angiography is recommended (within 2 h from hospital admission) with intent to perform coronary revascularization.³⁷ Continuous ECG, blood pressure, and invasive arterial monitoring are recommended. Intravenous inotropic agents (dobutamine) may be considered to increase cardiac output. Vasopressors (norepinephrine preferable over dopamine) may be considered if there is a need to maintain systolic pressure in the presence of persistent

hypoperfusion. IABP is not routinely recommended in cardiogenic shock. Short-term mechanical circulatory support may be considered in refractory cardiogenic shock.³⁴

When to Discharge Acute Decompensated Heart Failure Patients

Patients admitted with ADHF are medically fit for discharge when they are hemodynamically stable, euvolemic, put on evidence-based oral medication and with stable renal function for at least 24 hours before discharge (Box 2).³⁸

Goals of Treatment During the Different Stages of Management of Acute Heart Failure

The goals of treatment during the different stages of management of acute heart failure as shown in box 3.³⁹

BOX 2 Discharge checklist-discharge planning goals¹

- Guideline-directed medical therapy has been reviewed and patient has been stable for 24 h
- Potential exacerbating/confounding comorbidities have been addressed
- Exercise tolerance has returned to New York Heart Association Class II
- Volume status has been optimized
- Education has been provided
- Clinic follow-up has been scheduled

BOX 3 Goals of treatment in acute decompensated heart failure¹

Immediate (ED/ICU/CCU):

- Improve hemodynamic and organ perfusion
- Restore oxygenation
- Alleviate symptoms
- Limit cardiac and renal damage
- Prevent thromboembolism
- Minimize ICU length of stay

Intermediate (in hospital):

- Identify etiology and relevant comorbidities
- Titrate therapy to control symptoms and congestion and optimize blood pressure
- Initiate and up-titrate disease – modifying pharmacological therapy
- Consider device therapy in appropriate patients

Predischarge and long-term management:

- Develop a care plan that provides:
 - A schedule for up-titration and monitoring of pharmacological therapy
 - Need and timing for review for device therapy
 - Who will see the patient for follow-up and when
- Enroll in disease management program, educate, and initiate appropriate lifestyle adjustments
- Prevent early readmission
- Improve symptoms, quality of life, and survival

CCU, coronary care unit; ED, emergency department; ICU, intensive care unit.

CONCLUSION

Inpatient therapy for patients with ADHF should be directed at decongestion and symptom improvement. Always treat possible precipitating events, identify comorbid conditions that exacerbate HF, evaluate and update current guideline-directed medical therapy, and perform risk stratification for all patients. Effort should be made to educate patients about the importance of restricting sodium and fluid, monitoring daily weights, and adhering to a graded exercise program. Early discharge follow-up and continued optimization of guideline-directed medical therapy are key to preventing future ADHF readmissions.

Advanced Heart Failure Therapies—An Overview

Rishi A Bhargava, Prafulla G Kerkar

INTRODUCTION

Therapy for cardiac disease could be considered as the best example of triumph of mankind over the disease. Heart failure (HF), however, still exists in the scale of an epidemic across the world with significant impact on lives and economy of the people. Most HF-related hospitalizations and deaths are incurred by a subgroup of patients that is refractory to guideline-based medical management, a group categorized as having “advanced HF” [stage D, as per the American College of Cardiology (ACC)/American Heart Association (AHA) classification of HF] (Flowchart 1).¹ For these individuals, average survival is less than 6 months² and until recently, there was little available to support these patients, to extend life, and to improve functional status. However, advances in therapies like transplantation, emerging mechanical technologies, and novel, multidisciplinary approaches have all contributed substantially to the care of this growing patient population.

This chapter intends to present a comprehensive review of various treatment modalities available for the management of end-stage HF.

ESTIMATING PROGNOSIS IN ADVANCED HEART FAILURE

Assessment of prognosis is the basis for selecting therapies for most life-threatening diseases, but this is particularly challenging for HF. The clinical course varies dramatically across the spectrum of disease severity and is relatively unpredictable for individual patients.^{3,4} This contrasts with the more linear decline of patients with advanced cancer, which has traditionally been the model for approaches to end-stage disease. Even late in HF, patients often enjoy “good days” and brief interludes of apparent stability, which can lull them and their care providers into postponing vital decisions. Prognosis is further clouded by the unique contrast between unexpected sudden death (i.e., lethal arrhythmia) and lingering death with congestive symptoms (i.e., progressive

pump failure). Many models, comprising of multiple variables, have been published in an effort to provide more accurate predictions of prognosis in patients with HF. These models have shown the importance of natriuretic peptides, renal function, and low blood pressure as predictors of survival in patients with advanced HF.⁵⁻⁸

ADVANCED HEART FAILURE—TREATMENT STRATEGIES

As duration of disease and treatment options have increased, decision making for advanced HF has become both more critical and more challenging. Medically reasonable options are analyzed to make suitable decision, in alignment with preferences, values, and goals of informed patients and relatives.

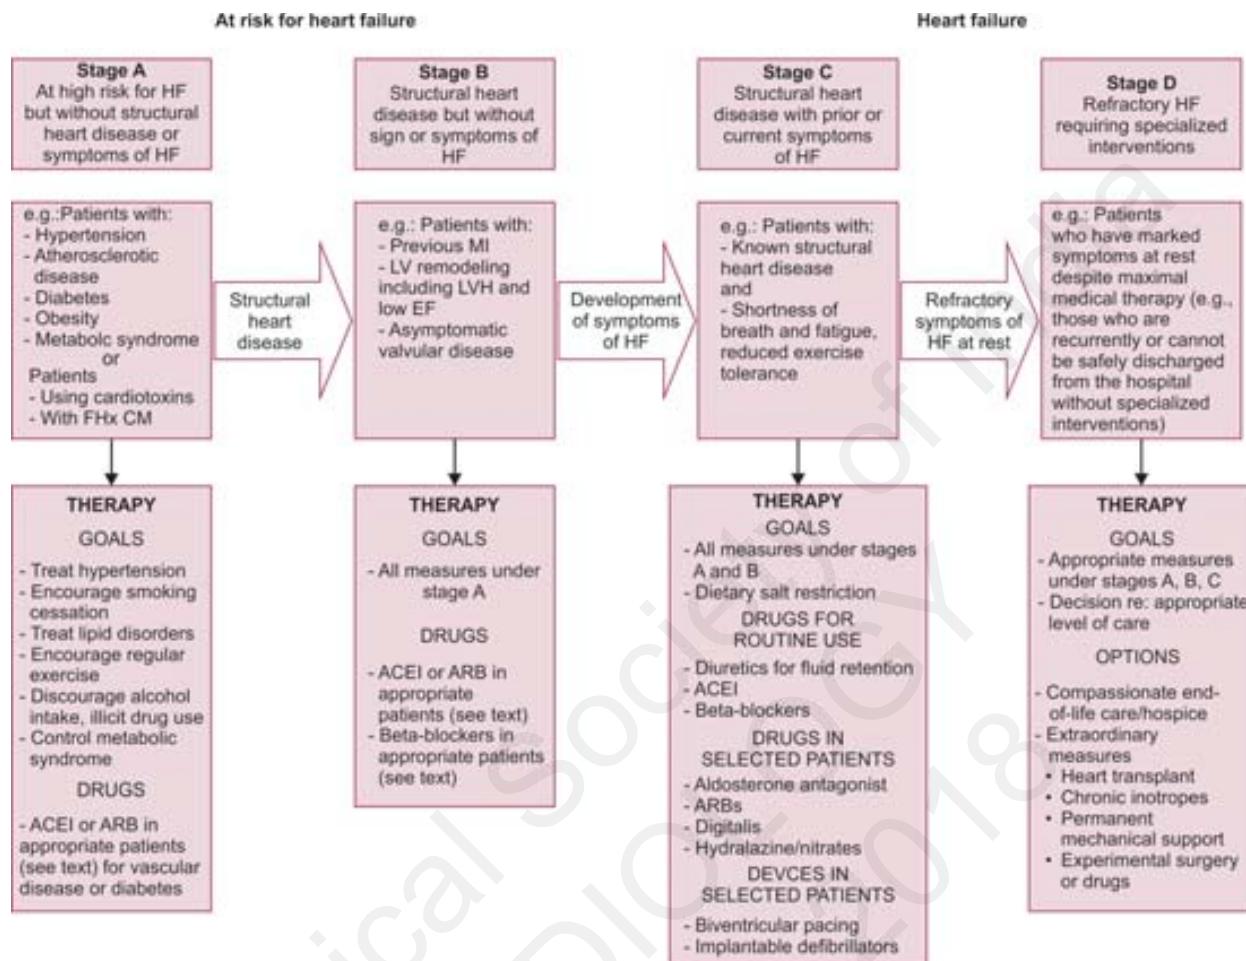

Following are the key areas:

- Communication about treatment options
- Pharmacotherapy
- Interventions and surgeries
- Pacing device therapy
- Mechanical circulatory support (MCS)
- Heart transplant
- Palliative care.

Communication about Treatment Options

It is the onus of the treating physician to define the range of options that are medically appropriate. Following aspects need to be considered:⁹

- Counseling about major interventions should always include specific description of alternative approaches, including withdrawal or continuation of ongoing treatments and focus on symptomatic care
- Discussions should include various anticipated outcomes, including, not only, survival but also adverse events, independence, functional capacity, and quality of life for both patient and caregiver. There should be no

ACEI, angiotensin-converting enzyme inhibitor; ARBs, angiotensin receptor blockers; EF, ejection fraction; HF, heart failure; LVH, left ventricular hypertrophy; MI, myocardial infarction.

FLOWCHART 1: American College of Cardiology/American Heart Association classification of heart failure.

Source: Hunt SA, Abraham WT, Chin MH, et al. ACC/AHA 2005 guideline update for the diagnosis and management of chronic heart failure in the adult: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Update the 2001 Guidelines for the Evaluation and Management of Heart Failure). Circulation. 2005;112:e154-235.

hesitation to even acknowledge lack of this information for some interventions

- Some therapies may lead to dependence [e.g., intravenous (IV) inotropes, renal replacement therapy, and intubation] and need to be weighed and discussed carefully before initiation even when anticipated to be temporary
- Risk-benefit of noncardiac procedures (e.g., hip replacement, repair of asymptomatic aortic aneurysm, or screening tests) should be analyzed in the context of competing risks of functional limitation and death caused by HF
- Major cardiac and noncardiac interventions discussion should include consideration of unanticipated adversities and options to deal with them (“what if” situation discussion)
- Palliative care team should be considered for assistance with symptom management in advanced disease, difficult decision-making, and caregiver support even as patients

continue to receive supportive or disease-modifying therapies.

Management discussion should not be a one-time process and needs to be carried out at different steps of the disease stages.

Pharmacotherapy

- Medical therapy generally comprise of all stage C therapies like angiotensin-converting enzyme inhibitor (ACEI)/angiotensin receptor blocker (ARB), mineralocorticoid receptor antagonist (MRA), beta-blocker and diuretics.^{10,11} The initial approach to advanced HF is optimization of these treatments to attain maximum tolerated dose. Some patients with end-stage HF with reduced ejection fraction (HFrEF) may tolerate little, if any, of the oral medications proven to reduce morbidity or prolong life. In other instances, patients may develop symptoms that are refractory to these oral therapies. Advanced therapies like left ventricular assist device

(LVAD) and cardiac transplantation (CT) remain the only valid treatment options for them

- **Inotropes:** Current HFrEF management guidelines recommend consideration of IV inotropic therapy for palliation of symptoms in stage D patients.¹² Although two meta-analyses have reported that mortality is not reduced with the administration of inotropes,^{13,14} inotropes can reduce hospitalizations and improve functional status and, thus, are often used as bridge to CT, destination therapy (DT), or as part of palliative care. The use of inotropic infusions either on continuous basis at home or intermittently in cardiovascular (CV) clinics to allow patients to be discharged home waiting for CT was shown to be a viable management option.¹⁵ Among 20 patients with continuous home infusions of dobutamine, dopamine, or both there were no sudden deaths. Mean duration of inotropic therapy was 5 months, with 70% of the time spent as an outpatient, leading to considerable cost savings. In a larger study, 73 patients received intermittent 4-hour inotropic infusions in a CV clinic two or three times per week.¹⁶ Over a 49-month period, the time free of HF symptoms after the final infusion treatment ranged from 201 to 489 days, with no need for hospitalization or emergency room visits. However, randomized trials of intermittent dobutamine have consistently failed to demonstrate mortality or significant symptom benefit.^{17,18} One trial, however, reported a decrease in hospitalization.¹⁸ Dobutamine and milrinone are most commonly used for chronic home infusion. In a retrospective study of 112 patients considered ineligible for transplantation or LVAD implantation and discharged to home palliative care receiving continuous dobutamine or milrinone, the mean dose for dobutamine was $5.4 \pm 2.5 \mu\text{g}/\text{kg}/\text{min}$ and milrinone was $0.4 \pm 0.2 \mu\text{g}/\text{kg}/\text{min}$. There was no difference in the likelihood of death or hospitalization with the use of either inotropic. Dobutamine overall demonstrated a cost-saving effect at 1 year, while milrinone was costlier than the standard therapy.¹⁹ The ACC/AHA guidelines, given the lack of survival benefit, classify IV inotropes as a class IIB indication for end-stage HF
- **Newer agents:** Angiotensin receptor-neprilysin inhibitor (ARNI) (sacubitril-valsartan; or LCZ696) is a combination of ARB (valsartan) and neprilysin inhibitor (sacubitril), and is indicated for use in symptomatic HFrEF [with left ventricular ejection fraction (LVEF) $\leq 35\%$]. The Prospective Comparison of ARNI with Angiotensin Converting Enzyme Inhibitors to Determine Impact on Global Mortality and Morbidity in Heart Failure (PARADIGM-HF) trial was a landmark study comparing the novel agent ARNI with the standard of care ACEI, enalapril in symptomatic New York Heart Association (NYHA) Class II-IV patients.²⁰ The primary objective of the trial was to determine whether sacubitril-valsartan (ARNI) was superior to a renin-angiotensin inhibitor (enalapril—an ACEI) alone in reducing the risk of the combined endpoint of CV death or hospitalization for HF. The trial was stopped prematurely at 27 months of a

planned 4-year duration in light of the significant benefit with use of ARNI. There was a 20% incremental reduction in CV death with ARNI beyond that achieved with the enalapril and an absolute risk reduction of 4.7%. The PARADIGM-HF trial, thus, demonstrated that ARNI was superior to enalapril in reducing the risk of the combined endpoint of CV death or hospitalization for HF, based on a time-to-event analysis ($p < 0.0001$). Reduction in both CV death and HF hospitalization were reflected. However, it must be noted that only 1.5% of randomized patients in this trial were in NYHA class IV. Hypotension may be a limiting factor for use of ARNI in patients with advanced HF.

Intervention and Surgeries

High-risk Cardiac Surgery

Underlying disease condition may warrant cardiac surgery for coronary, valvular, and pericardial pathologies in these patients. As a consequence of the patient's advanced HF, these surgeries are particularly high-risk. These procedures may be performed either with the hope of improving the status of HF or in response to a superimposed diagnosis such as acquired aortic stenosis. The potential for loss of independence and protracted postoperative rehabilitation must be considered and included thoughtfully in the discussion, as surgery can inherently increase short-term risk for the prospect of longer-term benefit.

Percutaneous Interventions

Percutaneous approaches for the treatment of coronary and valvular diseases seems appealing in advanced HF because of the increased surgical risk among these patients. Catheter approaches to both aortic²¹ and mitral valve²² disease [transcatheter aortic valve replacement (TAVR) and MitraClip, respectively] have now gained reputation as reasonable alternatives to surgery in certain populations. Discussion regarding percutaneous interventions should also give due consideration to whether "bail out" surgery (in case of adverse event) would be appropriate and feasible.

Electrophysiological Device Therapy

Cardiac Resynchronization Therapy and Implantable Cardioverter Defibrillators

Cardiomyopathy patients are prone to cardiac dyssynchrony. It is complex and multifaceted phenomenon. Due to prolongation of the atrioventricular (AV) interval, systolic contraction of the ventricle is delayed, which then might encroach on early diastolic filling. Also, if ventricular contraction is delayed and occupies the diastolic filling, the LV diastolic pressures will exceed atrial pressure, causing diastolic mitral regurgitation (MR). This leads to underfilling of the ventricle, causing loss of ventricular preload and ultimately leading to reduction in LV contractility, due to loss of the Starling mechanism. Inter- and intraventricular conduction delays lead to asynchronous contraction of LV wall regions (ventricular dyssynchrony), thereby impairing

cardiac efficiency and reducing stroke volume and systolic blood pressure. Also, poorly coordinated papillary muscle function may cause or aggravate functional systolic MR. Impaired performance enhances adverse LV remodeling.

Cardiac resynchronization therapy (CRT) intends to pace both the left and right ventricles simultaneously with the aim of restoring synchrony, thus improving cardiac function with the aim of achieving symptomatic improvement.

Implantable cardioverter defibrillators (ICDs) are effective in correcting potentially lethal ventricular arrhythmias and preventing bradycardia, thus reducing the risk of sudden death.

These treatment options are recommended for patients with HF who have LV dysfunction with an ejection fraction (EF) of less than 35% according to NYHA class, QRS duration, and presence of bundle branch block. Type of device to be implanted is decided as per clinical presentation (HF with/without ventricular arrhythmia). In cases with left bundle branch block (LBBB), QRS duration more than 150 ms, LVEF less than 35%, and who remains in NYHA functional class II, III, or ambulatory IV, CRT is class I indication.²³

Mechanical Circulatory Support (MCS)

Mechanical circulatory support devices (Fig. 1) are mechanical pumps designed to assist or replace the function of either the left or right ventricle, or both ventricles, of the heart. Important characteristics of MCS devices include: (1) location of the pumping chamber; (2) specific ventricle(s) supported; (3) pumping mechanism; and (4) indicated duration of support, for either temporary (days to weeks) or long-term (months to years) use.

Typically, short-term devices are extracorporeal or paracorporeal pumps (located outside the body), whereas durable devices are implantable (intracorporeal) systems.

There are several different CV circuits available for MCS (Box 1):

- Short-term right atrium (RA) to artery support can be provided by central or peripheral venoarterial extracorporeal membrane oxygenation (VA-ECMO) or extracorporeal life supports (ECLSs)
- The primary left atrium (LA) to aorta support system is the TandemHeart percutaneous LVAD (CardiacAssist, Inc., Pittsburgh, Pennsylvania)

A

B

C

D

FIG. 1: Examples of commonly used mechanical circulatory support systems. A, Intra-aortic balloon pump; B, Impella; C, TandemHeart; D, HeartMate 3.

BOX 1**Types of mechanical circulatory support devices**

- Short-term right atrium to artery support
 - Short-term left atrium to aorta support
 - Short-term left ventricle (LV) to aorta support: Percutaneous and central/surgical
 - Long-term LV to aorta support.
- Short-term percutaneous LV to aorta support devices includes the Impella devices (Abiomed, Danvers, Massachusetts) and the percutaneous heart pump (PHP, Thoratec, Pleasanton, California)
 - Short-term central LV to aorta support can be provided in the form of CentriMag ventricular assist device (Thoratec, Pleasanton, California)
 - Multiple LV to aorta devices are available for durable, long-term support, commonly known as LVADs. LVADs currently available in the United States include the HeartMate II (St Jude Medical, St Paul, Minnesota) and HeartWare ventricular assist device (HVAD) (HeartWare International, Framingham, Massachusetts)
 - Additionally, the HeartMate 3 (St Jude Medical, St Paul, Minnesota), Jarvik 2000 (Jarvik Heart Inc., New York, New York), and HeartAssist5 (ReliantHeart Inc., Houston, Texas) are investigational through clinical trials.

Nondurable mechanical circulatory support (MCS), including the use of percutaneous and extracorporeal ventricular assist devices (VADs), is reasonable as a “bridge to recovery” or “bridge to decision” for carefully selected patients with HFrEF with acute, profound hemodynamic compromise. As per Indian guidelines for management of HF, LVAD should be considered in the following scenarios:²⁴

- Patients who have symptomatic advanced HF with reduced EF, despite optimal medical and device therapy, and who are eligible for heart transplantation, as bridge to transplant
- As DT in patients who have end-stage HFrEF despite maximum medical and optimum device therapy and who are not eligible for heart transplantation
- Patients with severe symptoms of more than 2 months duration despite optimal medical and device therapy and one or more of the following: (1) LVEF less than 25%, and if measured, peak VO₂ less than 12 mL/kg/min; (2) more than or equal to three HF hospitalizations in previous 12 months without an obvious precipitating cause; (3) dependence on IV inotropic therapy; (4) progressive end-organ dysfunction (worsening renal and/or hepatic function) due to reduced perfusion and not due to inadequate ventricular filling pressure [pulmonary capillary wedge pressure (PCWP) more than or equal to 20 mm Hg and systolic BP less than or equal to 80–90 mm Hg or cardiac index (CI) less than or equal to 2 L/min/m²]; and (5) absence of severe right ventricular (RV) dysfunction together with severe tricuspid regurgitation.

For implanted MCS, patients are dependent on a device with possible complications of infection and stroke. Also, there are chances of continued symptoms and need of therapies for right-sided HF symptoms. Thus, whether to initiate these therapies represents one of the most crucial decisions that patients and clinicians can make. There may be an increase in the use of MCS as the technology improves but is likely to remain less commonly employed for the majority of patients with HF because of the large number of patients of HF with normal EF, multiple comorbidities, very advanced age, and lack of availability.^{25,26}

Heart Transplant

The true “cure” for refractory or end-stage HFrEF is CT. The first CT using a cadaveric donor was performed on December 3, 1967 by Dr Christian Barnard in Cape Town, South Africa. Within 1 year of this event, Dr PK Sen performed first CT (heterologous) in India at Municipal-run King Edward Memorial (KEM) Hospital, Mumbai.²⁷ Considering the increasing incidence of advanced HF and need of CT, the Government of India has drafted a policy to determine suitable donor and recipient.²⁸

Categorization of Potential Cardiac Recipients

Three categories are proposed:

1. *Priority 1 (emergency)*: These are patients on VADs, but still critical, like those on intra-aortic balloon pump (IABP) waiting for heart/heart lung transplantation. These recipients will get priority based on blood group and size matching. Their status needs to be confirmed on weekly basis
2. *Priority 2 (semi-emergency)*: These are patients in intensive care unit dependent on inotropic support for at least a week and not maintaining hemodynamics if inotropes are being weaned off. Their category needs to be updated every 48 hours. Based on their progress, they may stay in priority 2 or change to other priorities. If a deceased donor organ is available, their status needs to be confirmed by three members of the Heart Subcommittee as appointed by the Chairman of the Subcommittee
3. *Priority 3 (elective)*: These are patients electively waiting for transplantation. Their status needs to be confirmed or changed as per their progress on monthly basis.

Criteria for Suitable Donors for Heart

Apart from the general criteria for donors, the following criteria are needed:

- Age less than 60 years. If donor is more than 40 years, coronary angiogram is desirable to exclude asymptomatic coronary artery disease
- No history of heart disease and echocardiogram showing good cardiac function and no anatomical abnormalities
- Maintaining good hemodynamics and not on high doses of inotropes (dopamine less than 10 µg/kg/min; epinephrine, norepinephrine less than 0.1 µg/kg/min; and dobutamine less than 10 µg/kg/min)

- **Cardiac arrest:** Donors revived after a brief cardiac arrest must be assessed more carefully; but can be considered if the cardiac function is absolutely normal.

Cardiac transplantation and MCS can fundamentally alter the clinical course of HF by exchanging it for an invasive therapy and the need to adjust to living with a different set of risks, benefits, burdens, and complications. In the case of CT, patients must adapt to the risks of surgical procedure, immunosuppression, its side effects, and threat of organ rejection. The use of CT is constrained by a limited supply of donor hearts, a situation that likely will not change in the near future. An appropriate policy for equitable and judicious allocation of any available donated organ (heart and lungs) is mandatory and needs systematic efforts to promote awareness about organ donation among citizens.

Palliative Care

The word “palliative” is derived from the Latin word palliare, which means to cloak. Palliative care aspires to relieve suffering by a holistic and multidisciplinary approach that addresses patient’s and caregiver’s physical, emotional, logistical, and spiritual needs.

The natural course of HF is marked by acute exacerbations, usually requiring inpatient treatment, followed by periods of moderate symptoms, with gradual overall deterioration in health status. This pattern of stuttering decline often results in significant confusion among providers when considering the timing of palliative care and advanced directive discussions. Nevertheless, physicians treating patients with NYHA class IV, stage D HF should establish goals-of-care with their patients.

Following are the points related with palliation in the advanced HF:

- Liaison between the specialist palliative care and HF teams, or the primary care physician in a shared care approach, is encouraged to optimally address and coordinate the patient’s needs
- Dyspnea, pain, depression, fatigue, and edema constitutes the most common symptoms and comorbidities among patients with end-stage HF.^{3,29,30} Effective palliative approaches based on evidences should be advised³¹
- In patients with ICD implanted, as HF worsens, they are likely to receive more frequent shocks, which cause significant pain and anxiety. If the stage diagnosed as near end of life, turning off the ICD is a viable option after discussion among the caregivers and the treating physician
- Near the end of life, the management of VAD presents serious challenges to the patient, treating physician, and the family. Patients may have sudden VAD mechanical dysfunction causing fall in cardiac output and rapid decompensation. Alternatively, patient develops other serious and potential life-threatening complications or pathologies (e.g., infections, embolic, or renal) while the device is still functional. The decision making is challenging in both the scenarios and should take into

account patient’s and relative’s choices along with the guidelines

- If a patient is deemed to be ineligible for LVAD/CT, a more focused discussion regarding palliative care options should be pursued.

ADVANCED HEART FAILURE THERAPIES—INDIAN SCENARIO

Advanced HF is increasing rapidly in India and need dedicated efforts at every level to timely provide suitable treatment to these patients. Pertaining to Indian scenario, following points are noteworthy:

- *Delay in seeking treatment:* Many patients do not report symptoms at initial stages and seek treatment during refractory HF. Delayed referral to higher-level health facility further adds to the problems
- *Lack of resources at peripheral health centers:* Primary health centers (PHCs) and urban health centers continues to be the first medical contact for significant numbers of Indians. These centers are not fully equipped with diagnostic armamentarium and therapeutic capabilities to treat HF patients and its risk factors
- *Empirical use of inotropes:* Though not supported by the evidences and guidelines, inotropes still considered to be a necessary treatment for all patients of HF with hypotension irrespective of the etiology. Nonavailability of MCS is one of the reasons behind the frequent use of the inotropic drugs. Individualized approach needs to be followed
- *Financial constraints:* A large number of people in India are not under cover of government health schemes and private health insurance plans and end up spending money for health care from their own pockets. Advanced HF therapies are expensive and financial issues poses significant constraint in their uses
- *Lack of availability of MCS:* Many tertiary care facilities in India lacks necessary expertise and infrastructure for the use of MCS and hence not commonly used
- *Cardiac transplantation:* Lack of awareness about the organ donation leads to unmet need of CT. Also, the expenses of the preprocedural assessment, procedure, medications, and follow-up costs in lakhs and puts significant financial burden on nonaffording patients.

CONCLUSION

Management of the advanced HF patient can be complex. Along with approved HF medications, therapies include CT, MCS, and inotropic agents for the short duration. Despite an ever-increasing armamentarium of resources, the physician must critically weigh the risks and benefits of each therapy to develop an optimal treatment approach, which necessarily be individualized. While CT remains the only true “cure” for advanced stage disease, its application is limited and the demand continues to outpace the supply. VAD therapy has emerged as a feasible option for improving morbidity and

mortality for patients who are transplant ineligible or likely to succumb to their illness prior to transplant. IV inotropes can be used for symptom control in patients who are nonoperable or for treatment prior to surgery. Management of the HF patient requires, irrespective of the treatment strategy chosen, thoughtful discussion, multidisciplinary approach, and individualized care. Though the survival is crucial, most patients desire improved quality of life above all outcomes. Adding life to years rather than years to life may be more relevant.³² It is important that clinicians make goals-of-care discussions a priority when seeing patients with advanced HF. Palliative care consultation facilitates these difficult conversations to ensure that all patient needs, curative or supportive, are ultimately met.

Although there are exciting developments in the field of advanced HF therapies, invasive as well as noninvasive, changing the paradigm will take time. It is, thus, the duty of every caregiver to strive hard and provide the best available treatment at the moment that sometimes may be palliative at best.

Takotsubo Cardiomyopathy—An Update

Pintu Nahata

INTRODUCTION

Takotsubo cardiomyopathy (TCM) is a syndrome characterized by transient left ventricular (LV) dysfunction in the absence of angiographic evidence of significant obstructive disease in the coronary arteries, most commonly occurring after sudden emotional breakdown.¹ Usually, the regional wall motion abnormality (RWMA) extends beyond the supply area of a single coronary artery.

The term “Takotsubo” is taken from the Japanese name for an octopus trap. The shape of the Octopus trap is similar to the LV angiographic appearance seen in this disease characterized by systolic apical ballooning of the LV along with depressed mid and apical segments of the LV, and hyperkinesis of the basal walls.²

This disorder is also known as stress cardiomyopathy, broken heart syndrome, and transient apical ballooning syndrome.

HISTORY

The first case of its type was reported by Iga et al. in which they noted transient LV dysfunction which was reversible with characteristic takotsubo appearance in the patient of pheochromocytoma, but the term takotsubo was not used by them. They also noted high level of circulating catecholamines in the patient.³ However, only in 1990 Sato et al. first described this reversible cardiomyopathy as *takotsubo* like

LV dysfunction. This phenomenon was labelled as apical ballooning or stress cardiomyopathy outside Japan.⁴⁻⁶

DIAGNOSTIC CRITERIA

The diagnostic criteria are proposed by Mayo clinic (Table 1).⁷

All the criteria must be satisfied to establish the diagnosis of TCM.

EPIDEMIOLOGY

Takotsubo cardiomyopathy is more common in women than in men; postmenopausal women are more commonly affected. Frequently preceded by an emotional and physical trigger. In the International Takotsubo registry (a consortium of 26 centers in Europe and the United States), out of 1,750 patients with TCM, a vast majority were women (89.9%) and mean age was 66.4 years.⁸ Most of the patients are Asian or Caucasian. Condition probably accounts for 1–2% of all cases of suspected acute myocardial infarction.⁹

ETIOPATHOGENESIS

The pathogenesis of this disorder is not well-understood. Why the condition has strong predilection for postmenopausal women is not clear? Further, why predominantly the LV mid-cavity and apex are affected is also not fully understood. Several mechanisms have been proposed:¹⁰

TABLE 1: Diagnostic criteria proposed by Mayo clinic

1.	Transient hypokinesis, akinesis, or dyskinesis in the left ventricular midsegments with or without apical involvement; regional wall motion abnormalities that extend beyond a single epicardial vascular distribution; and frequently, but not always, after a stressful trigger
2.	The absence of obstructive coronary disease or angiographic evidence of acute plaque rupture
3.	New ECG abnormalities (ST-segment elevation and/or T-wave inversion) or modest elevation in cardiac troponin
4.	The absence of pheochromocytoma and myocarditis

- Multi vessel epicardial coronary artery spasm
- Coronary microvascular impairment
- Catecholamine cardiotoxicity
- Neurogenic stunned myocardium.

At rest and during aerobic activity, our heart utilizes major portion (approximately 90%) of energy by fatty acid metabolism. However, when the heart is subjected to ischemia glucose is utilized largely, and fatty acid metabolism is suppressed. This may result in cardiac dysfunction. In patients with TCM despite the lack of ischemia the glucose pathway as a source of energy is activated and this is detrimental to cardiac function.

The most commonly discussed mechanism for TCM is stress-induced catecholamine release, which may result in myocardial toxicity and subsequent stunning of the myocardium. The apical parts of the heart have very high concentration of sympathetic receptors, which may explain why these excess catecholamines affect the apices more.¹¹

Myocardial biopsy often shows interstitial infiltrates consisting predominantly of mononuclear lymphocytes, leukocytes, and macrophages; along with myocardial fibrosis; and contraction bands with or without myocardial necrosis. The inflammation and contraction bands characterize TCM, as compared to coagulation necrosis seen in acute myocardial infarction.

CLINICAL FEATURES

The most common presenting symptom is acute substernal chest pain, but some patients present with dyspnea or syncope. In the International Takotsubo Registry study, the most common symptoms were chest pain, dyspnea, and syncope (75.9%, 46.9%, and 7.7%, respectively).⁸

Minority of patients may develop signs of heart failure, tachyarrhythmia as ventricular tachycardia (VT) or ventricular fibrillation (VF), bradyarrhythmias, significant mitral regurgitation (MR) or sudden cardiac arrest. 10% patients may develop shock also.

Takotsubo cardiomyopathy is often preceded by emotional or physical stress such as an unexpected death in the family, physical, or emotional outbursts exhausting work, however, in some patients no such precipitant stressor could be found.

Electrocardiography

Electrocardiography (ECG) findings in TCM resemble that of ST-elevation myocardial infarction (STEMI) and most of the times it is impossible to distinguish between two conditions on the basis of ECG.¹²

Following are the varied ECG findings:⁸

- ST-segment elevation is frequent (43.7% in the International Takotsubo Registry study). ST-segment elevation involves the anterior precordial leads and is often similar to that seen with an acute anterior wall STEMI
- ST-depression is a less common finding (7.7%) among patients with TCM

- Other findings include QT interval prolongation, T-wave inversion, abnormal Q waves, and nonspecific abnormalities.

In a retrospective study of 33 patients with TCM, the authors proposed ECG criteria to distinguish TCM from anterior acute myocardial infarction in those who presented within 6 hours of symptom onset. The combination of absent abnormal Q waves, absent reciprocal changes, lack of ST-segment elevation in lead V₁, and presence of ST-segment elevation in lead augmented vector right (aVR) had more than 91% sensitivity and 96% specificity for TCM.¹³

Various ECG criteria have been evaluated for differentiating TCM from acute STEMI. In one of the retrospective study involving 33 patients of TCM within 6 hours of symptom onset, a combination of absent Q waves, absent reciprocal ST changes, ST elevation in aVR and absence of ST elevation in V1 had a 91% sensitivity and specificity for TCM (Fig. 1).

Biomarkers

Patients with TCM have high levels of circulating catecholamines and B-type natriuretic peptide (BNP), also these patients have slight elevation of creatinine kinase and troponin. BNP elevation pattern in TCM is often similar to that of STEMI patients.¹⁴

In one of the studies, a higher values of following ratios were capable of distinguishing TCM from STEMI at an early stage:

- Ratio of N-terminal pro-BNP (NT-proBNP) to troponin I (TnI)
- Ratio of NT-proBNP to creatine kinase-MB (CK-MB) mass
- Ratio of NTproBNP to ejection fraction (EF)
- Of all these, NT-proBNP-to-TnI ratio showed greater accuracy.¹⁵

Echocardiography

Transthoracic echocardiography is an easy and quick method of diagnosing RWMA, especially hypokinesia and akinesia of mid and apical segment of LV along with hypercontractile basal segments. Characteristically, the RWMA extends beyond a supply territory of any single coronary artery. Basal hyperkinesia might be related with LV end-diastolic pressure and BNP release (Figs. 2 and 3).¹⁶

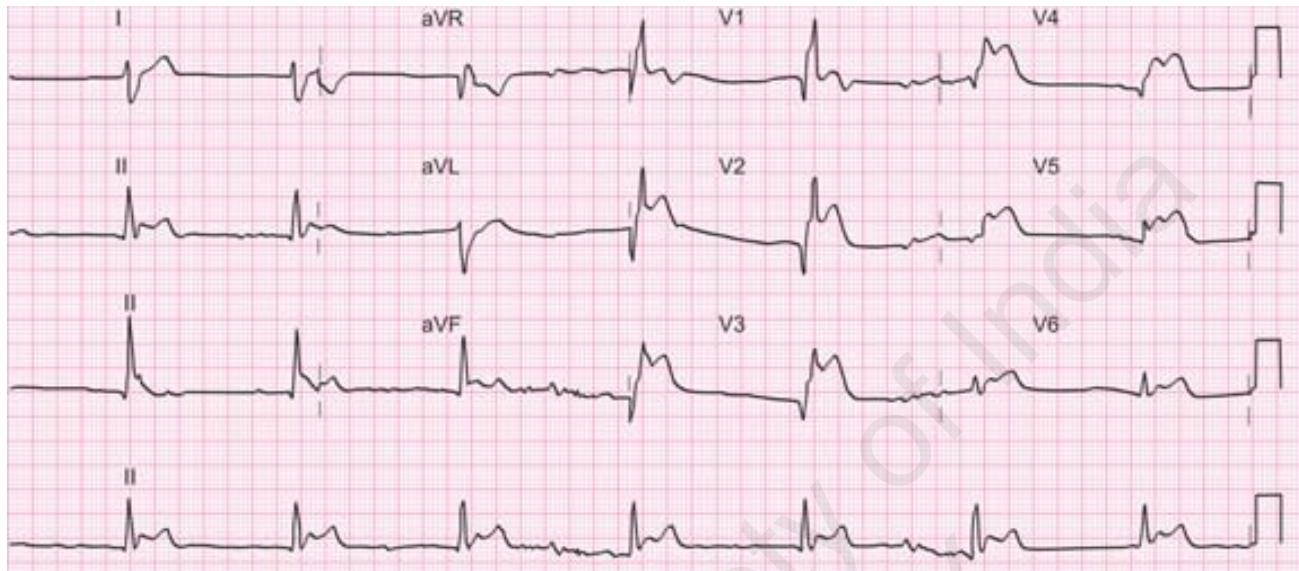

Coronary Angiography

Coronary angiography is the best tool to diagnose TCM as most of the patients lack significant obstruction in spite of having severe LV dysfunction. In the International Takotsubo Registry study, concurrent obstructive coronary artery disease was found in coronary angiography among 15.3% of patients with TCM.⁸

Left ventriculogram is considered as the best imaging modality for showing the pathognomonic RWMA as seen in TCM (Fig. 4).

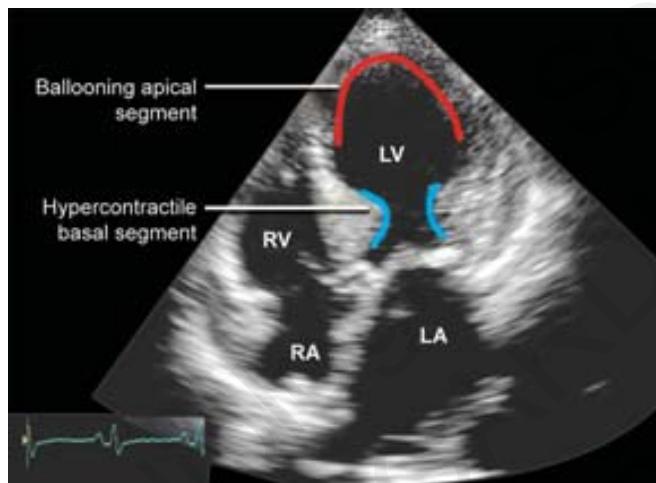

Cardiac Magnetic Resonance Imaging

Cardiac magnetic resonance imaging (MRI) can be a useful tool in differentiating TCM from myocardial infarction and

aVF, augmented vector foot; aVL, augmented vector left; aVR, augmented vector right. aVF, augmented vector foot; aVL, augmented vector left; aVR, augmented vector right.

also from myocarditis. Late gadolinium enhancement (LGE) subendocardial or transmural which is typically present in myocardial infarction is not seen in TCM. Also in myocarditis there is patchy LGE which is not there in TCM.¹⁷

Positron Emission Tomography

Inverse flow metabolism mismatch is seen, i.e., normal perfusion and decreased glucose utilization.¹⁸

VARIANT⁸

Apical type: This type was present in 81.7% of patients in the International Takotsubo Registry study. In the typical form, there is systolic apical ballooning of the LV, due to severely depressed mid and apical segments, along with hyperkinesia of the basal walls.

Less common (atypical) variants:

- *Mid-ventricular type* (14.6%): In the second most common type, ventricular hypokinesia was restricted to the mid-part of the LV with relative sparing of the apex. Basal type reverse or inverted takotsubo—hypokinesia of the base with sparing of the mid- and apical part of LV. This type was present in 2.2% of patients in the International Takotsubo Registry study
- *Focal type*: Very rarely a focal variant is also reported. Only an isolated segment, most commonly the anterolateral segment of the LV via only affected. This type was present in 1.5% of patients in the International Takotsubo Registry study
- *Global type*: Rarely, patients have global hypokinesia
- Variants with biventricular involvement were described in about one-fourth of patients
- It has also been described as one of the case report after transcatheter aortic valve replacement (TAVR)¹⁹
- Isolated right ventricle TCM has also been illustrated without simultaneous involvement of left ventricle.²⁰

MANAGEMENT

Patients with TCM are managed on supportive therapy. Measures to relieve stress and anxiety may help in arresting the disease process. But some patients may develop complications in the form of heart failure or shock. Heart failure is managed as per standard protocols. Mainstay of treatment includes supplemental oxygen, assisted ventilation, diuretics, β -blockers, and ace inhibitors or angiotensin II receptor blockers (ARBs).

Approximately, 10% of patients are complicated by shock. Urgent echo is warranted to rule out LV outflow tract (LVOT) obstruction which can be seen in 10–25% of patients with shock. In the patients without LVOT obstruction management includes fluid resuscitation, inotropes with close watch to whether out flow obstruction is setting in. In extremes of LV dysfunction vasopressors and intra-aortic balloon pump (IABP) remains the bailout methods.

In patients with LVOT obstruction complicating shock, inotropes are contraindicated. Management includes increasing preload by fluid support and passive leg raising, β -blockers are useful in decreasing gradients of LVOT obstruction. In patients with LVOT obstruction presenting with hypotension an α -agonist may be added with caution, if the patient is not able to tolerate a β -blocker or there is inadequate response to a β -blocker. Phenylephrine is a pure β -adrenergic agonist that may reduce the gradient by increasing afterload, thereby improving overall hemodynamics. This treatment may be helpful to support blood pressure while a β -blocker is administered to reduce inotropy. However, the vasoconstrictive effects of α -agonists may be harmful, particularly in those patients who can be prone to coronary vasospasm. Thus, if phenylephrine is used, it should be done with a high degree of caution and very close monitoring of hemodynamics and tissue perfusion.

Patients developing thrombus in left ventricle are treated with warfarin as standard anticoagulant therapy.

Because of the occasional association with acute QT prolongation, care should be taken to avoid using QT-prolonging medications, such as macrolide antibiotics or certain antiarrhythmic agents (Table 2).

PROGNOSIS

The prognosis in TCM is usually considered as excellent, with nearly 95% of patients recover completely within 4–8 weeks. Mortality ranges from 1 to 3.2%. Annual recurrence rate is approximately 1.5%.^{21,22}

Complications can occur in approximately 20% of cases. They are more common in early stage. Following can be the complications:^{23,24}

- Left heart failure with and without pulmonary edema
- Cardiogenic shock
- LV outflow obstruction
- Mitral regurgitation
- Ventricular arrhythmias
- LV mural thrombus formation

TABLE 2: American Heart Association Guidelines for management of Takotsubo cardiomyopathy

COR		LOE
I	Stress (Takotsubo) cardiomyopathy should be considered in patients who present with apparent ACS and nonobstructive CAD at angiography	C
I	Imaging with ventriculography, echocardiography, or magnetic resonance imaging should be performed to confirm or exclude the diagnosis of stress (Takotsubo) cardiomyopathy	B
I	Patients should be treated with conventional agents (ACE inhibitors, β -blockers, aspirin, and diuretics) as otherwise indicated if hemodynamically stable	C
I	Anticoagulation should be administered in patients who develop LV thrombi	C
IIa	It is reasonable to use catecholamines for patients with symptomatic hypotension if outflow tract obstruction is not present	C
IIa	The use of IABP is reasonable for patients with refractory shock	C
IIa	It is reasonable to use β -blockers and α -adrenergic agents in patients with outflow tract obstruction	C
IIb	Prophylactic anticoagulation may be considered to inhibit the development of LV thrombi	C

ACE, angiotensin-converting enzyme; ACS, acute coronary syndrome; CAD, coronary artery disease; COR, class of recommendation; IABP, intra-aortic balloon pump; LOE, level of evidence; LV, left ventricular.

- LV free-wall rupture
- Death.

CONCLUSION

To conclude, stress cardiomyopathy or TCM is a fascinating disease characterized by transient regional LV dysfunction in the absence of significant coronary artery disease. The pathogenesis and diagnostic criteria are evolving. Conservative treatment and resolution of physical or emotional stress usually results in rapid resolution of symptoms. To understand the pathogenesis and to devise rational treatment and prevention strategies, more attention should be paid not only to the myocardium and coronary arteries but also to the integration of central neural, autonomic, endocrine, and circulatory systems in emotional distress.²⁵

SECTION 14

Syncope

Syncope: What is New?

Satish K Kaushik, Surendra K Chutani

INTRODUCTION

The European Society of Cardiology (ESC) 2018 guidelines¹ for diagnosis and management of syncope have been published. In this chapter we are going to discuss what is new or revised as compared to 2009 edition.²

Syncope is a common potentially high-risk complaint in emergency department (ED). Lifetime risk for syncope is 50% in the general population.

DEFINITION

Syncope is a transient loss of consciousness due to cerebral hypoperfusion with rapid onset, short duration, and complete spontaneous recovery.

Compared to previous version, 2018 ESC guidelines include separate supplementary data for further explanation on specific points and web practical instructions where advice is given on how to evaluate patients with loss of consciousness (LOC), and how to perform and interpret tests properly; whenever possible, they have provided relevant tracings, videos, flow charts, and checklists. The document aims to be patient-orientated and focused on therapy.

THE NEW OR REVISED CONCEPTS

New Revised Clinical Settings and Tests

- *Tilt testing:* Concept of hypotensive susceptibility has been highlighted
- *Increased role of prolonged electrocardiographic (ECG) monitoring:* External loop recorder (ELR) or internal loop recorder (ILR); especially ILR in early phase of evaluation of unexplained syncope, patients with bundle branch block (BBB) in whom atrioventricular (AV) block is likely despite electrophysiological studies (EPS) is negative, patients with suspected unproven epilepsy where treatment is ineffective, in patients with primary cardiomyopathy or inherited arrhythmogenic disorders who are

at low risk of sudden cardiac death (SCD) as an alternate to implantable cardioverter defibrillator (ICD). In this way it has eclipsed EPS to some extent

- *Video recording* at home or hospital in suspected syncope, especially useful to diagnose psychogenic nonepileptic seizures (PNES) and psychogenic pseudosyncope (PPS). This can also be added to tilt test
- Assess *adenosine sensitive syncope:* Syncope without prodrom, normal ECG and normal heart
- *Neurological causes:* "Ictal asystole"
- *Electrophysiological studies-guided pacemaker implantation:* In patients with prolonged sinus node recovery time (SNRT), HV interval more than 70 ms.

New Revised Indications of Treatment

- Reflex syncope:
 1. Algorithms for selection of appropriate therapy based on age, severity of syncope, and clinical forms have been given
 2. Algorithms for selection of best candidates for pacemaker therapy, primarily patients with cardioinhibitory syncope will respond better to pacemaker rather than patients with vasodepressor or hypotensive susceptibility this has been clearly made out
- *Patients at risk of SCD:* Definition of unexplained syncope and indication of ICD has been given
- Implantable loop recorder as alternative to ICD in selected cases has been recommended.

Guidelines for Management in Emergency Department are Clearly Defined

- List of low-risk and high-risk features has been defined
- Risk stratification flowchart has been given
- Indications for management in ED or fast track to syncope unit (SU) have been mentioned
- Restricted admission criteria "Who should be admitted?" is defined. Thus as per these guidelines low-risk patients

should be discharged from ED, while high-risk patient should have intensive evaluation in ED or SU or hospitalized as per guidelines. Those patients who are neither high nor low risk are observed in ED or SU instead of being hospitalized

- Limited usefulness of risk stratification scores has been highlighted and they are not recommended to be used alone for risk stratification in ED.

Details on creating an outpatient SU with details of staff, equipment, tests, referrals, role of clinical nurse specialist, etc. is defined.

Multiple elements have been downgraded, e.g., discussion on contraindications of carotid sinus massage (CSM), tilt testing indications, and Holter monitoring.

These guidelines propose a care pathway for the management of patients with transient loss of consciousness (TLOC) from their arrival in the ED, and give practical instructions on how to set up outpatient syncope clinics (SU) aimed at reducing hospitalization, under- and misdiagnoses.

Syncope shares many clinical features with other disorders; it therefore presents in many differential diagnoses. This group of disorders is labeled as TLOC.

Transient Loss of Consciousness

Transient loss of consciousness is defined as a state of real or apparent LOC with loss of awareness, characterized by amnesia for the period of unconsciousness, abnormal motor control, loss of responsiveness, and a short duration.

The two main groups of TLOC are "TLOC due to head trauma" and "nontraumatic TLOC".

Classification of Transient Loss of Consciousness

A. Traumatic

B. Nontraumatic:

1. *Syncope*, e.g., reflex syncope, orthostatic hypotension (OH), and cardiac
2. *Epileptic seizures*: Generalized—tonic, clonic, and atonic
3. *Psychogenic*: PPS and PNES.

These guidelines have discussed only nontraumatic TLOC. Transient loss of consciousness groups have following characteristics:

- Syncope is characterized by cerebral hypoperfusion
- Epileptic seizures are characterized by abnormal excessive brain activity.
- Psychogenic TLoC has psychological cause.

Syncope can be classified as:

- *Reflex syncope*: which includes vasovagal, carotid sinus syndrome, or situational (cough/micturition)
- *Orthostatic hypotension leading to syncope*: Volume depletion, drug induced, autonomic failure, etc.
- *Cardiac causes leading to syncope*: Arrhythmias, structural diseases of heart, pulmonary embolism, etc.

The guidelines have framed clear questions, which should be answered by attending clinician for evaluation and management of TLOC.

At the time of initial evaluation clinician should answer the following key questions:

- Was the event TLOC?
- In case of TLOC, is it of syncopal or nonsyncopal origin?
- In case of suspected syncope, is there a clear etiology?
- Is there evidence to suggest a high risk of cardiovascular events or death?

Transient loss of consciousness has four specific characteristics: short duration, abnormal motor control, loss of responsiveness, and amnesia for the period of LOC.

Transient loss of consciousness is probably syncope when: (1) there are signs and symptoms specific for reflex syncope, syncope due to OH, or cardiac syncope, and (2) signs and symptoms specific for other forms of TLOC (head trauma, epileptic seizures, psychogenic TLOC, and/or rare causes) are absent.

Diagnosis of Syncope

Initial syncope evaluation of suspected syncope includes:

- Careful history-taking concerning present and previous attacks, as well as eyewitness accounts, in person or through a telephone interview
- Physical examination, including supine and standing blood pressure (BP) measurements
- ECG.

Based on history, physical examination, and ECG they have been classified into low-risk and high-risk category. Following investigations as indicated should be done:

- Electrocardiographic monitoring, if arrhythmia is suspected
- Echocardiogram, if structural heart disease is suspected
- Carotid sinus massage in persons above 40 years age where cause of syncope is not known
- Tilt test if orthostatic hypotension or reflex syncope is suspected.

Patients coming to emergency should have risk stratification:

- Patient with low-risk condition can be identified and can be discharged from emergency with adequate counseling.
- High-risk patients will require urgent investigation and hospitalization.

Syncope Severity

Cardiac syncope is associated with high morbidity and considerable mortality, meaning that any syncope due to a proven cardiac cause is classified as severe syncope, even if the actual episode was short-lived and had no adverse effects. High-risk patients are more likely to have cardiac syncope.

High-risk or low-risk features are decided by features of syncopal event, past medical history, physical examination, and ECG pattern.

Syncopal Event

- *High-risk features*: Syncopal event, with new onset chest pain, breathlessness, syncope during exertion or when supine, sudden onset of palpitation immediately followed by syncope. Minor or high risk if associated with structural heart disease or abnormal ECG, no warning symptoms or short prodrome, family history of SCD at young age, syncope in sitting position
- *Low-risk features*: Associated with prodrome typical of reflex syncope, after sudden unexpected unpleasant

sight, sound smell, pain; after prolonged standing, during or after meal.

Triggered by cough, defecation, micturition, with head rotation or pressure on carotid sinus, and standing from sitting or supine position.

Past Medical History

- High-risk features:* Severe structural or coronary artery disease, heart failure, and low left ventricular ejection fraction (LVEF)
- Low-risk features:* Long history of recurrent syncope with low-risk features with same characteristics of the current syncope

Physical Examination

- High-risk features:* Unexplained systolic BP in ED less than 90 mm Hg, gastrointestinal (GI) bleed, bradycardia, and undiagnosed systolic murmur
- Low-risk features:* Normal examination.

Electrocardiogram

- High-risk features:* ECG changes consistent with acute ischemia, Mobitz II or III degree AV block, atrial fibrillation (AF) with slow ventricular response (VR) <40 beats/min, sinus pauses more than 3 seconds, persistent bradycardia, BBB, intraventricular conduction disturbance, ventricular hypertrophy, Q waves, ventricular tachycardia, pacemaker or ICD malfunction, Brugada syndrome type I, long QT
- Low-risk features:* Normal ECG.

Patients with Low-risk Features

These patients do not need further diagnostic tests in the ED as they are likely to have reflex, situational, or orthostatic syncope. They will benefit from reassurance and counseling.

Patients with High-risk Features

- These patients require an intensive diagnostic approach and may need urgent treatment and admission. High-risk patients should be monitored 6–24 hours in ED
- External loop recorder or internal loop recorder:* For recurrent and unexplained syncope if features suggest arrhythmic syncope
- Electrophysiological studies are indicated in patients with bifascicular BBB or if tachycardia is suspected
- Treadmill/other stress test should be done in patients who have syncope during or shortly after exertion
- Ambulatory blood pressure monitoring (ABPM) and autonomic function evaluation in patients where neurogenic orthostatic hypotension is suspected
- If TLOC is suspected of nonsyncopal in nature then video recording is recommended

Patients with intermediate risk can probably be managed in OPD setting.

Treatment

Treatment is based on identification of specific mechanism and risk stratification. Effectiveness of treatment to prevent recurrences is determined by mechanisms of syncope rather

than its etiology, e.g., treatment of symptomatic bradycardia is pacemaker but it will be less effective if hypotension coexists. Often therapy to prevent recurrence differs from that for underlying disease.

Reflex Syncope

Algorithm based on age, severity of syncope, and clinical forms has been given. Overlap between subgroup is expected.

- Education and lifestyle measures
- Severe or recurrent form:
 - Low BP (chronic systolic BP <110 mm Hg) phenotype younger patient (40 years) can be prescribed drugs, e.g., fludrocortisone, midodrine
 - Patients with prodrome are advised counter pressure measures/tilt training
 - Patients with no or very short prodromes should have ILR-guided management
 - In patients on hypotensive drugs, we can stop or reduce dose of drugs
 - Patients with dominant cardioinhibition, especially older patients more than 60 years are advised pacemaker.

To all patients with reflex syncope and OH, explain the diagnosis, reassure, explain the risk of recurrence, and give advice on how to avoid triggers and situations. These measures are the cornerstone of treatment and have a high impact in reducing the recurrence of syncope.

Orthostatic Hypotension

- Educate patients regarding lifestyle maneuvers including adequate salt intake and hydration
- Stop or reduce antihypertensive therapy
- Counter pressure maneuvers
- Supportive stocking or abdominal binders
- Sleeping in head up tilt position.
- Drugs-Fludrocortisone midodrine can be prescribed.

Cardiac Syncope

All patients with cardiac syncope should receive the specific treatment for arrhythmia/or of the underlying disease causing syncope. ICD may be considered in high-risk patients with unexplained syncope.

CONCLUSION

In conclusion, syncope is a common presentation in ED, majority of cases are low risk and can be identified and discharged from ED with reassurance, education and advice, while high-risk patients should be identified and have intensive diagnostic workup and monitored for 6–24 hrs in ED, SU or hospitalized and treated promptly as per guidelines. The new points of 2018 guidelines have been discussed.

Tilt Table Testing in Syncope

Surender Deora, Kewal C Goswami

INTRODUCTION

Syncope is one of the differential diagnoses of group of disorders known as transient loss of consciousness (TLOC). TLOC is defined as per the European Society of Cardiology (ESC) guidelines as a state of real or apparent loss of consciousness with loss of awareness, characterized by amnesia for the period of unconsciousness, abnormal motor control, loss of responsiveness, and a short duration.¹ Essential within this diagnosis are two key facts: that the loss of consciousness is brief in duration and that recovery is complete. There are various differential diagnoses of TLOC including syncope, seizure disorder, blunt trauma head, psychogenic pseudosyncope (PPS), cataplexy, transient ischemic attack (TIA), and metabolic disturbances like hypoglycemia. Syncope is defined as TLOC due to cerebral hypoperfusion characterized by rapid onset, short duration, and spontaneous complete recovery. The *sine qua non* of syncope pathophysiology is transient cerebral hypoperfusion due to fall in systemic arterial blood pressure (BP) below cerebral perfusion pressure. Sudden fall of systolic BP in upright position below 50–60 mm Hg (cardiac level; 30–45 mm Hg at brain level) for 6–8 seconds can cause complete loss of consciousness.¹ Syncope is mainly classified based on the mechanism leading to cerebral hypoperfusion as neurally mediated (reflex mediated), cardiac syncope or due to orthostatic hypotension. The approach to the patient with syncope includes meticulous history given by patient as well as eye witness if available. If the diagnosis of syncope is suspected then further investigations are warranted. Measurement of BP in both supine and standing, Electrocardiogram (ECG) and echocardiogram are initially done in the evaluation of syncope. Head-up tilt test (HUTT) has been performed for evaluation of patients of reflex syncope [most common vasovagal syncope (VVS)]. The clinical utility of this test in diagnosis and management of the patients with reflex syncope is limited. The purpose of this test has been changed recently from diagnosing the reflex syncope to know the susceptibility for reflex or postural hypotension.¹

PATHOPHYSIOLOGY OF VASOVAGAL SYNCOPE

During tilted position there is redistribution of 750–1000 mL of venous blood from central blood compartment to lower limb and splanchnic organs.² This results in decrease in ventricular preload, stroke volume, and systolic BP. In response to this and to provide adequate perfusion pressure to vital organs, the nervous system gets activated and releases catecholamines and activates the renin-angiotensin-aldosterone system releasing various neuropeptides like endothelin, etc. which increases the peripheral vascular resistance and increase in rate and force of left ventricular contraction. Patients with autonomic dysfunction and neurohormonal deficiency, the compensatory mechanism to increase the heart rate (HR) and peripheral resistance are insufficient which leads to cerebral hypoperfusion and TLOC. Neurocardiogenic reflex also contributes to the symptoms but the mechanism is not very well understood.

HEAD-UP TILT TEST

The tilt table was used earlier for the evaluation of HR and BP in upright position. While evaluating these parameters, some patients developed faintness or TLOC with hypotension which was associated with bradycardia in some patients mimicking the vasovagal reaction.^{3,4} These initial observation in case studies formed the basis for further evaluation of syncope patient with HUTT. The first report of HUTT as a tool to diagnose syncope was reported by Kenny et al. in a landmark study published in Lancet.⁵ They studied 15 patients with undiagnosed recurrent syncope despite complete clinical and electrophysiological assessment. During HUTT with 40° elevation for 60 minutes, ten patients developed significant bradycardia with hypotension and reproduced similar clinical symptoms as previously experienced. Since then the test is used in assessment of VVS if the diagnosis is doubtful after thorough clinical examination. Thereafter, various parameters have been adapted regarding the angle of tilt, duration of tilt

and if any provocative stimulus is needed. Fitzpatrick et al. studied 71 patients with recurrent unexplained syncope for the angle of tilt, duration of tilt, and method of tilt support. The authors first time defined standard protocol for HUTT. They concluded tilt angle of 60° with tilt timing of 45 minutes is sufficient and use of foot board for support increases the specificity as compared to bicycle saddle or seat.⁶ The use of isoproterenol as a provocative agent is based on studies showing excess catecholamine before the syncopal episode may paradoxically increase the susceptibility to bradycardia and hypotension.^{7,8} The studies by Alquist et al. and Waxman et al. showed the clinical use of isoproterenol in provoking neurally mediated syncope during tilt testing.^{9,10} Because of provocation agents, the duration of the tilt was reduced to 20 minutes in some studies. Although isoproterenol in dosage up to 5 µg/min increases the sensitivity of the test but it decreases the specificity (45–65%) and its use as a provocative agent became questionable.¹¹ But with reduced dosage of isoproterenol up to 3 µg/min, the specificity of the test was found up to 93%.¹² Because of significant risk of arrhythmia and ischemia in patients with coronary artery disease the use of isoproterenol is gradually decreased. Moreover, it is time consuming to infuse it through syringe pump. Therefore, nitroglycerine (NTG) given as sublingual dosage became more preferred choice. Raviele et al. first introduced the NTG in HUTT protocol as an infusion.¹³ Later the same group evaluated sublingual NTG in 235 patients with syncope of unknown origin and no evidence of organic heart disease. All patients underwent HUTT with 60° tilt for 45 minutes followed by 300 µg sublingual NTG in next 20 minutes. They concluded the addition of NTG maintained the high specificity (94%) and doubled the rate of positive test.¹⁴

The following are the standard protocols for HUTT:

- Patients should be NPO (nil per orally) for 3–4 hours before the test. The longer fasting period may lead to dehydration which may affect the test result. If the patients are fasting for more than 4 hours intravenous (IV) saline may be infused prior to the test according to the volume status of patients
- The room should be equipped with emergency crash cart, defibrillator nearby and trained nurse, technician, and physician assistant should be available. Physician may not be needed all time but should be in the premises if emergency occurs¹⁵
- Patient should be gently wrapped and supported by footboard to avoid fall in case syncope occurs
- Electrocardiogram leads (minimum three) should be recorded continuously with continuous noninvasive beat-to-beat BP monitoring. If continuous noninvasive beat to beat monitoring of BP is not possible, then BP may be monitored by arm cuff though this is less desirable
- The tilt table should be capable of achieving tilt angle between 60° and 70° (Fig. 1)
- Pretilt a resting supine period of 5–10 minutes should be ensured in which the patient is monitored. If any venous or arterial cannulation beyond a routine peripheral IV line is required then a longer period of rest of at least 20 minutes is required (so that endogenous catecholamine levels

settle back to baseline). We advise venous cannulation for all patients for HUTT

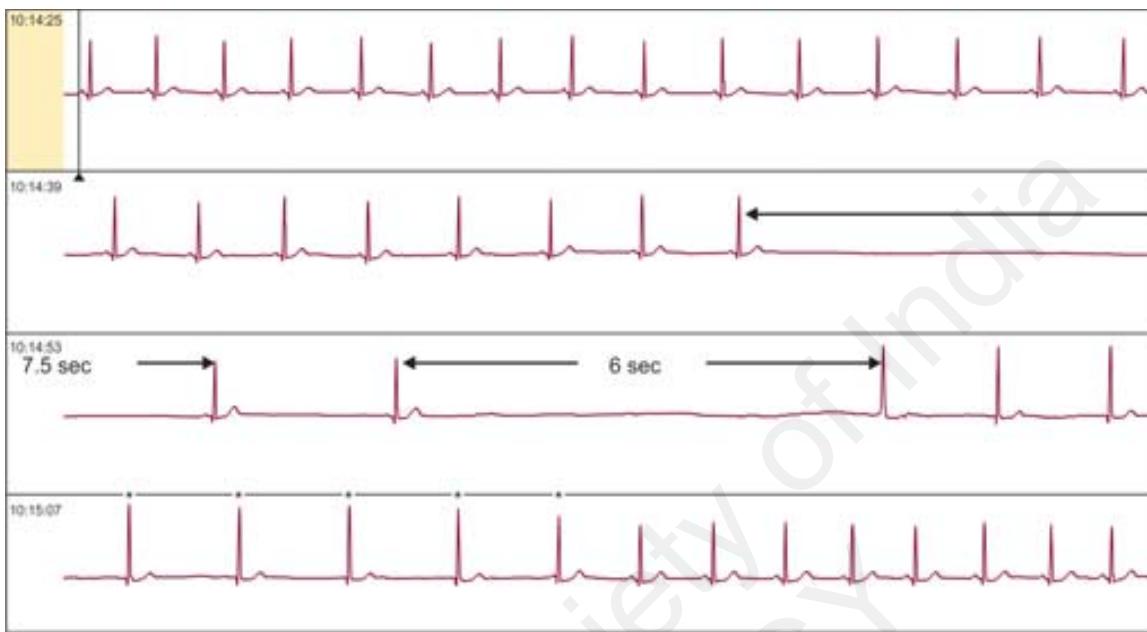

- Passive phase of tilt of 20–45 minutes depending on patient's clinical parameters and symptoms.
- If the passive phase is negative, a drug provocation with either sublingual NTG (300–400 µg) or IV isoproterenol (1–3 µg/min to increase HR ~20–25% above baseline) may be done
- The test should be continued until either the test is positive or the protocol is completed.

RESPONSE TO HEAD-UP TILT TEST

- Normal response is defined as no change in BP or HR or increase of less than or equal to 10% till patient is brought to supine position
- In patients with reflex syncope, BP falls after a latent period of tilt with rate of fall increasing (convex curve) associated with decrease in HR (Fig. 2)
- In patients with orthostatic hypotension, BP starts falling just after tilt with rate of fall decreases progressively (concave curve) associated with increase in HR
- In patients with psychogenic pseudosyncope, both BP and HR do not change or rather may increase. The event (pseudosyncope) occurs at variable interval after head-up tilt

FIG. 1: Head-up tilt test: Patient is first monitored in a supine position for 5–10 minutes and is then tilted to 70°. If there is no drop in heart rate or blood pressure then drug provocation is performed.

*Junctional beat.

FIG. 2: Positive head-up tilt test: With a 70° and on drug provocation (nitroglycerine) there is a drop in blood pressure (not shown) and progressive bradycardia culminating in asystole and syncope. The patient was quickly brought back to supine position. The blood pressure and heart rate gradually returned to baseline.

- Patients with postural orthostatic tachycardia syndrome (POTS) manifest increase in HR more than or equal to 30 beats/min or a HR of more than or equal to 120 beats/min during the tilt without a fall in BP.

INDICATIONS

Before HUTT all patients should be thoroughly evaluated by history taking, clinical examination, orthostatic BP measurement, ECG, and echocardiography. The following are the indications for HUTT:

- Recurrent reflex syncope of unknown origin
- Recurrent orthostatic hypotension
- Postural orthostatic tachycardia syndrome
- Psychogenic pseudosyncope
- To diagnose convulsive syncope and to differentiate it from seizure disorder
- Unexplained falls.

COMPLICATIONS AND CONTRAINDICATIONS

Head-up tilt test is a safe procedure and till date no mortality has been reported. Patients should be informed about the test and explained about the headache and fatigue which may appear after the syncopal episode. Most of the problems experienced by the patients are relieved once the supine position is achieved. NTG may cause headache during the test. There are reports of ventricular arrhythmia with the use of other provocative agent like isoproterenol in patients with ischemic heart disease (IHD) and sick sinus syndrome.^{16,17} Patients may develop transient atrial fibrillation during or

post-HUTT.¹⁸ Prolonged asystole may occur during the tilt and mostly is resolved on returning the patient to supine position. It hardly ever needs any resuscitation measures like atropine, pacing or cardiopulmonary resuscitation. Very rarely, the syncopal episode may be associated with myoclonic jerks which may be confused with seizure disorder.

There are no absolute contraindications for HUTT except if provocative test with isoproterenol is required. Patients with aortic stenosis, subvalvular obstruction [e.g., hypertrophic obstructive cardiomyopathy (HOCM)], IHD or uncontrolled hypertension, past history of ventricular arrhythmias with exertion should not be given isoproterenol as provocative agents.

FUTURE PROSPECTS

The role cardiac pacing in prevention of recurrent event in patients with reflex syncope is always controversial.^{19,20} There are two components in the pathophysiology of reflex syncope: (1) cardioinhibition, and (2) vasodepressor. In most of the cases, it is mixed type of mechanisms and therefore cardiac pacing has controversial benefit. The ISSUE-2 (International Study on Syncope of Uncertain Etiology 2) was prospective observational study in patients with reflex syncope and implantable loop recorder (ILR) for studying the mechanism of syncope. It revealed that half of the patients with reflex syncope had asystolic event and cardiac pacing resulted in 80% relative risk reduction in syncope recurrence.²¹ The ISSUE-3 was double blinded, randomized, multicentric trial in patients with recurrent syncope to assess the apparent pacing benefit in ISSUE-2 trial. It concluded that dual chamber cardiac pacing in patients of reflex syncope

with significant asystolic component showed 32% absolute risk reduction and 57% relative risk reduction in symptom recurrence.²² Therefore, the combination of ILR and HUTT is proposed for evaluating the patients with reflex syncope for risk stratification and selecting those who will be benefitted with cardiac pacing.

CONCLUSION

Vasovagal syncope is a clinical diagnosis and careful history taking with thorough clinical examination is of utmost importance. There is no gold standard investigation for the diagnosis of reflex syncope. HUTT with or without provocation is a low cost, noninvasive, readily available modality for assessment of hypotensive susceptibility in patients with syncope. The HUTT has clinical value only when it reproduces the similar symptoms as during the event. The interpretation of HR and BP response during tilt helps in differentiating VVS from other similar presenting diagnosis. Its role in assessment of therapeutic options is limited at present but is an evolving opportunity.

Implantable and External Loop Recorders: Indications in My Practice

Praloy Chakraborty

INTRODUCTION

Arrhythmia can present as sudden cardiac arrest, syncope [with total loss of consciousness (TLoC)], presyncope, and palpitation. The gold standard procedure to diagnose arrhythmia is symptom-electrocardiogram (ECG) correlation. The ECG recordings during symptoms allow physicians to either confirm or exclude an arrhythmia as the mechanism of symptom. Recording of ECG during symptom is the most challenging task in clinical practice. Most of cardiac arrhythmias are intermittent and are of unpredictable frequency. The frequency may vary from few episodes in an hour to minimal episodes in years. Recent guidelines for the management of patients with cardiac arrhythmias recommend the use of prolonged electrocardiogram monitoring techniques for better correlation between the symptoms and the arrhythmias and to detect asymptomatic significant rhythm disturbances. There are several prolong ECG monitoring systems depending on the duration of monitoring, the duration varies from 24 hours to 3 years. Choice of each system depends on frequency of symptoms.

Features of different prolong ECG monitors are described in table 1.¹ Conventional Holter monitoring can record ECG for 24 hours to few days. If the symptoms are less frequent, Holter monitoring is unlikely to be effective in detecting events. ECG loop recorders can continuously record and deletes the patient's ECG. They are either activated by patient-activation function as a result of symptoms or an autoactivation feature allowing the capture of arrhythmic events without relying on patient compliance or perception of symptoms. Loop recorders can be implantable (ILR) and external (ELR). Presence of retrospective memory differentiates loop recorders from prospective-only event recorders. While event recorders have some usefulness in patients with intermittent palpitations, they have no indication to detect syncope. In the current chapter use of ECG loop recorder in clinical practice will be discussed.

PATIENTS WITH SYNCOPE

Prolong ECG monitoring, in the form of loop recorder (ILR or ELR), is required in investigating arrhythmic syncope. Although syncope is a very common presenting symptom¹ (more than 50% of general population complains of an episode of suspected syncope in life time), reflex syncope being the most common, arrhythmic syncope is less common.² Initial clinical history including the clinical settings, examinations, and base line ECG can diagnose the etiology of a syncope in about half of the patient population.³ A smaller proportion of patients require specialized evaluation. The clinical clues to arrhythmic etiology of syncope include:⁴

- Syncope at rest or exertion
- Brief or absent prodrome
- Rapid recovery (<5 min)
- May be preceded by palpitations
- Abnormality in baseline ECG.

In patients with suspected arrhythmic syncope, an initial attempt should be made to identify those patients who are at high risk of sudden cardiac death with subsequent attack. The "high-risk" features consist of presence of external bleeding, persistent hypotension [systolic blood pressure (SBP) <90 mm Hg] or bradycardia [heart rate (HR) <40 beats/min], evidence of structural [heart failure, old or new myocardial infarction (MI), low ejection fraction] or electrical [short or long QT, Brugada pattern, epsilon wave, fascicular or atrioventricular (AV) nodal block, intraventricular conduction delay (IVCD), etc.] cardiac disorders.⁵

For all other patient with high-risk feature initial evaluation can be done in emergency department or syncope unit. These patients should be managed with standard guideline instead of extensive investigations. If ECG monitoring is required, they should be subjected to in hospital ECG monitoring. In patients with suspected arrhythmic syncope and who are at low risk, besides baseline ECG, echocardiography and Holter monitoring are to be done. Besides that, few specific tests should also be done like.

TABLE 1: Salient features of prolong electrocardiogram monitoring¹

Name	Holter monitoring	External event recorder	External loop recorder	Implantable loop recorder
Duration of monitoring	Usually 24–48 h, may be up to 7 days	Specific time for single even (for example up to 30 s) or even. Total number of events depends on capacity of memory card	Up to 4 weeks	Up to 3 years
Noninvasive/invasive	Noninvasive	Noninvasive	Noninvasive	Invasive
Autodeletion of records	No	No	Yes	Yes
Storage memory of retrospective ECG	Not required	No	Yes	Yes
Total memory	Usually whole monitoring time	Depends on capacity of memory card	Few hours to 4 weeks	40–45 min
Patient activation	Yes	Yes	Yes	Yes
Auto activation	No	No	Yes	Yes
Clinical indication	Palpitations and syncope	Palpitations	Palpitations and syncope	Palpitations and syncope
Cost	Inexpensive	Inexpensive	Inexpensive	expensive

- Exercise testing (for exertional syncope)
 - Carotid sinus massage
 - Head-up tilt test (HUTT for suspected neurocardiogenic syncope).
- Early use of electrophysiological studies should be considered in clinical situations listed here.
- Presence of asymptomatic sinus bradycardia (<50 beats/min) or sinoatrial block, documented by 12-lead ECG or 24 hours ECG monitoring⁶
 - In patients with syncope preceded by sudden-onset brief palpitations suggesting supraventricular tachycardia (SVT), if only curative catheter ablation is planned
 - Presence of pre-excited QRS complex
 - In patients with previous MI and preserved left ventricular ejection fraction (LVEF), induction of sustained monomorphic ventricular tachycardia (VT) is strongly predictive of the cause of syncope.⁷ The absence of inducible ventricular arrhythmias identifies a group of patients at lower risk of arrhythmic syncope^{8,9}
 - *Syncope in patients with bundle branch block:*^{10,11} Prolonged HV interval or induction of AV block by pacing or by pharmacological stress identifies a group of patients at higher risk of developing AV block in follow-up, but the absence of abnormal findings does not exclude the development of AV block.

If the mechanism of syncope is unexplained after initial evaluation, prolong ECG monitoring is required for symptom and arrhythmia correlation. The usage of particular loop recorder depends on the expected frequency of recurrence of syncope.

In the initial clinical experience, where ILR was used for diagnosis in patients with unexplained syncope at the end of unsuccessful full conventional work-up, ILR was found to diagnose the etiology of syncope in 35% cases.¹ Consequently, early implantation with ILR was found to be more effective compared to the conventional strategy.^{11,12} Early implantation of ILR is cost effective,¹¹ associated with improved quality of life¹³ and does not increase the mortality.^{11,13} Apart from

diagnosis of unexplained, low risk, infrequent syncope ILR can also be used in some specific situations:

- *Unexplained syncope in presence of detectable cardiac disease:*
 - Syncope, bundle branch block, and normal electrophysiological studies.¹⁴ About one-third of patients with negative electrophysiological study in whom an ILR was implanted, developed intermittent or permanent AV block on follow-up¹⁵
 - Patients with definite structural heart disease in whom an arrhythmia is likely despite a negative work-up.¹⁶ For example, patient with old MI and nonsustained VT when electrophysiological study failed to induce sustained monomorphic VT
 - Patients with cardioinhibitory carotid sinus hypersensitivity when the understanding of the exact mechanism of spontaneous syncope is needed to guide a specific therapy¹⁷
 - Pediatric patients in whom a cardiac cause of syncope is suspected due to structural heart disease or electrocardiographical abnormalities.¹⁸
- *Where justification of therapy is required:* In patients with suspected neurocardiogenic syncope, even if tilt test is positive, in order to capture an asystolic event when cardiac pacing would be justified by the severity and unpredictability of symptoms and lack of alternative therapies¹⁹
- *Suspected but not established syncope:*
 - Patients in whom epilepsy was suspected but the treatment has proved ineffective²⁰
 - Patients with established epilepsy in order to detect peri-ictal cardiac arrhythmias that require treatment²¹
 - Patients with major depressive diseases and frequent recurrent unexplained episodes of LoC in order to exclude an arrhythmic cause of syncope²²
 - In older patients with nonaccidental falls to establish the syncopal nature of the event.²³

Although studies suggest that ELR has similar diagnostic yield like ILR in the same timeframe,²⁴⁻²⁶ usage of ELR is limited by patient compliance, failure to operate the device correctly and difficulties in handling cutaneous patch electrodes.²⁵ A cost-effective analysis has indicated that ELRs are an economically attractive alternative when compared to Holter.²⁷ The ELR appears to have its greatest role in motivated patients with frequent syncope where spontaneous symptoms are likely to recur within 4–6 weeks.

Although documentation of arrhythmia during spontaneous syncope is considered as diagnostic gold standard, however presence of some asymptomatic significant arrhythmias like prolonged asystole (3 seconds or more), rapid SVTs (160 beats/min for 32 beats), or VT, are also considered by several authors as a diagnostic finding.¹ Absence of documented arrhythmia during a syncopal episode allows exclusion of an arrhythmia as the mechanism of the syncope.

There are specific criteria to diagnose arrhythmias in loop recorders.²⁸ The diagnostic yield of ILR was hampered by the failure to document a syncopal relapse in further 5–9% of the patients (16% of the events) despite the manual and automated features of the device²⁹ and by false-positive arrhythmia detection even in the most recent devices.

As per guidelines, loop recorders can be used in following conditions:⁵

- *Implantable loop recorder:* It is useful in any of the following conditions:
 - In patients with recurrent syncope if high-risk features are absent and recurrence rate is low
 - In patients with high-risk features, if immediate comprehensive evaluation failed to demonstrate any cause and there is no indication of immediate implantation of implantable cardioverter defibrillator (ICD) or pacemaker
 - In patients with suspected or definitive reflex syncope to understand the mechanism in presence of frequent or severe episodes
 - In patients with unexplained falls
 - If epilepsy is suspected but the patient does not respond to treatment.
- *External loop recorder:* It may be used instead of ILR in patients with nonhigh-risk unexplained syncope of suspected arrhythmic origin if intersymptom interval of 4 weeks.

PATIENTS WITH PALPITATIONS

Palpitations resulting from either primary cardiac arrhythmias or due to sinus tachycardia secondary to noncardiac disorders are one of the most common clinical symptoms. If symptoms a less frequent, it is difficult to establish symptom-ECG correlation despite careful evaluation that includes standard ECG and Holter monitoring. Event recorders are unable to detect the mechanism of onset of episodes and some short-lasting episodes due to lack of automatic detection.¹ Like syncope, high-risk patients may need aggressive inter-

ventions, including hospitalization and invasive tests to rule out life-threatening arrhythmias. The patients at low risk with frequent and/or severe symptoms are the best candidates for loop recorders. ILR, due to their invasive nature and costs, play a minor role in patients with recurrent unexplained palpitations when compared with those with syncope. In patients with infrequent (1 episode/month) and sustained (>1 min) palpitations, ILR implantation with 1-year monitoring was found to be more effective.³⁰

External loop recorders can be more useful for palpitation than for syncope evaluation. In a consecutive series of 125 patients all with an intersymptom interval of 4 weeks, ELR was found to be effective.³¹

As per guideline,¹ ELRs can be used in patients with recurrent palpitations, normal baseline ECG, frequent symptoms (intersymptom interval <4 weeks), and absence of high-risk criteria. ILRs may be indicated if symptoms are infrequent and normal result in ELRs and other ECG monitoring systems. The specificity of the technique is high when an arrhythmia is documented during symptoms. Normal ECG recording during palpitations excludes an arrhythmic cause. The outcome of asymptomatic arrhythmias remains uncertain.

NONESTABLISHED INDICATIONS

Although the current guideline approves usage of loop recorders only for unexplained syncope and palpitations, there are fewer emerging indications in clinical practice:

- In rhythm control trial, when intermittent or continuous capturing of symptomatic or asymptomatic atrial fibrillation is required¹
- In cryptogenic ischemic stroke in presence of minimal or no structural heart disease, to look for atrial fibrillation
- To detect asymptomatic arrhythmias in patients after MI, most commonly in clinical research³²
- Documentation of arrhythmic origin of syncope or presyncope in patients with phenotypic or genotypic evidence of inherited arrhythmias. In this setting syncope is usually considered as high risk of sudden cardiac death and ICD implantation is indicated. The mechanism of syncope may be heterogeneous and most of the patients have inherited arrhythmias, who received ICD for syncope, are not at risk of recurrent ICD discharge in follow-up studies.³³ In many patients, ILR can be used to identify the mechanism of syncope before embarking in ICD therapy. This hypothesis requires to be validated by clinical trials.³⁴

Loop recorders are increasingly used to detect symptomatic and asymptomatic arrhythmias. Ultimate goal of using loop recorders should be prevention of syncopal recurrences, severe injuries, and death. Further research is required to minimize artifact as well as to reduce the device size. Device miniaturization could increase the use of cardiac monitors, which could become the new standard of care for serious adverse event prevention and long-term monitoring of patients with chronic cardiac diseases.

Sudden Death in Dilated Cardiomyopathy—What is New in 2018?

Kamal K Sethi, Ashish K Govil

INTRODUCTION

Sudden cardiac death (SCD) is one of the leading causes of mortality in dilated cardiomyopathy (DCM) apart from terminal pump failure. Defined as natural death heralded by abrupt loss of consciousness within 1 hour of the onset of an acute change in cardiovascular status, its key elements are natural, rapid, and an unexpected event.¹ The risk of SCD is most pronounced in patients with heart failure (HF); 1-year absolute risk between 4 and 13%.²

The term DCM refers to a spectrum of heterogeneous myocardial disorders that are characterized by ventricular dilation and depressed myocardial performance in the absence of hypertension, valvular, congenital, or ischemic heart disease.³ The term nonischemic cardiomyopathy (NICM) has been interchangeably used with DCM. Although this approach might be practical, it fails to recognize that NICM can include cardiomyopathies caused by volume or pressure overload (such as hypertension or valvular heart disease) that are not conventionally accepted under the definition of DCM.⁴

In general, ventricular tachyarrhythmias (VTs), including ventricular fibrillation and pulseless ventricular tachycardia, are the most common electrophysiological mechanisms leading to SCD.^{5,6} Other physiological events that can result in SCD include pulseless electric activity, bradyarrhythmias, and asystole.⁷ The risk of SCD has almost halved over the past two decades among patients with symptomatic heart failure and reduced ejection fraction (HFrEF).⁸ The primary contribution in this paradigm shift is of the sequential introduction of medications including angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), β -blockers, mineralocorticoid receptor antagonists (MRAs) and the latest, angiotensin receptor-neprilysin inhibitor (ARNI).⁹

Implantable cardioverter defibrillators (ICDs) play an important role in reducing arrhythmic events and have a clear indication in secondary prevention of SCD. However, their benefit in primary prevention in DCM has become a

matter of debate in the era of improved medical treatment and application of cardiac resynchronization therapy (CRT).¹⁰

PATHOPHYSIOLOGY OF DILATED CARDIOMYOPATHY

The dilatation of left ventricle (LV) is a result of the maladaptive changes in surviving myocytes and extracellular matrix which leads to pathological remodeling and impaired contractility. This activates the sympathetic and renin-angiotensin-aldosterone system which in turn produces syndrome of HF and myocardial electrical instability, the substrate for ventricular arrhythmias.^{11,12}

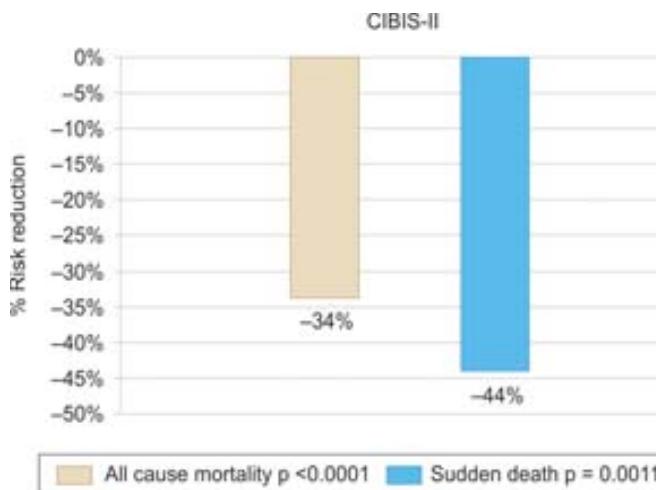

ROLE OF DRUG THERAPY IN SUDDEN CARDIAC DEATH

Pharmacological treatment is the backbone for prevention of disease progression in DCM. Drugs which modify the underlying substrate for LV remodeling not only prevent progression to terminal HF but also reduce the arrhythmic burden (Figs. 1 to 4).

Beta-blockers

Beta-blockers reduce myocardial oxygen demand and electrical excitability. Their antiarrhythmic efficacy is related to adrenergic blockade on sympathetically mediated triggering mechanisms, slowing of the sinus rate and inhibition of excess calcium release by the ryanodine receptors. Beta-blockers reduce the risk of SCD by 31%, cardiovascular disease (CVD) by 29%, and all-cause mortality by 33%.¹³

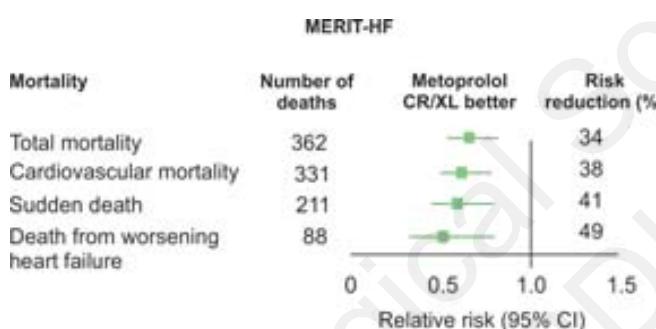

Three β -blockers (i.e., bisoprolol, carvedilol, sustained-release metoprolol succinate) have been proven to reduce mortality in patients with current or prior symptoms of HFrEF, with almost similar reductions in SCD. There is some evidence for greater benefit of vasodilating β -blockers compared with the nonvasodilating agents in patients with NICM.¹⁴

Mineralocorticoid Receptor Antagonists

The therapeutic effect of SCD prevention with MRAs are derived from a variety of mechanisms. MRAs limit potassium and magnesium loss and decrease myocardial fibrosis and hypertrophy. They also decrease stimulation of central adrenergic system, reduce the release of norepinephrine from sympathetic nerve terminals through enhanced parasympathetic activity and increase myocardial uptake of norepinephrine.¹⁵ Therapies with the MRAs, spironolactone, and eplerenone, have demonstrated reductions in both all-cause mortality and SCD.¹⁶

Angiotensin-converting Enzyme Inhibitors and Angiotensin Receptor Blockers

Local renin-angiotensin system (RAS) expression contributes substantially to myocardial structural changes that favor cardiac arrhythmias.¹⁷ ACEI have been postulated to reduce SCD by their sympatholytic activity and reduction in angiotensin II which is a facilitator of adrenergic transmission.¹⁸ Similarly, ARBs are indicated in patients who require RAS inhibition but are intolerant to ACEI. Both the drugs conserve potassium which is also involved in suppression of VAs.

Angiotensin Receptor-Neprilysin Inhibitor

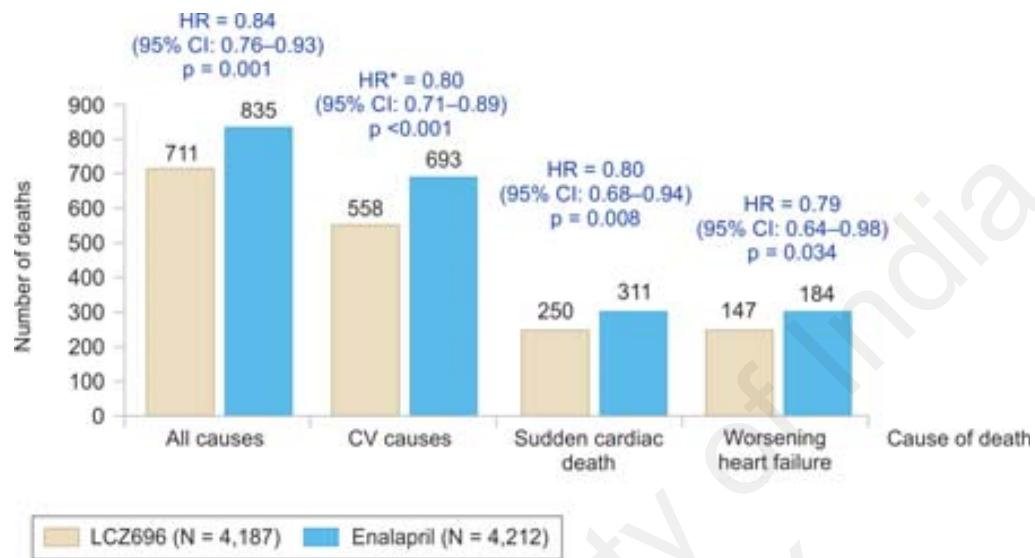

The newest drug in the armamentarium for the management of HF has proved superior to enalapril in reducing the risks of death and of hospitalization for HF.¹⁹ The benefit was observed in both SCDs and deaths from worsening HF, which accounted for the majority of cardiovascular deaths.²⁰

ROLE OF IMPLANTABLE CARDIOVERTER DEFIBRILLATOR

The evidence supporting prophylactic ICD implantation in patients with nonischemic DCM has been inconclusive from the very beginning. The initial trials which compared ICD to either medical therapy or amiodarone showed no significant benefit in primary end point of all-cause mortality.

In the Cardiomyopathy Trial (CAT), 104 patients having recent onset DCM with an ejection fraction of less than or equal to 30% were randomly assigned to an ICD or control. With a mean follow up of 5.5 + 2.2 years there was no significant difference in cumulative survival between control and ICD groups at 2 and 4 years, respectively. However, in this trial there were no sudden deaths in either group during the initial 2 years and only 4% of the population received β-blockers. This trial was limited by small number of patients and overall low observed mortality rates.²¹

The amiodarone versus implantable cardioverter-defibrillator randomized trial in patients with nonischemic DCM and asymptomatic nonsustained ventricular tachycardia (AMIOVIRT) randomized 103 patients with DCM, left ventricular ejection fraction (LVEF) of less than or equal to 35% and NSVT to either amiodarone or ICD. There was no significant difference in the primary end point of

CI, confidence interval; CV, cardiovascular; HR, hazard ratio.

FIG. 4: Modes of death in Paradigm-heart failure: The Mortality benefit of LCZ696 is related to the observed reduction in sudden cardiac death and death due to worsening heart failure.

Source: Desai AS, McMurray JJ, Packer M, et al. Effect of the angiotensin-receptor-neprilysin inhibitor LCZ696 compared with enalapril on mode of death in heart failure patients. Eur Heart J. 2015;36:1990-7.

3-year survival rate which was approximately 89% in both the groups. However, there was a trend towards improved arrhythmia-free survival and up-to 60% cost savings with amiodarone therapy. Again, the trial was limited by a small sample size and absence of control group.²²

The third trial in succession was DEFINITE which randomized 458 patients with nonischemic DCM, a LVEF of less than or equal to 36%, and PVCs or nonsustained ventricular tachycardia (NSVT) to receive either standard medical therapy or standard medical therapy plus a single chamber ICD. In this trial therapy with an ICD significantly reduced the risk of sudden death from arrhythmia (hazard ratio, 0.20; p = 0.006) and a nonsignificant trend towards reduction in all-cause mortality. Patients in New York Heart Association (NYHA) class III derived the largest survival benefit from ICD therapy. This was the first trial which laid the foundation of role of ICD in primary prevention of SCD.²³

The sudden cardiac death in heart failure trial (SCD-HeFT) which randomized 2,521 patients with congestive heart failure (CHF) (both ischemic and nonischemic etiologies) and LVEF of 35% or less to therapy with shock only ICD, amiodarone, or placebo. ICD therapy had a significant benefit in patients in NYHA class II with an overall reduction in mortality by 23% but not in those in NYHA class III CHF. In the subgroup of patients with NICM the hazard ratio for all-cause death was 0.73 with a 95% confidence interval (CI) between 0.50 and 1.04.²⁴

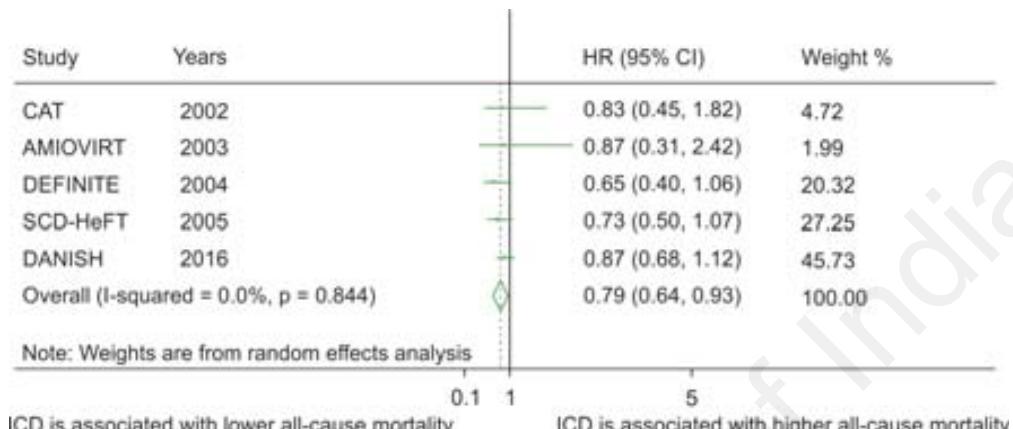

Pooling these and three other secondary prevention trials, a meta-analysis by Desai et al. found an overall 31% mortality reduction with ICD in patients having nonischemic DCM.²⁵ The present American College of Cardiology/American Heart Association (ACC/AHA) guidelines for primary prevention of

SCD in nonischemic DCM is largely based on the data from these trials and meta-analysis,¹ and recommend ICDs as a class I A indication for prevention of SCD in DCM.

However, with the trials in present era of CRTs and improved medical therapy, more controversy has erupted than a sound consensus. The Danish study to Assess the Efficacy of ICDs in Patients with Nonischemic Systolic Heart Failure on Mortality (DANISH) randomized 1,116 patients without ischemic heart disease having NYHA class II or III HF symptoms or NYHA class IV symptoms if CRT planned, LVEF of less than or equal to 35%, and an increased N-terminal pro B-type natriuretic peptide (NT-proBNP) despite guideline-directed medical therapy to an ICD or medical therapy alone. There was a significant reduction in secondary outcome of SCD but a neutral effect on primary outcome of all-cause mortality over a median follow up of 5.6 years with the use of an ICD. Younger patients fared much better with an ICD than those over 70 years.²⁶ The reasons behind nonachievement of primary endpoints as speculated are primarily due to overall low risk of SCD in the selected population attributed to robust medical management including full throttle use of β-blockers, ACEI or ARBs and in up to two-thirds, addition of MRA. However, 58% of the patients in both the arms received CRT, thus confounding the results as it was not a pure ICD trial.

As the results were directly in confrontation with the recommended American and European guidelines, more meta-analyses including or excluding DANISH trial have been done in an attempt to resolve the dilemma.

A meta-analysis done by Barakat A et al.²⁷ which included five multicenter randomized controlled trials (RCTs) with 2,573 patients found that ICD therapy for primary prevention

in patients with nonischemic DCM was associated with 21% relative risk reduction and 3% absolute risk reduction in all-cause mortality (number needed to treat = 33) compared with medical therapy alone, at a mean follow-up of approximately 4 years. The benefit was seen across a wide spectrum of nonischemic DCM patients, with diverse demographics and clinical presentations. There was a suggestion of possible effect modification by age, with more benefit in patients less than 60 years (Fig. 5).²⁸

The COMPANION trial was excluded from this meta-analysis due to unbalanced use of CRT between the intervention and control arms. Pooled data from another meta-analysis done by Al-Khatib et al. which included four RCTs of nonischemic DCM with 1,874 unique patients equally divided into ICD and control group, showed a significant reduction in all-cause mortality with an ICD (hazard ratio, 0.75; 95% CI, 0.61–0.93; p = 0.008; p = 0.87 for heterogeneity).

The strength of this meta-analysis was a more robust approach to reduce heterogeneity by excluding trials of CRT and anti-arrhythmic medications. However, actual mortality rates were available for only DEFINITE and SCD-HeFT trials due to nonavailability of patient level data from the CAT and DANISH trials which was a major limitation here.

An updated meta-analysis by Golwalla H et al. enrolled 2,970 patients from six RCTs (including those with CRT defibrillator) to study the efficacy of ICD in primary prevention. Pooled analysis demonstrated a statistically significant 23% reduction in all-cause mortality in favor of ICD therapy (hazard ratio, 0.77; 95% CI, 0.64–0.91).²⁹

Even on doing a separate analysis by excluding trials of CRTs there was still a 24% reduction in all-cause mortality. Also, despite the individual subgroup analysis of COMPANION and DANISH trials demonstrating no incremental benefit of ICD in patients with CRT, when combined,

it was found that ICDs may still reduce all-cause mortality in patients who are also candidates for CRT therapy, although the results did not meet statistical significance.

RISK STRATIFICATION

In the absence of better markers, LVEF continues to be used as a key criterion to select patients for primary prevention ICDs. However, LVEF has a low sensitivity and specificity for SCD prediction³⁰ as reflected by delivery of appropriate therapies from device follow up which are seen in only about 20% of patients with DCM who have ICDs for primary prevention.²³

Registry data suggest that some of patients with DCM and an out-of-hospital cardiac arrest do not have a markedly reduced LVEF. In addition, many patients with reduced LVEF die of nonsudden causes of death.³¹

There are various risk stratification models which try to predict chances of SCD but none have been proven useful. There is a clear need to improve this prediction (Table 1).

Cardiac Magnetic Resonance Imaging Late Gadolinium Enhancement as a Marker of Increased Risk

Ventricular fibrosis identified by cardiac magnetic resonance (CMR) with late gadolinium enhancement (LGE) has emerged as a promising tool for targeted stratification of SCD in nonischemic DCM. Patients with DCM have characteristic mid-wall fibrosis which can be detected by LGE-CMR³² and have been associated with adverse cardiac events such as HF hospitalizations, appropriate ICD therapy, and SCD as well as all-cause mortality.^{33–35}

In a recent systemic review and meta-analysis of the association between LGE-based myocardial scar and the

TABLE 1: Traditional and novel risk markers

risk for VT in patients with DCM, it was found that LGE is a strong independent predictor of arrhythmic events and could improve risk stratification for SCD and appropriateness of ICD therapy. A total of 2,948 patients from 29 studies were included in this meta-analysis who were followed for an average of 3 years. LGE was found to be present in 44% of patients. The arrhythmic endpoint was defined as sustained ventricular arrhythmias, appropriate ICD intervention, or SCD. In this meta-analysis, LGE had the strongest association with the arrhythmic outcome (odds ratio: 7.8) in patients who were implanted ICDs for primary prevention. Patients with LGE had a relatively high annual event rate (17.2% per year) as compared to those without LGE (2.1% per year).³⁶

However, in one study, myocardial scar assessed by LGE-CMR predicted only monomorphic VT, but not polymorphic VT/ventricular fibrillation (VF) in patients with nonischemic DCM, who remain at risk for potentially fatal polymorphic VT/VF.³⁷ Also, due to marked variability in methodology and interpretation of LGE, there is a need for standardization of qualitative and quantitative criteria to reinforce its role in decision making in patients with DCM.

CONCLUSION

While data on secondary prevention of SCD in DCM are robust, those in primary prevention are relatively handicapped by small number of patients in almost all studies making them unable to reach statistical significance in individual trials. The majority of meta-analysis, however, including those with or without CRT, show a reduction of mortality by ICDs in primary prevention. The current ACC/AHA/HRS (the Heart Rhythm Society) guidelines for prevention of SCD have retained ICDs as a class I indication in nonischemic DCM in primary prevention. Till we see a large RCT on primary prevention in nonischemic DCM proving otherwise, ICDs shall continue to be prescribed in patients with nonischemic DCM. In the absence of definite risk predictors, LVEF shall remain as the only deciding criterion for selection of patients for ICD. CMR imaging

appears promising but only observational data is available in a relatively small number of patients. Clearly, there is a need for further research in this area.

Orthostatic Hypotension

Siddharthan Deepti, Kewal C Goswami

INTRODUCTION

Orthostatic hypotension results from a sustained reduction in blood pressure (BP) upon standing and may present as a disabling condition. Most commonly seen in the elderly, orthostatic hypotension may cause postural instability, syncope, and falls and is associated with an increased risk of stroke, myocardial ischemia, and mortality.

DEFINITION

Orthostatic hypotension is a clinical sign defined as a sustained decrease in systolic BP of at least 20 mm Hg or diastolic BP of at least 10 mm Hg or both within 3 minutes of standing or head-up tilt to at least 60° on a tilt table.¹ A reduction in systolic BP of 30 mm Hg may be a considered a better criterion in patients with supine hypertension, because the extent of the postural fall in BP is dependent on the baseline BP. Orthostatic hypotension is a clinical sign by definition and therefore, may be symptomatic or not.

EPIDEMIOLOGY

The prevalence of orthostatic hypotension is variable in different epidemiological studies, depending on the definitions used, the population studied (age range, institutions) and the composition of the population (unselected healthy population versus select groups). Overall, in a population of unselected middle-aged subjects (>40 years), the cross-sectional prevalence is estimated to be approximately 5–6%.^{2,3} There is a gradual increase in the prevalence with age ranging from 10 to 30% in older subjects,⁴ with orthostatic hypotension affecting more than two-fifths of the population aged older than or equal to 80 years, more commonly in the institutionalized elderly.⁵ Its prevalence is increased in certain neurological disorders and with use of certain drugs.

Orthostatic hypotension may cause postural instability, syncope, and falls. It is a negative prognostic factor, which

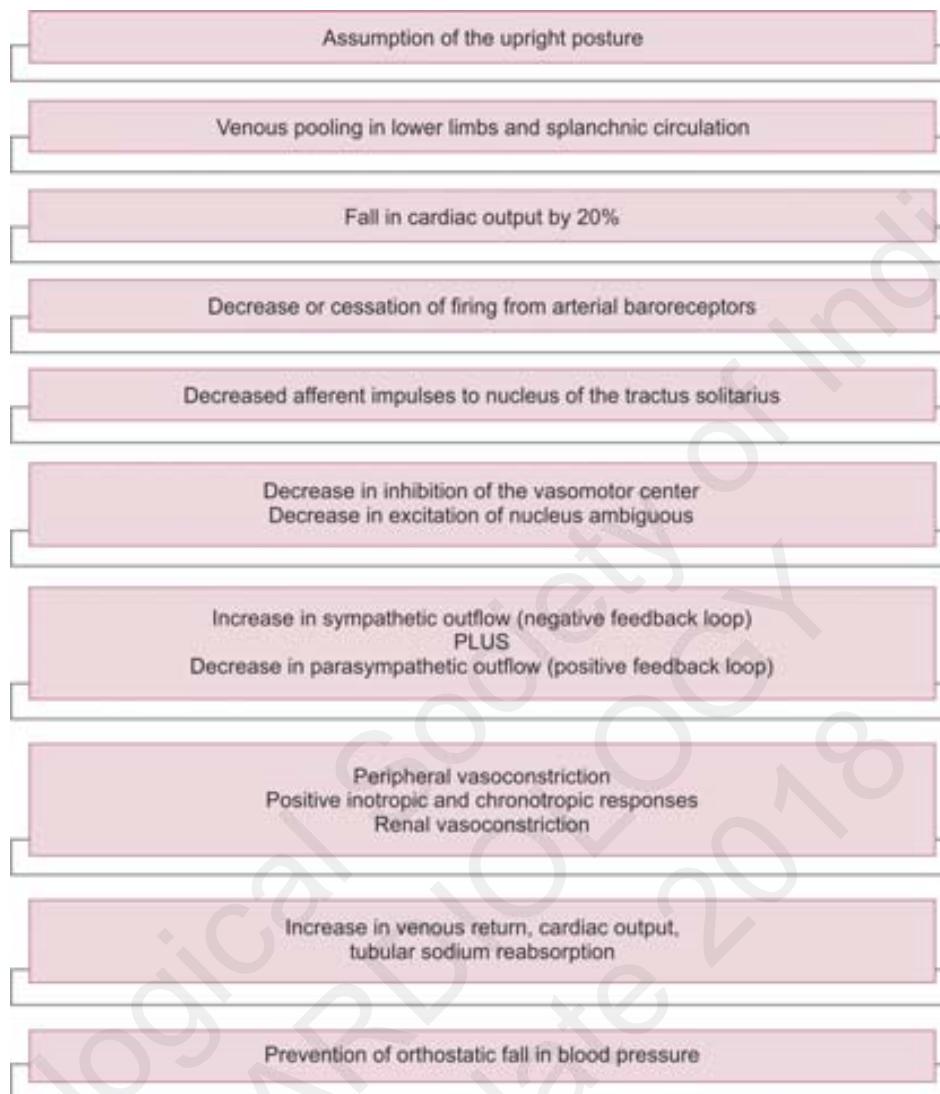

has been shown in longitudinal studies to be associated with an increased risk of stroke, myocardial ischemia, and mortality.^{6,7}

PHYSIOLOGY OF THE NORMAL ORTHOSTATIC RESPONSE

Assumption of the upright posture from supine or sitting positions leads to a series of changes. Due to the effect of gravity, there is pooling of 500–700 mL of blood from the upper body to the venous capacitance vessels of the lower limbs and splanchnic circulation within a few seconds of standing. Additionally, there is a shift of approximately 10% of the intravascular plasma toward the interstitial compartment due to increased hydrostatic pressure within 10–30 minutes of upright posture. The resultant decrease in venous return leads to a fall in right ventricular filling pressure, and ultimately cardiac output by approximately 20%. The ensuing reduction in BP would compromise perfusion of organs above heart level if not for the compensatory mechanisms that have evolved to counteract the gravitational stress, and thus allow humans to maintain an erect posture for prolonged periods of time. The compensatory mechanisms include the following.

Baroreflex

The autonomic nervous system is the main physiological system involved in maintenance of homeostasis upon assuming the upright posture. The reflex is primarily mediated via baroreceptors which are stretch-dependent mechanoreceptors located within the wall of vessels, that detect small variations in arterial pressure or central blood volume, through deformations of the vessel wall. There are two types of baroreceptor each having separate roles. Arterial or high-pressure baroreceptors are located in the carotid sinuses, the aortic arch and the origin of the right subclavian artery. They are the most significant players in the acute adaptation to the upright posture.

FLOWCHART 1: Baroreceptor reflex.

Cardiopulmonary or low-pressure baroreceptors are located in major cardiopulmonary vessels. They respond to changes in central blood volume and are involved in the control of renal sympathetic nerves.

Afferent impulses travel via the glossopharyngeal (IX) and vagus (X) nerves from carotid and aortic baroreceptors, respectively, and via nonmyelinated vagal nerve fibers from low-pressure baroreceptors to the nucleus of the tractus solitarius (NTS). The NTS sends inhibitory fibers to the vasomotor center in the caudal ventrolateral medulla and the rostral ventrolateral medulla, which controls sympathetic output to the arteries, veins, and heart through the intermediolateral column of the thoracic spinal cord. Additionally, the NTS sends excitatory fibers to the nucleus ambiguus, which controls parasympathetic output to the sinoatrial node of the heart.

Distension of a vessel with rise in BP leads to the activation of baroreceptors that generate action potentials increasing

in frequency in correlation to the amount of stretch. The frequency of these potentials is taken as a surrogate measure of BP at the level of the NTS, with higher frequency correlating with higher BP. The high-pressure baroreceptors remain tonically active at a mean arterial pressure above 70 mm Hg, which is termed the baroreceptor set point. At a mean arterial pressure below this set point, the receptors become essentially silent.

A fall in BP upon standing leads to decrease or cessation of firing from the arterial baroreceptors, causing an increase in sympathetic outflow (negative feedback loop) and a decrease in parasympathetic outflow (positive feedback loop). These changes lead to peripheral vasoconstriction, positive inotropic and chronotropic responses, and renal vasoconstriction. All these homeostatic mechanisms in turn increase venous return, cardiac output, and tubular sodium reabsorption, thereby preventing orthostatic fall in BP. The baroreceptor reflex has been summarized in flowchart 1.

Muscle Pump

Muscle contractions involved in the assumption and maintenance of upright posture contribute to prevention of orthostatic fall in BP by compressing capacitance vessels and by increasing peripheral vascular resistance.

Renin–Angiotensin–Aldosterone System

The renin–angiotensin–aldosterone system enables long-term orthostatic homeostasis (minutes and hours) unlike the baroreflexes which govern the beat-to-beat variations in BP. The transient fall in glomerular afferent arteriole perfusion pressure upon standing leads to the production of renin by the juxtaglomerular apparatus. Renin promotes the production of angiotensin II via angiotensin converting enzyme. Angiotensin II results in vasoconstriction, increased tubular reabsorption of sodium, secretion of aldosterone from the adrenal cortex, which in turn again promotes reabsorption of water and sodium and finally, increase in central sympathetic outflow.

These compensatory mechanisms ensure that there is only a small decrease in systolic and diastolic BP (~5 mm Hg) and an increase in heart rate (15–30%, <30 beats/min) during the first 10 seconds after standing, followed by a return to baseline value (or slightly above) for systolic BP and typically a small increase in diastolic BP, resulting in a decrease in pulse pressure (5–10%).

Etiology

The causes of orthostatic hypotension are listed in table 1.

Drugs

The most common causes of orthostatic hypotension are drugs that cause either volume depletion or vasodilation. The most intuitive culprits are the antihypertensive drugs. But not all antihypertensive drugs cause orthostatic fall in BP to the same extent. The most notorious are the α -adrenergic blocking drugs, β -adrenergic blocking drugs, diuretics including spironolactone, centrally acting hypotensive drugs and peripheral vasodilators. The angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and calcium channel blockers are found to be less associated with orthostatic hypotension.

Apart from antihypertensive drugs, other classes including antidepressants, antipsychotic drugs, sedatives, pulmonary vasodilators, and dopamine agonists are associated with orthostatic hypotension.

Neurogenic Causes

Orthostatic hypotension may also be caused by autonomic nervous system dysfunction which may be primary or secondary.

Primary Autonomic Failure

Primary causes of autonomic dysfunction are usually idiopathic and include pure autonomic failure (PAF), multiple

system atrophy (MSA), and Parkinson's disease (PD) with autonomic failure.

Pure autonomic failure, also known as Bradbury-Eggleston syndrome after the physicians who first described this condition, is an idiopathic sporadic disorder with onset in the fifth or sixth decades and a slowly progressive course. The underlying pathology involves deposition of α -synuclein in the peripheral autonomic neurons. Alpha-synuclein is a small, highly conserved and natively unfolded protein which is found in the cytoplasm of neurons. The exact physiological role is not known. In α -synucleinopathies, there is abnormal deposition of fibrillar α -synuclein in cytoplasm of neurons or glial cells leading to different yet overlapping syndromes depending on the cells involved. PAF is characterized by manifestations of widespread dysautonomia including orthostatic hypotension in conjunction with disturbances in bowel (diarrhea or constipation), bladder (urgency or atonic bladder), sexual function (erectile dysfunction), and/or thermoregulatory function (hypo or hyperhidrosis). Supine plasma norepinephrine levels are reduced.

A close differential diagnosis is MSA also known as Shy–Drager syndrome. MSA is a sporadic, progressive, adult-onset disorder occurring due to accumulation of α -synuclein in glial cells of basal ganglia, cortex, and spinal cord. The cardinal features of MSA include dysautonomia, Parkinsonism, and ataxia in any combination. The presence of symptoms or signs of central neurodegeneration and rapid eye movements, sleep behavior disorders favor MSA over PAF. Often, demonstration of an isolated autonomic dysfunction after careful neurological examination over a prolonged period of follow-up (up to 5 years) is required to conclusively establish the diagnosis of PAF.

A third cause of primary autonomic failure is a subset of PD with primarily autonomic dysfunction. Also, an α -synucleinopathy, dysautonomia results from deposition of α -synuclein in not only in brainstem nuclei, but also in peripheral autonomic neurons, unlike MSA. The parkinsonian form of MSA may be distinguished from PD with autonomic failure by good response of Parkinsonism to levodopa in PD, though this feature is not completely sensitive. An additional aspect of orthostatic hypotension in PD is the fact that most drugs used for treatment of Parkinsonism (levodopa, anticholinergic drugs, and monoamine oxidase inhibitors) can themselves cause orthostatic hypotension.

Secondary Neurogenic Causes

The secondary neurogenic causes of orthostatic hypotension are listed in table 1. The most important of these are discussed below:

- **Diabetes:** Orthostatic hypotension is more prevalent in diabetic patients than in age- and sex-matched control subjects and is associated with increasing age and chronic poor glycemic control. The prevalence of orthostatic hypotension in diabetes varies from 7–18% depending on the definitions used and populations sampled. This figure compares with the prevalence in unselected subjects above the age of 65 years. In diabetic patients, orthostatic

hypotension is usually associated with generalized polyneuropathy, with diabetes being the most common cause of autonomic dysfunction in developed countries.

- **Amyloidosis:** Mixed sensory and motor peripheral neuropathy and/or autonomic neuropathy account for 20% and 15% of cases of amyloid light-chain (AL) amyloidosis.⁸ Nerve injury is attributed to direct compression by accumulation of fibrils in vasa nervorum walls. Autonomic dysfunction, including orthostatic hypotension, is frequently associated with polyneuropathy at an advanced stage and is associated with a poor prognosis.
- **Paraneoplastic autonomic neuropathies:** Dysautonomia leading to orthostatic hypotension may be the presenting feature of an underlying neoplasm. It is most often observed with neoplasms of the lung [more common with small-cell lung cancer (anti-Hu antibodies)] followed by cancers of gastrointestinal tract, prostate, breast, bladder, kidney, pancreas, testicle, and ovary.
- **Hereditary autonomic neuropathies:** Hereditary sensory and autonomic neuropathy (HSAN) type III (also called familial dysautonomia) is an autosomal recessive disorder seen primarily in Ashkenazi Jewish children. Orthostatic hypotension is associated with lack of sensitivity to pain and temperature stimuli, hyporeflexia, absence of tears (alacrima), and absence of lingual fungiform papillae.
- **Miscellaneous:** Other causes of peripheral autonomic dysfunction include infectious diseases like HIV/AIDS (human immunodeficiency virus/acquired immune deficiency syndrome) and Chagas disease, neurotoxic drugs like vincristine and azole antifungals, vitamin B12 deficiency and primary Sjögren's syndrome.

Non-neurogenic Causes

In the vast majority of cases, an obvious neurogenic cause is lacking. The main inciting factors in such cases include hypovolemia, either absolute (dehydration, diarrhea, bleeding, hemodialysis, adrenal insufficiency, and hypoaldosteronism) or relative, due to vasodilatation (alcohol, heat, carcinoid syndrome, and mastocytosis) or venous pooling

(cirrhosis). Orthostatic hypotension is frequently seen in heart failure without involvement of the autonomic nervous system. Another important mechanism for non-neurogenic orthostatic hypotension is deconditioning, commonly seen in elderly hospitalized patients after prolonged bed rest.

CLINICAL PRESENTATION

Orthostatic hypotension, by definition, is a clinical sign and therefore, may be entirely asymptomatic. Symptoms will result if the postural reduction in BP is severe enough to cause cerebral hypoperfusion. Characteristic symptoms include dizziness, light-headedness, or even syncope in response to sudden postural changes. However, the symptoms may be nonspecific such as fatigue, altered mentation, generalized weakness, nausea, headache, pain in the neck and shoulders (the so-called "coat hanger pain", due to hypoperfusion of neck muscles), leg buckling, and low back pain. Retinal or occipital lobe ischemia may cause blurring of vision upon standing. Other less common forms of clinical presentation include orthostatic dyspnea (attributed to ventilation-perfusion mismatch due to inadequate perfusion of ventilated lung apices) or orthostatic angina (attributed to impaired myocardial perfusion even in patients with normal coronary arteries). These symptoms are aggravated by exercise, meals, in the mornings or in hot weather and are characteristically relieved with sitting or lying down.

ORTHOSTATIC TESTING AND VARIANTS OF ORTHOSTATIC HYPOTENSION

Testing for orthostatic hypotension should be done in a quiet room, at a temperature between 20 and 24°C after the patient has been resting for 5 minutes with an empty bladder. Orthostatic testing may be done either at the bedside or on a tilt table.

This mode of testing may miss two important variants of orthostatic hypotension listed below:

1. The first variant is initial orthostatic hypotension which is seen more commonly in young subjects. The orthostatic fall in BP occurs within 15 seconds of standing (more

than 40 mm Hg systolic or more than 20 mm Hg diastolic BP) and recovers quickly, though this might be enough to cause syncope. This is likely to be thought to be due to a transient mismatch between cardiac output and peripheral vascular resistance rather than autonomic failure. Beat-to-beat measurement of BP is required to diagnose this condition.

2. The second variant is delayed orthostatic hypotension, wherein orthostatic hypotension occurs after 3 minutes of standing. This variant may represent an early form of sympathetic dysfunction. Prolonged measurements may be necessary for diagnosis.

Simultaneous monitoring of heart rate enables differentiation between the neurogenic and non-neurogenic causes of orthostatic hypotension. Non-neurogenic hypotension is often accompanied by a compensatory increase in heart rate (approximately 15 beats/min) reflecting preserved autonomic function.

DIFFERENTIAL DIAGNOSIS

Orthostatic hypotension should be differentiated from the following closely related disorders:

- Orthostatic intolerance is a distinct entity seen most commonly in young women who present with symptoms similar to that of orthostatic hypotension. However, no drop in BP is observed on orthostatic testing. This condition is associated with problems of localized excess noradrenergic stimulation to abnormalities of the baroreflex response.
- Postural orthostatic tachycardia syndrome (POTS) is defined by symptoms of orthostatic intolerance accompanied by a sustained increase in heart rate of more than 30 beats/min upon assuming the upright posture. However, there is characteristic absence of significant hypotension, or sometimes even a mild increase in BP on standing. This condition is usually seen in the second or third decades of life and is far more common in women than men. POTS is believed to result from impaired sympathetic tone, resulting in a reduced venoconstriction and pooling of blood volume in the lower limb and splanchnic vascular beds or secondary to deconditioning after prolonged bed rest. Standing serum norepinephrine levels are increased. A hyperadrenergic form of POTS is also described which is associated with increase in BP upon standing.
- Neurally mediated or reflex syncope may present with symptoms similar to orthostatic hypotension but the autonomic function testing between the episodes is normal. The mechanism of reflex syncope differs from that of orthostatic hypotension and involves cardiac hypercontractility secondary to decreased venous return to the heart resulting from increased peripheral venous pooling of blood. In this condition, the reflex bradycardia and hypotension are similar to those evoked by the Bezold–Jarisch reflex and are not due to baroreceptor inactivation.

MANAGEMENT

The etiologic work-up should begin with the establishment of the diagnosis with orthostatic testing. A detailed treatment history should be taken to exclude the use of drugs causing orthostatic hypotension. If the postural fall in BP is associated with a compensatory increase in heart rate, non-neurogenic causes should be looked for (e.g., absolute or relative hypovolemia). If a heart rate response is absent, a neurogenic cause should be suspected. A structured history, physical and neurological examination, should be done in search of central and peripheral neurological symptoms and signs. Important investigations include blood glucose (diabetes), serum electrophoresis and urine protein (AL amyloid), and serum cortisol levels (Addison's disease) if no clue is found on clinical evaluation.

TREATMENT

The mainstay of treatment is education of the patient regarding the nature of the condition and nonpharmacological measures.¹¹

Nonpharmacological Treatment

The obvious first measure should be stop any offending drugs after weighing the risk-benefit ratio. The nonpharmacologic measures include:

- Avoidance of triggering factors or situations like hot weather, prolonged standing, and abrupt standing
- Gradual staged movements with change from supine to standing positions, especially in the morning, when orthostatic tolerance is lowest
- Physical counter-maneuvers like leg-crossing, toe raising, stooping, squatting and tensing the muscles of the leg, abdomen, or buttocks or of the whole body
- Use of elastic compression stockings covering both lower limbs and lower abdomen or a separate binder for abdomen; however, these are poorly accepted by patients due to discomfort
- Sleeping after raising the head of the bed by 10–20°
- Avoiding prolonged recumbency
- Avoidance of large meals, foods rich in carbohydrates, and alcohol intake to minimize postprandial orthostatic hypotension. (Sudden standing or physical activity immediately after eating should be avoided)
- Performing isotonic exercises (recumbent or seated exercise may be preferable with avoidance of straining during exercise)
- Increasing intake of water (2–2.5 L/day) and salt (up to 6–10 g/day), if feasible
- Rapid ingestion of tap water or preferably intake of cold water.

Pharmacological Treatment

If there is inadequate response to nonpharmacologic measures, the following drugs are recommended.

- *Fludrocortisone acetate:* A potent synthetic mineralocorticoid analog, fludrocortisone increases renal sodium reabsorption and leads to expansion of intravascular volume. Additionally, it enhances the release of norepinephrine from sympathetic neurons thereby potentiating the vasoconstrictive effect of norepinephrine. However, though these effects are useful in decreasing orthostatic hypotension, they are also responsible for supine hypertension and decompensation in patients with heart failure. Accordingly, fludrocortisone was recommended by the European Federation of Neurological Societies in 2006 as the first-line drug for orthostatic hypotension refractory to nonpharmacologic measures provided supine hypertension and heart failure are absent.⁹ Robust evidence for the use of this drug is however lacking. A Cochrane systematic review is currently underway to ascertain the efficacy of this drug in orthostatic hypotension.

Dose is 50 µg/day at initiation with up-titration up to 300 µg/day depending on the clinical response. Adverse effects include exacerbation of heart failure, hypokalemia, hypomagnesemia, and supine hypertension. Additionally, mineralocorticoids have been shown to promote cardiac fibrosis through the induction of oxidative stress and endothelial dysfunction in animal models.

- *Midodrine:* Midodrine, a selective and direct α -adrenoreceptor agonist, increases peripheral resistance. This drug is approved by the US Food and Drug Administration (FDA) in orthostatic hypotension. Evidence to recommend the use of midodrine in orthostatic hypotension is insufficient and low-quality.¹⁰ The half-life is only 4 hours with increase in BP lasting for 2–3 hours. Therefore, dosing needs to be individualized according to patient's activities. The first dose is usually administered 30 minutes before morning rise. The drug should be avoided after 4 PM as it promotes nighttime supine hypertension. The daily dose varies greatly, from 2.5 to 37.5 mg depending on the degree of desensitization. Adverse events include piloerection, scalp pruritus, paresthesias, urinary hesitancy or retention, and supine hypertension
- *Droxidopa:* L-threo-3,4-dihydroxyphenylserine (L-DOPS) or droxidopa is an oral sympathomimetic amino acid which is metabolized into norepinephrine both peripherally and centrally by DOPA decarboxylase. This drug was approved by the US FDA in February 2014 for use in symptomatic orthostatic hypotension secondary to primary autonomic failure, dopamine β -hydroxylase deficiency(DBHD) or nondiabetic autonomic neuropathy. A recent meta-analysis concluded that there is moderate level of evidence for improvement with droxidopa in both dizziness and general orthostatic hypotension-related symptoms in patients with neurogenic orthostatic hypotension, in the short term. The starting dose is 100 mg three times a day with the final dose before 5 PM to avoid supine hypertension. The dose may be up-titrated to a maximum of 600 mg thrice daily depending on the clinical response. There are no significant adverse effects apart from supine hypertension

- *Atomoxetine:* It is a selective norepinephrine reuptake inhibitor that selectively inhibits the reuptake of norepinephrine with little to no activity at the other neuronal reuptake pumps or receptor sites. The role of this drug in the treatment of orthostatic hypotension has been explored recently. In a randomized study in patients with severe autonomic dysfunction, atomoxetine was shown to be a viable and possibly superior treatment option compared with midodrine. Before initiation, the possible adverse effects should be discussed, including suicidal ideation (though reported mainly in children and adolescents), depression, aggressive behavior, priapism, urination retention, and hepatotoxicity (requiring monitoring with liver function tests). This drug should be avoided in patients with serious structural heart disease because of risk of sudden death, stroke, and myocardial infarction
- *Miscellaneous:* Other agents that have been tried in orthostatic hypotension include pyridostigmine, erythropoietin, octreotide, phenylpropanolamine, pseudoephedrine, and arginine vasopressin. However, the evidence in support of their use is poor and low quality.

CONCLUSION

Orthostatic hypotension is a common yet underreported clinical sign, which is associated with an increased morbidity and mortality. A clear understanding of the pathophysiology is required for diagnosis. Treatment should always first rely on elimination of the causative mechanism and nonpharmacological measures, which are sufficient in a large number of patients. Pharmacologic treatment is based on a weak level of evidence.

SECTION 15

Atrial Fibrillation

Stroke Prevention in Atrial Fibrillation: New Oral Anticoagulants

Sharad Agrawal

INTRODUCTION

Stroke has long been recognized as a devastating complication of atrial fibrillation (AF). Long-term anticoagulation with warfarin (with all its inherent problems) has been the standard treatment for majority of such patients for many decades. Understandably, the patient with AF may well feel stuck between a devil and the deep sea, because of high risk of stroke associated with AF on one hand and the problems associated with standard warfarin therapy on the other.¹

However, several new oral anticoagulants (NOACs), have now been approved for clinical use and offer much better efficacy and safety than the standard warfarin therapy even without the need for regular therapeutic monitoring.¹ The field of stroke prevention in AF is being revolutionized not just by NOACs but also by the development of new risk scoring systems for better identification of patients at higher risk of stroke and the bleeding complications.^{1,2}

Most of the morbidity and mortality associated with AF is primarily due to thromboembolic complications resulting into ischemic strokes.³ Mortality due to stroke can largely be mitigated by effective anticoagulation,⁴ while other cardiovascular deaths, i.e., due to heart failure and sudden death, remain unaffected despite the contemporary evidence-based treatment.⁵

EPIDEMIOLOGY OF STROKE IN ATRIAL FIBRILLATION

Atrial fibrillation is quite common sustained cardiac arrhythmia. It is currently estimated to affect approximately 1–2% of general population, but its prevalence is expected to at least double in the next 50 years.² AF may often remain undiagnosed (silent AF) for a long time due to relative paucity of symptoms. The increase in prevalence of AF can be attributed to better detection of silent AF,⁶ increasing average age of population as well as conditions predisposing to AF.⁷

Even if silent, AF is not a benign condition. It may confer a fivefold increase in the overall risk of stroke, and it is responsible for up to 15% of all strokes.⁸ Strokes in AF have particularly higher significance as they are often large, likely recurrent and therefore result in long-term disability or death.^{2,9} Mortality from AF-related stroke is doubled and the cost of care is also significantly increased.⁹

RISK STRATIFICATION TOOLS IN ATRIAL FIBRILLATION

Previously available schemes categorized the stroke risks with AF into a “low”, “medium”, or the “high” risk groups with overlapping features; and therefore, leading to inconsistent recommendations regarding the use of anticoagulants. Several risk stratification tools have now been developed to objectively assess the risk of stroke as well as the bleeding complications depending upon their associated clinical features.¹⁰

Estimation of Stroke Risk in Atrial Fibrillation

The risk of stroke is not homogeneous among all patients with AF and can vary up to 20-fold depending on presence of other associated clinical features.¹¹ The most consistent predictors of stroke in AF are previous history of stroke or transient ischemic attack (TIA) or systemic embolism, advanced age, hypertension, diabetes mellitus, and congestive heart failure.¹¹ Although a number of risk stratification tools are currently available, the CHA₂DS₂-VASc score is most widely used and recommended by the European Society of Cardiology (ESC) guidelines.^{2,4}

The CHA₂DS₂-VASc score¹² is based on a point system in which 2 or 1 points are assigned for various associated clinical features as shown in table 1.

Several validation studies have shown incremental risk of stroke with increasing CHA₂DS₂-VASc scores as shown in table 2.¹³

TABLE 1: The CHA₂DS₂-VASc scoring system¹²

Letter	Clinical features	Score (points)
C	Congestive heart failure/LV dysfunction	1
H	Hypertension	1
A ₂	Age >75 years	2
D	Diabetes mellitus	1
S ₂	Previous stroke/TIA	2
V	Vascular disease (includes old MI, peripheral arterial disease)	1
A	Age 65–74 years	1
Sc	Sex category (i.e., female sex)	1

LV, left ventricular; MI, myocardial infarction; TIA, transient ischemic attack.

TABLE 2: The CHA₂DS₂-VASc score and the stroke rate¹³

CHA ₂ DS ₂ -VASc score	Number of patients (n = 7,329)	Adjusted stroke rate (% per year)
0	1	0%
1	422	1.3%
2	1,230	2.2%
3	1,730	3.2%
4	1,718	4.0%
5	1,159	6.7%
6	679	9.8%
7	294	9.6%
8	82	6.7%
9	14	15.2%

Estimation of Bleeding Risk for Anticoagulant Therapy in Atrial Fibrillation

Although several bleeding risk scores have been developed and validated, but most widely used risk score is HAS-BLED (Hypertension; Abnormal renal and liver function; Stroke; Bleeding; Labile INR; Elderly; Drugs or alcohol), which was developed using data from 3,978 European subjects with AF from the Euro Heart Survey (Table 3).¹⁴

A score of more than or equal to 3 indicates “high risk”, and some caution and regular review of the patient is needed following the initiation of antithrombotic therapy.²

Recent validation study has shown that HAS-BLED scores work better as compared to several other schemes tested (Table 4).¹⁵

ANTITHROMBOTIC MANAGEMENT OF ATRIAL FIBRILLATION

The currently available therapeutic options are:

- Antiplatelet agents (aspirin and clopidogrel)—mostly abandoned now
- Vitamin K antagonist (warfarin)—has been standard therapy but less popular

TABLE 3: The HAS-BLED bleeding risk score¹⁴

Letter	Clinical features	Score (points)
H	Hypertension	1
A	Abnormal renal and/or liver functions (1 point each)	1 or 2
S	Stroke	1
B	Bleeding	1
L	Labile INRs	1
E	Elderly (age >65 years)	1
D	Drugs and/or alcohol (1 point each)	1 or 2

INR, international normalized ratio.

TABLE 4: The HAS-BLED scores and the bleed rates¹⁵

HAS-BLED score	Number of patients (n = 3,071)	Bleeds/100 patients
0	798	1.13
1	1,286	1.02
2	744	1.88
3	187	3.74
4	46	8.70
5	8	12.50
Any score	3,071	1.56

- New oral anticoagulants—fast becoming treatment of choice:
 - Direct thrombin inhibitors—dabigatran
 - Factor Xa inhibitors—rivaroxaban, apixaban, and edoxaban.

Antiplatelet Therapy (As an Alternative to Oral Anticoagulants?)

Up until recently, aspirin has traditionally been used very widely in thromboprophylaxis for stroke prevention in patients with AF. This was partly because of the reluctance of patients to accept warfarin therapy.¹ In a recent meta-analysis of eight independent trials by Hart, aspirin compared with placebo showed only a nonsignificant effect or even no effect in reducing the risk of stroke in AF.¹⁶ In another study aspirin appears to confer no benefit, but more bleeding events.¹⁷

Dual Antiplatelet Therapy in Stroke Prevention in Atrial Fibrillation

The possibility that dual antiplatelet therapy might represent a safe and simpler alternative to oral anticoagulation was evaluated in the prospective ACTIVE-W trial¹⁸ in which 6,706 patients with AF at high risk of stroke were randomized to treatment with either aspirin + clopidogrel or warfarin [target international normalized ratio (INR) 2.0–3.0]. The trial was stopped early because of the superiority of warfarin therapy in stroke prevention with no significant difference in bleeding events between treatment arms.¹⁸

Latest ESC guidelines 2016 therefore conclude that the antiplatelet therapy cannot be recommended for stroke prevention in AF patients.⁴

Vitamin K Antagonist

Vitamin K antagonist (VKA), such as warfarin, has been in the clinical use for over 50 years and has been the most common oral anticoagulant agent, used in the prevention of stroke in patients with AF. Warfarin has shown unequivocal superiority over aspirin and reduces the risk of AF-related stroke by about 70%.² VKAs produce their anticoagulant effect by preventing the γ -carboxylation of the vitamin K-dependent coagulation factors prothrombin and factors VII, IX, and X.²

Unfortunately, VKAs have a narrow therapeutic window. Therefore, regular blood tests and dose adjustments are necessary to maintain target intensity corresponding to INR 2.0–3.0.¹⁹ Warfarin also has unpredictable pharmacokinetics and pharmacodynamics, which are affected by genetic factors, drug-drug interactions, and consumption of foods containing vitamin K.

New Oral Anticoagulants

The limitations and the problems associated with the use of warfarin exposed the unmet need for new anticoagulants in stroke prevention in patients with AF.²⁰ Serious efforts have been made over many years to develop specific

inhibitors against factors in the coagulation cascade like thrombin and factor Xa (Fig. 1).²¹ Four NOAC agents are now commercially available and have been approved for clinical use:

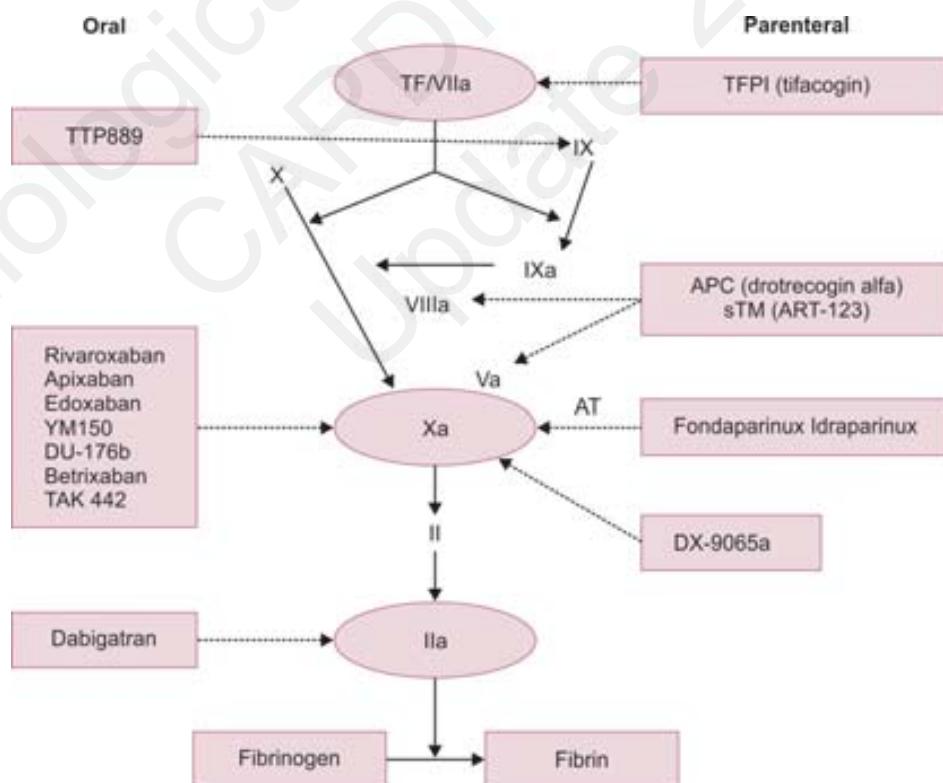

- Direct thrombin inhibitors—dabigatran
- Factor Xa inhibitors—rivaroxaban, apixaban, and edoxaban.

Direct Thrombin Inhibitors (Dabigatran)

Ximelagatran was the first direct thrombin inhibitor which underwent an extensive clinical trial program for prevention and treatment of venous thromboembolism (VTE) after orthopedic surgery,²¹ but it had to be withdrawn from the market in February 2006, due to severe hepatotoxicity and major adverse cardiovascular events.

Dabigatran etexilate was then introduced which is a prodrug and is rapidly converted to active compound dabigatran, which is a direct thrombin (factor IIa) inhibitor. It has an absolute bioavailability of 6.5% and 80% of the given dose is excreted by the kidneys. Its serum half-life is 12–17 hours, and it does not require regular monitoring.²² It needs to be given in twice daily dosage.

In the randomized evaluation of long-term anticoagulant therapy (RE-LY) study, dabigatran was compared head to head with warfarin in 18,113 patients with AF who were at increased risk of stroke.²²

APC, activated protein C; TFPI, tissue factor pathway inhibitor.

FIG. 1: Various new anticoagulants and their target sites.

Dabigatran etexilate was administered in two different dose regimen either 110 mg or 150 mg twice daily, in a blinded fashion and compared with open-labeled warfarin with a target INR ratio of 2.0–3.0. Dabigatran 110 mg bid was noninferior to warfarin for the prevention of stroke and systemic embolism with lower rates of major bleeding (relative risk reduction 20%), while dabigatran 150 mg bid was associated with lower rates of stroke and systemic embolism (relative risk reduction by 35%) with similar rates of major hemorrhage, compared with warfarin.²² Both the doses significantly reduced the relative risk of intracranial hemorrhage by 70% and 59%, respectively as compared to warfarin.²²

Factor Xa Inhibitors—Rivaroxaban, Apixaban, Edoxaban

An attractive alternative to direct thrombin inhibition is selective inhibition of factor Xa. In fact, factor Xa may be a better target than thrombin (factor IIa) because it has fewer functions outside coagulation; thus, inhibition of factor Xa may cause fewer side-effects.²³ Numerous direct oral factor Xa inhibitors are currently at various stages of clinical development.²³ Crucial phase III studies of stroke prevention in patients with AF have been completed for rivaroxaban (ROCKET-AF), apixaban (AVERROES and ARISTOTLE) as well as edoxaban (ENGAGE AF-TIMI 48) and they have also been licensed for clinical use.

Rivaroxaban

It is an oral, direct factor Xa inhibitor with a rapid onset of action and a dual mode of elimination, (one-third eliminated by kidneys and the remaining two-thirds metabolized by the liver).²⁰ It can be used as once daily dose.

The ROCKET-AF is a randomized double blind multi-center trial, that compared rivaroxaban with warfarin for the prevention of stroke or systemic embolism among 14,264 patients with nonvalvular AF who were at moderate-to-high risk for stroke.²⁴ Results showed that rivaroxaban was noninferior to warfarin in terms of the primary endpoint [composite of stroke and non-central nervous system (CNS) embolism]. The rates of major and nonmajor clinically relevant bleeding were comparable in both groups, with less fatal bleeding and intracranial hemorrhage with rivaroxaban as compared to warfarin.²⁵

Apixaban

It is also an oral direct factor Xa inhibitor which is a highly selective and potent inhibitor of free factor Xa and prothrombinase activity and needs to be given in twice daily dosage.²

The ARISTOTLE is a large randomized double-blind multi-center trial that compared apixaban (5 mg twice daily) with warfarin (target INR of 2.0–3.0) in 18,201 patients with AF and at least one additional risk factor for stroke.²⁶ The primary outcome was ischemic or hemorrhagic stroke or systemic embolism. Apixaban was not only noninferior, but actually superior to warfarin, reducing the risk of stroke or systemic embolism by 21% and the risk of major bleeding by 31%.

Moreover, apixaban is the first of the newer anticoagulants to show a significant reduction in the risk of death from any cause by 11%, as compared with warfarin.²⁶

Edoxaban

It is the latest factor Xa inhibitor which is used in once daily dosage. Phase III clinical trial on edoxaban (ENGAGE AF-TIMI 48) compared it with warfarin in a double-blind, double-dummy, randomized controlled noninferiority design for the prevention of thromboembolism in patients with AF.²⁴

Two dose regimen of edoxaban 60 mg or 30 mg od were compared with warfarin. Edoxaban 60 mg once daily was noninferior to warfarin and significantly reduced stroke or systemic embolism by 21% and significantly reduced major bleeding events by 20% compared with warfarin. Edoxaban 30 mg once daily was also noninferior to warfarin for prevention of stroke and systemic embolism but significantly reduced major bleeding events by 53%.²⁴ Only the higher dose regimen has been approved for stroke prevention in AF.⁴

CURRENT RECOMMENDATIONS FOR ANTITHROMBOTIC THERAPY IN ATRIAL FIBRILLATION

Current ESC guidelines on the management of AF recommends oral anticoagulant should be considered for men with a CHA₂DS₂-VASc score of 1 and women with a score of 2, balancing the expected stroke reduction, bleeding risk, and patient preference.⁴ Precautions in patients with high HAS-BLED score, include lower anticoagulation intensity, more careful dose regulation, or better control of hypertension.²⁴

CONCLUSION

Atrial fibrillation significantly increases the risk of stroke by promoting thrombus formation particularly in the left atrium. New ESC guidelines for the management of AF recommend the use of formal risk scoring systems like CHA₂DS₂-VASc and HAS-BLED for the formal risk stratification of patients.⁴ The routine use of these scores has proved extremely helpful for the patients and their clinicians alike to identify the correct group of patients who will benefit by long term anticoagulation without undue risk of bleeding complications.

There is a growing realization about the limited efficacy of aspirin and its use for thromboprophylaxis in AF is no longer recommended. Direct thrombin inhibitor (dabigatran) and factor Xa inhibitors (rivaroxaban, apixaban, and edoxaban) are among the several new anticoagulant agents which are currently licensed for clinical use for prevention of stroke in patients with nonvalvular AF. These new anticoagulants now appear to be all set to replace warfarin, which has been the standard medication for over 50 years to reduce the risk of strokes and systemic embolism in patients with AF. NOACs have shown favorable bleeding profiles as compared to warfarin and have also overcome the need for routine INR monitoring and frequent dose adjustments. A new era of anticoagulation seems to be emerging for patients with AF.²⁸

These NOACs are not licensed for thromboprophylaxis in patients with prosthetic heart valves and or significant mitral stenosis, where warfarin remains the drug of choice.

Catheter Ablation of Atrial Fibrillation

Dinkar Bhasin, Gautam Sharma

INTRODUCTION

Atrial fibrillation (AF) is the most common arrhythmia in clinical practice. The prevalence increases with age and up to 10% octogenarians having AF.¹ AF is associated with debilitating symptoms, poor quality of life (QoL), increased incidence of systemic embolism, vascular dementia, and heart failure (HF).^{2,3} The risk of stroke with AF increases by 5-fold for patients with nonvalvular AF and 17-fold in patients with rheumatic heart disease (RHD).⁴ Risk factors for developing AF include hypertension, diabetes mellitus, thyroid disorders, chronic lung disease, cardiac disease, and sleep apnea. Data derived from Indian cohorts of international registries has shown RHD to be the most common cause of AF in the Indian population. Traditionally the management of AF has focused on rate control with results of rhythm control being less satisfactory. However, the development of catheter ablation for AF has increased the management options available in the current era.

ADVANTAGES OF MAINTAINING SINUS RHYTHM

Maintenance of sinus rhythm in patients with AF has been long debated. Overall, data from studies that used antiarrhythmic drugs (AAD) for rhythm control suggested no difference in mortality and stroke risk when comparing rhythm control versus rate control. These studies were handicapped by the adverse effects and tolerability issues associated with AADs. However, several studies have shown that maintenance of sinus rhythm per se in patients with AF is associated with better symptom control and improvement of QoL.⁵ Catheter ablation has offered a non-AAD option for the quest of sinus rhythm in patients with AF. A recent randomized control trial (RCT) evaluated the role of catheter ablation of AF in patients with HF with reduced ejection fraction (EF <35%) and showed that catheter ablation was associated with a 16.1% absolute risk reduction in the composite endpoint of death

from any cause or hospitalization for worsening HF [28.5% vs. 44.6%; hazard ratio (HR) = 0.62; 95%; p = 0.007]. There was a significant reduction in death from any cause with catheter ablation (13.4% vs. 25.0%; HR, 0.53; p = 0.01) though the trial was not powered to study this outcome alone.⁶ Another small RCT (n = 68) studied the effects of AF ablation in patients with unexplained left ventricular (LV) dysfunction and showed significant improvement in left ventricular ejection fraction (LVEF) in patients undergoing catheter ablation ($18 \pm 13\%$ vs. $4.4 \pm 13\%$; p <0.0001) with normalization of EF (LVEF >50%) in 58% patients undergoing ablation compared to 9% managed with medical therapy (p = 0.0002). Further, lack of ventricular late gadolinium enhancement on cardiac magnetic resonance imaging was associated with greater improvement in LVEF and normalization at 6 months suggesting that preprocedural screening with MRI may be useful to select patients for catheter ablation.⁷

The largest trial comparing catheter ablation with drug therapy in patients with AF is the CABANA (Catheter Ablation Versus Anti-arrhythmic Drug Therapy for Atrial Fibrillation Trial) trial (n = 2,204). The results from this trial were recently presented and showed that there was no difference in the primary outcome (death, disabling stroke, serious bleeding, or cardiac arrest) between ablation or drug therapy at 5 years (8% vs. 9.2% HR = 0.86, p = 0.3). However, the rates of death or cardiovascular hospitalization was lower in patients undergoing ablation (51.7% vs. 58.1%, HR = 0.83, p = 0.002) and the on treatment analysis showed significant reduction in primary endpoint with ablation (7.0% vs. 10.9%, p = 0.006).⁸

PATOPHYSIOLOGY OF ATRIAL FIBRILLATION

Atrial fibrillation is a complex arrhythmia, and several mechanisms have been proposed to explain the pathogenesis of AF with both ectopic activity and reentrant mechanisms playing an important role. The three primary hypothesis are multiple reentrant wavelet theory, rapidly discharging automatic foci,

and a single reentrant circuit with fibrillatory conduction.⁹ However, crucial to the understanding was the observation that ectopic automatic firing from pulmonary vein (PV) foci can trigger and/or maintain AF. Such activity arises from muscle sleeves of left atrial musculature into the pulmonary veins. About 90% of paroxysmal AF originates from such PV foci.¹⁰ Further, there is electrical remodeling of the left atrium producing a substrate for the maintenance of the arrhythmia. This remodeling starts within hours of AF onset and involves altered expression and function of ion channels leading to abbreviation of atrial refractoriness and changes in calcium handling. In the long run, this electrical and contractile remodeling leads to structural remodeling via atrial stretch and atrial fibrosis.¹¹

A recent study has validated this hypothesis by electron microscopic demonstration of cardiomyocytes with depletion of the contractile elements (Z-bands), glycogen particle accumulation, and an increase in mitochondria. Majority of persistent AF cases showed interstitial collagen bundles and extensive fibrosis.¹² Hence, AF represents a continuum of pathophysiologic changes and initial paroxysmal episodes can progress into persistent and permanent AF. Nearly 25% of the patients with paroxysmal AF progress to persistent AF in 5 years and over 50% in 10 years.^{13,14}

INDICATIONS FOR ATRIAL FIBRILLATION ABLATION (TABLE 1)

The latest guidelines for catheter ablation of AF are provided in the HRS/EHRA/ECAS/APHRS/SOLAECE expert consensus statement.¹⁵ The strongest indication for AF ablation is the presence of symptoms despite adequate medical therapy as there is consistent evidence that ablation in this setting improves QoL. The level of evidence is highest for patients with paroxysmal AF who are symptomatic despite treatment with one class I or III antiarrhythmic drug as the likelihood of success is highest in these patients. It is reasonable to attempt catheter ablation in patients with persistent AF and can be considered in patients with long-standing AF

even though the expected success rates are lower in these settings. However, increasingly catheter ablation is being considered for first-line therapy in patients with paroxysmal and persistent AF without use of antiarrhythmic therapy. Evidence from recent studies suggests that such an approach may be associated with a lower rate of AF recurrence and no difference in rates of symptomatic AF. Certain patient populations where this strategy may be particularly useful include patients with tachy-brady syndrome who have symptomatic pauses and competitive athletes with AF.

Catheter ablation may also be considered as a first-line therapy for patients with HF with reduced ejection fraction who have AF. Maintenance of normal sinus rhythm is associated with better LV performance in such patients and evidence from recent studies suggests that this may translate into a survival benefit.^{6,16,17}

Patients with asymptomatic AF often have occult symptoms which are obvious once sinus rhythm is restored. Preprocedural cardioversion to sinus rhythm and reassessment of symptom status may help in decision making. Nonetheless, catheter ablation can be offered to select patients with asymptomatic with paroxysmal or persistent AF when procedural success rates are deemed to be high.

TECHNIQUE FOR PULMONARY VEIN ISOLATION

Catheter ablation can be done under conscious sedation or general anesthesia as per the preference of the operator. When general anesthesia is used, esophageal temperature monitoring is recommended to decrease the risk of esophageal injury. The procedure is done under fluoroscopic guidance and using a 3D electroanatomical map into which preacquired CT images can also be integrated. Standard septal puncture needles are used for left atrial access. Most centers prefer using both mapping catheters and radiofrequency ablation (RFA) catheters. Anticoagulation during the procedure is maintained with unfractionated heparin to maintain an activated clotting time of 300 seconds.

TABLE 1: Indications for catheter ablation of atrial fibrillation¹⁵

Symptomatic AF refractory or intolerant to at least one class I or III antiarrhythmic drug	
• Paroxysmal: Class Ia	
• Persistent: Class IIa	
• Permanent: Class IIb	
Symptomatic AF before trial of any anti-arrhythmic drug therapy	
• Paroxysmal: Class IIa	
• Persistent: Class IIb	
Specific patient groups	
Heart failure	Similar indications as for patients without heart failure
HCM	Similar indications as for patients without HCM
Tachy-brady syndrome	Catheter ablation may be offered as an alternative to pacemaker implantation (IIa)
Athletes with AF	Catheter ablation may be offered as first-line treatment (IIa)
Asymptomatic AF	Catheter ablation may be considered in selected asymptomatic patients with paroxysmal or persistent AF (IIb)

AF, atrial fibrillation; HCM, hypertrophic cardiomyopathy.

Cryoballoon ablation (CBA) is an alternative to RFA (Fig. 1). It isolates the PV by freezing the tissue to temperatures less than -80°C .¹⁸ While the use of RFA requires point-by-point ablation, cryoablation with a balloon allows a single shot ablation at the PV level. Both RFA and CBA have similar success rates and overall rates of complications. However, CBA is associated with higher rates of phrenic nerve (PN)

FIG. 1: Cryoablation balloon.

injury most of which are self-resolving with low rates of permanent injury (0.3%).¹⁹

The main objective of catheter ablation of AF is the permanent electrical isolation of the pulmonary veins by using either radiofrequency or cryoablation. In certain scenarios additional lesions may be used to target non-PV triggers and for substrate modification. By using mapping catheters circumferential mapping of PV potentials is done to define the activation sequence (Fig. 2). When such sites of earliest activity are ablated the technique is known as segmental PV isolation (Fig. 3). However, our current practice is to employ circumferential anatomic ablation around PV ostia either individually or by encircling both the ipsilateral veins (Fig. 4). The ablation site should ideally be in the antrum and not directly at the ostia or in the body of pulmonary veins which may increase the risk of PV stenosis. Ablation is often started at the posterior wall and then continued around the PV ostia. The endpoint of ablation is the elimination of PV vein potentials and demonstration of entrance block into the PVs. It is reasonable to monitor for 20–30 minutes after ablation for confirmation of PV isolation. Intravenous adenosine or pace-capture may be used to demonstrate isolation after this waiting period. When RFA is used, a force sensing catheter providing a minimum of 5–10 g of contact force is preferable. Use of such catheters is associated with lesser rates of dormant PV conduction and lower complication rates.

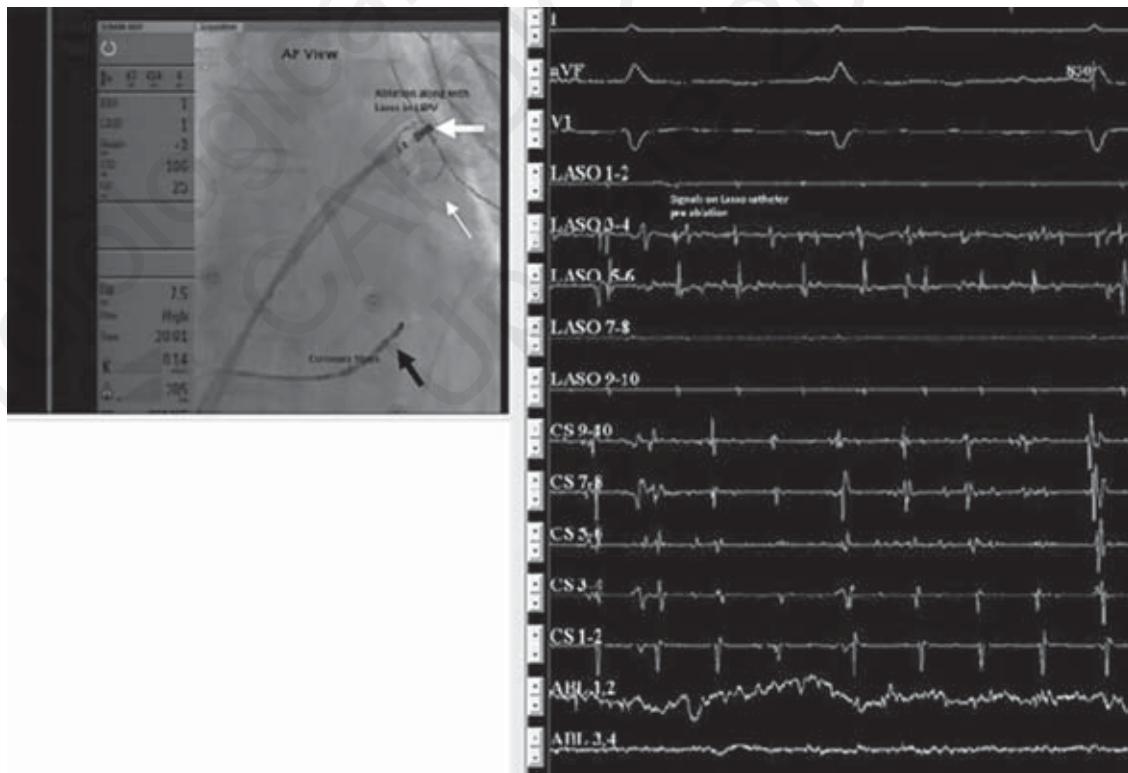

FIG. 2: Procedure for atrial fibrillation ablation. The mapping Lasso catheter has been positioned in the left superior pulmonary vein (PV) (thin white arrow) and the ablation catheter is at the PV antrum (thick white arrow). A decapolar catheter has been positioned in the coronary sinus (black arrow). Potentials picked by the 10 poles of the circular lasso catheter and the ablation catheter are used for mapping.

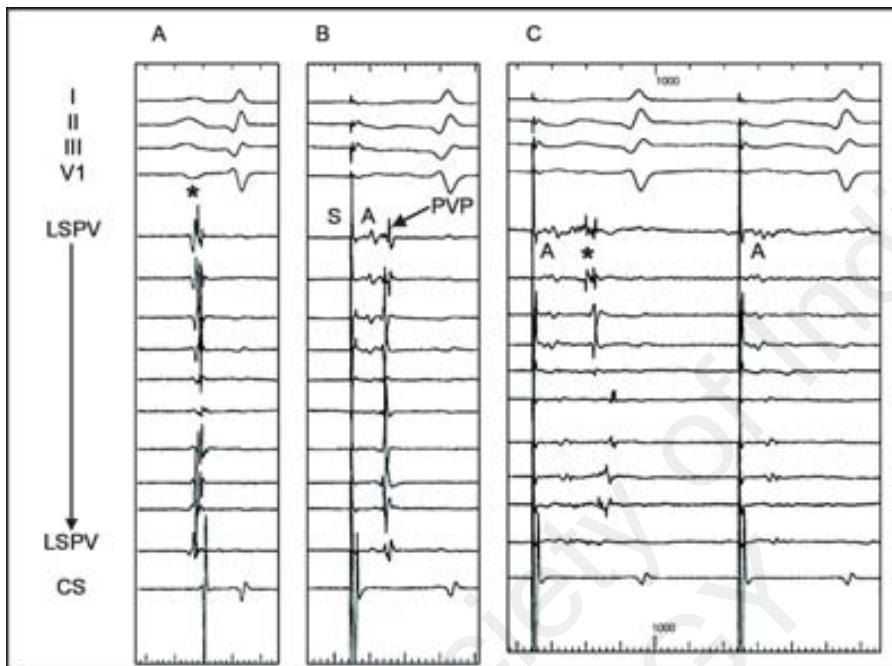

FIG. 3: Isolation of the left superior pulmonary vein (LSPV). **A**, Left atrial and pulmonary vein potentials (PVP) are superimposed; **B**, Pacing from the coronary sinus (CS) shows PVPs following the far-field atrial potential; **C**, PVPs disappear after radiofrequency ablation (RFA) demonstrating complete isolation.

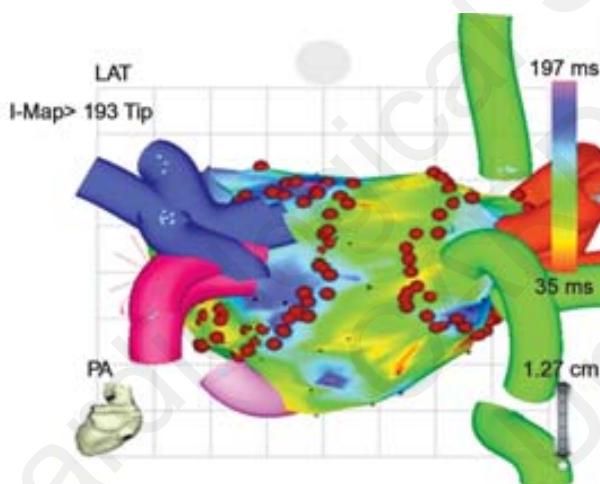

FIG. 4: Three-dimensional electroanatomical map of left atrium showing circumferential ablation points around pulmonary vein ostia.

ADJUNCTIVE ABLATION STRATEGIES

While pulmonary vein isolation (PVI) remains the cornerstone for ablation therapy for paroxysmal AF, additional strategies are often utilized in persistent or long-standing AF and those undergoing redo-ablation with the intent to increase success rates. Such additional lesions result in compartmentalization of the atria and prevent reentry. However, evidence in support of such additional techniques is limited. Hence, they are not universally recommended and the decision is made on a case to case basis depending upon operator preference and experience.

Focal triggers can be identified outside the PV in up to 10–30% cases. Common sites include the posterior wall of left atrium (LA), crista terminalis, and superior vena cava (SVC). These lesions are inducible with isoproterenol infusion and if provoked should be ablated. If typical atrial flutter is induced during AF ablation, additional linear lesions should be given at the cavotricuspid isthmus. Electrical isolation of the posterior wall involves linear lesions joining the superior PVs and the inferior PVs and can be considered in certain groups especially in patients with persistent AF and those undergoing repeat ablation. Linear lesions in LA roof and along the mitral valve have also been used in patients with persistent or long-standing AF. If such additional linear lesions are employed, pacing and mapping should be done to achieve complete isolation as incomplete ablation can be responsible for recurrence of AT. Complex fractionated atrial electrogram represent fractionated potentials which have a short cycle length. Ablation of such potentials has been hypothesized to decrease the recurrence rates. Mapping and ablating rotational activity and ablation of left atrial autonomic ganglia has also been proposed.

COMPLICATIONS OF ATRIAL FIBRILLATION ABLATION

Major complications associated with catheter ablation include cardiac tamponade, pulmonary vein stenosis, esophageal injury, PN injury, and periprocedural stroke. As per a multicenter survey of over 90,000 patients, the incidence of complications is estimated at 6.29% with an in-hospital mortality rate of 0.46%.²⁰ The rate of complications is

associated with operator experience and hospital procedure volumes. The reported mortality risk with the procedure is less than 0.1% and 30-day all-cause mortality rates are less than 1%.^{20,21}

The most common life-threatening complication is cardiac tamponade. Overall incidence is reported between 0.2 and 5% with an average of around 1.5%.^{15,20} Pulmonary veins stenosis has been described with both RFA and cryoablation. The incidence has been variable reported between 0 and 40% depending upon the modality used for diagnosis but has markedly decreased with increasing operator awareness.¹⁵ Esophageal injuries are infrequent but difficult to manage complications of AF ablation and include esophageal hematoma, esophageal ulcer, esophageal perforation and atrial-esophageal fistula. Prevention includes use of esophageal temperature monitoring while ablation, periprocedural use of proton pump inhibitors, and careful ablation along the posterior LA wall. PN palsy can be a significant complication of AF ablation. Rates of transient PN palsy vary from 3.5 to 11.2% but permanent injury beyond 1 year is rare (<0.5%). Management is conservative and most cases resolve spontaneously. Pacing to detect PN stimulation at the ablation site prior to delivery of the RF energy can reduce the risk of damage.

OUTCOMES

Atrial fibrillation ablation results in significantly higher success rates for maintaining sinus rhythm compared to antiarrhythmic drug therapy alone. Trials studying PV isolation for paroxysmal AF have reported success rates ranging from 59 to 89% at 12 months compared with drug therapy alone which had success rates of 5–23%. Trials studying AF ablation in patients with persistent and long-standing AF have utilized other strategies in addition to PV isolation and have reported success rates of 59–80% at 6–12 months.¹⁵

Postoperative Atrial Fibrillation: Clinical Correlates and Management

Krishnarpan Chatterjee, Naveen Garg

INTRODUCTION

Atrial fibrillation (AF) and atrial flutter occur frequently after cardiac surgery. Most episodes occur by the third postoperative day. Potential adverse outcomes of these atrial arrhythmias include a longer length of stay, stroke, or death and worse long-term prognosis.

INCIDENCE AND TIME COURSE

Atrial fibrillation occurs in 15–40% of patients in the early postoperative period following coronary artery bypass graft surgery (CABG).^{1–3} In a 2018 *post hoc* analysis of 1,812 patients without prior AF in the EXCEL trial, which compared CABG with percutaneous coronary intervention (PCI) for left main coronary artery disease, perioperative AF developed in 18.0% of those undergoing CABG (and 0.1% of those who received PCI). The incidence increases with increasing age.⁴ AF occurs in 37–50% after valve surgery, and in as many as 60% undergoing valve replacement plus CABG.¹

Atrial arrhythmias occur most often within the first few days after surgery.¹ In a prospective, multi-center study of 4,657 patients undergoing surgery, the majority of first episodes of AF occurred by day 2, while the majority of recurrent episodes occurred by day 3.⁵ Among patients with postoperative AF with no prior history of atrial arrhythmias, the AF is usually self-limited, as 15–30% convert within 2 hours and up to 80% in 24 hours.^{1,6,7} The mean duration of AF in one report was 12 hours and more than 90% are in sinus rhythm 6–8 weeks following surgery.^{1,7}

Atrial fibrillation may also occur late after cardiac surgery and the incidence is likely higher than appreciated because many patients may have continued asymptomatic episodes of AF.⁸ Late postoperative AF was associated with adverse outcomes, including heart failure and rehospitalization.

PATHOGENESIS

After cardiac surgery, AF and atrial flutter can occur early in the postoperative period or as a late complication.

Postoperative AF is related to a combination of factors. These include preexisting degenerative changes in the atrial myocardium and perioperative conditions that result in abnormalities of several electrophysiologic parameters that promote the development of AF.¹

Risk Factors

Most patients who develop AF after cardiac surgery have at least one clinical predictor.

- *Preoperative risk factors:*
 - Increasing age
 - Previous history of AF
 - Increased left atrial size or cardiomegaly
 - Mitral valvular disease, particularly mitral stenosis
 - Previous cardiac surgery
 - Chronic obstructive pulmonary disease (COPD)
 - Elevated preoperative HbA1c
 - Low-intensity physical activity in the year prior to surgery
 - Obesity
 - Caucasian race
 - Absence of β-blocker or angiotensin-converting enzyme inhibitor (ACEI) treatment or withdrawal of previous treatment
 - Preoperative digoxin use
 - Higher preoperative plasma concentration of brain natriuretic peptide (BNP)
 - Low-dose dopamine
 - Severe right coronary artery stenosis
 - Preoperative increase in P-wave duration on ECG
 - Hypokalemia and hypomagnesemia.
- *Perioperative risk factors:*
 - Pericarditis
 - Atrial injury from surgical handling, or cannulation, atrial suture lines
 - Acute atrial enlargement from pressure or volume overload
 - Atrial ischemia

- Long bypass and aortic cross-clamp times
- Inadequate myocardial protection during cardio-pulmonary bypass
- Hyperadrenergic state (e.g., postoperative inotropes)
- Pulmonary complications causing hypoxemia
- Hypokalemia and hypomagnesemia
- Oxidative stress.
- *Protective factors:*
 - *Off-pump CABG:* It is associated with a lower rate of postoperative AF than conventional CABG in some but not all studies
 - Preservation of the anterior fat pad; some but not all studies have found lower rate of postoperative AF with preservation of the anterior fat pad.

However, these risk factors do not have adequate predictive accuracy to identify the individual patient at risk for postoperative AF. As a result, risk models that use several factors have been created that predict any postoperative AF as well as recurrent AF.³ While these risk models are not routinely used, they highlight the individual risks.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

No studies have systematically characterized the clinical manifestations of postoperative AF in cardiac surgery patients. About 90% of these individuals are symptomatic and about 15% are hemodynamically unstable. The diagnosis of AF is not difficult as most patients are on continuous monitoring. All patients should have documentation of the rhythm with a 12-lead electrocardiogram.

Adverse Outcomes Following Atrial Fibrillation

Potential adverse outcomes after the development of postoperative AF include stroke, death, and prolongation of hospital stay.

PREVENTION OF ATRIAL FIBRILLATION AND COMPLICATIONS

Therapies to prevent the development of postoperative AF in patients undergoing cardiac surgery are recommended to decrease the duration of hospitalization, to possibly decrease the risk of in-hospital stroke and death and to decrease the need for anticoagulation in some patients.

Prevention of Atrial Fibrillation

The use of β-blockers, sotalol, amiodarone, atrial pacing, or antioxidant vitamins lowers the risk of postoperative AF.⁹ Beta-blockers are the best studied of these therapies and are preferred to sotalol or amiodarone based on their ease of use and better safety profile. Atrial pacing is not recommended in most cases. There has been no study comparing the traditional antiarrhythmic drugs to antioxidant vitamins.

Beta-blockers

Beta blocker administration is the most widely used prophylactic strategy based on numerous studies showing benefit, ease of use, and cost considerations.^{1,6} Meta-analyses of randomized trials found that they reduced the risk of AF compared to placebo or no therapy [odds ratio (OR) 0.35, 95% confidence interval (CI) 0.26–0.49 and 0.39, 95% CI 0.28–0.52].¹⁰ The issue of whether some β-blockers lower the risk of postoperative AF more successfully than others has not been well studied. In a meta-analysis of randomized trials with 601 patients that compared carvedilol to metoprolol (succinate and tartrate), carvedilol reduced the incidence of AF (OR 0.50, 95% CI 0.32–0.80).¹¹

The benefit is seen when β-blockers are begun prior to or immediately after surgery. Evidence is not strong enough to recommend one β-blocker over another. When possible, β-blockers should be started at least 48 hours before surgery, due to concerns about the induction of excessive bradycardia. There are also concerns about the increased risk of stroke seen in patients undergoing noncardiac surgery who receive β-blockers soon before surgery.

The optimal duration of β-blocker therapy for prevention of postoperative atrial arrhythmias is uncertain, but often continued until the first postoperative visit. Many patients undergoing CABG though have a clear indication for the long-term use of β-blocker therapy (e.g., previous myocardial infarction, left ventricular systolic dysfunction with heart failure, or hypertension).

Sotalol

Sotalol is a class III antiarrhythmic agent that has β blocking activity. Meta-analysis of 15 randomized studies of patients undergoing cardiac surgery found that sotalol lowers the risk of AF compared to placebo (RR 0.55, 95% CI 0.45–0.66).¹² Compared to β-blocker, sotalol was more effective. There was no significant difference in the rates between sotalol and amiodarone. Risks of sotalol include torsade de pointes and bradycardia. Sotalol is effective when begun 24–48 hours before surgery or 4 hours after surgery.

Amiodarone

Amiodarone lowers the incidence of postoperative AF by about 40–50%.¹⁰ Meta-analysis of 18 trials that included nearly 3,000 patients found that amiodarone lowers the risk of AF or atrial flutter compared to placebo (OR 0.48, 95% CI 0.40–0.57).¹³ However, amiodarone is associated with more adverse cardiac events compared to placebo, including bradycardia requiring temporary pacing (5.7% vs. 2%), and QT prolongation (1.3% vs. 0%).¹⁴ The rates of the development of AF were similar (23.9% and 24.8%, respectively) when metoprolol was directly compared to amiodarone in a trial of patients who underwent CABG or valve surgery.¹⁵

A number of different preoperative regimens of amiodarone have been tried. It has been given orally 1–7 days before surgery, intravenously immediately after surgery, or intravenously for 24 hours followed by oral therapy for 4 days.

Intravenous amiodarone begun on call to the operating room and continued for 48 hours, followed by oral amiodarone for 3 days has also significantly reduced postoperative AF.

Although, some have suggested that amiodarone might be more effective than a β -blocker for the prevention of AF after cardiac surgery, this was not confirmed in two meta-analyses.¹⁰

Antioxidant Vitamins

Oxidative stress contributes to ischemia-reperfusion injury, which occurs in open heart surgery and is involved in the pathogenesis of AF. Despite of limited supportive evidence, due to absence of side effects and low cost, antioxidant vitamins to lower the rate of postoperative AF may be considered.¹⁶ Supplementation with vitamin C (1 g/day), and vitamin E (400 IU/day) 2 days before cardiac surgery have been studied. Treatment was continued until hospital discharge.

Atrial Pacing

Atrial pacing to prevent postoperative AF has been examined in a number of studies. Most studies, but not all showed benefit.

Ineffective or Possibly Effective Therapies

The following preventive strategies to prevent the development of atrial arrhythmias are not recommended:

- *Digoxin*: Digoxin, given preoperatively or postoperatively, does not appear to prevent AF¹⁷
- *Antiarrhythmic drugs*: Data about the prophylactic use of class I antiarrhythmic drugs to prevent postoperative AF are limited. Procainamide appears to reduce the number of episodes and duration of AF compared to placebo, but not the incidence of AF¹⁸
- *Calcium channel blockers*: These have uncertain utility in preventing AF after cardiac surgery¹⁹
- *Intravenous magnesium*: Based on the fact that hypomagnesemia is a risk factor for AF, magnesium supplementation has been evaluated as a possible therapy to reduce postoperative atrial arrhythmias. In a meta-analysis, supraventricular arrhythmia occurred significantly less often in patients treated with magnesium compared to controls.¹³ However, there was no effect on hospital stay, perioperative myocardial infarction, or mortality.
- *Angiotensin inhibition*: Although ACEIs and angiotensin II receptor blockers (ARBs) have suggested benefit as a therapy of AF in nonsurgical settings. A significant reduction in the incidence of postoperative AF (20% vs. 34%) with ACEIs was seen in an observational study of 4,657 patients undergoing CABG.⁵ A retrospective analysis of 8,889 patients undergoing CABG described an increase in major adverse events, including postoperative renal dysfunction as well as AF, in patients receiving pre-operative ACEIs.²⁰ Given the inconsistency in the results among these studies, preoperative ACEIs specifically for prevention of AF in patients undergoing CABG are not recommended.
- *Statins*: Some, but not all studies have shown that statins lower the rate of postoperative AF. One meta-analysis of randomized trials that compared statin therapy with either placebo or no therapy prior to cardiac surgery (predominantly CABG surgery) found that such treatment reduced the incidence of postoperative AF but failed to influence short-term mortality or postoperative stroke.²¹ The largest randomized trial of preoperative statin therapy was the STICS trial, showed a similar rate of the primary outcome of postoperative AF within 5 days of surgery was in both groups.²² In addition, rosuvastatin was associated with a significant absolute excess in the rate of postoperative acute kidney injury. Based upon established benefits of statin therapy in patients with coronary heart disease, all patients should be on long-term statin. However, for patients not on statin therapy before CABG, it should be started after surgery, as there is no clear evidence of benefit from preoperative initiation and possible harm
- *N-acetylcysteine (NAC)*: It has the potential to protect against the development of perioperative AF due to its antioxidant and anti-inflammatory properties. But more data is required before advocating its routine clinical use
- *Colchicine*: It reduces the incidence of the postpericardiotomy syndrome. In the COPPS-2 trial, 360 patients scheduled for cardiac surgery were randomly assigned to oral colchicine or placebo before surgery.²³ The drug was continued for 1 month after surgery. At 3 months, there was no significant difference between the two groups in the secondary endpoint of postoperative AF. There is insufficient evidence to recommend the routine use of colchicine, due to concern that it may negatively impact wound healing and that it leads to gastrointestinal side effects
- *Naproxen*: The potential benefit from naproxen was evaluated in the NAFARM trial.²⁴ There was no significant difference in the rate of postoperative AF. The study was stopped early because of an increase in renal failure in the naproxen group
- *Glucocorticoid*: Based upon the hypothesis that perioperative inflammation may contribute to the development of AF, glucocorticoids have been suggested as prophylactic therapy. The large, randomized SIRS trial, found no difference in the rate of new AF.²⁵ Due to their potential adverse effects on glucose metabolism, wound healing, infection, and the absence of a lowering of the risk of death, the routine use of glucocorticoid therapy to prevent AF is not recommended.

Prevention of Complications of Atrial Fibrillation

While β -blockers, sotalol, amiodarone, and pacing decrease the risk of postoperative AF, the evidence is less robust that the risk of complications such as stroke, death, or length of stay can be prevented. It may be difficult to demonstrate a lowering of the risk of in-hospital stroke with these therapies, as AF is only one risk factor for stroke and as the incidence

of stroke is low. The best available evidence of the impact of these interventions on the complications of AF comes from a meta-analysis of heterogeneous trials, which noted the following:¹³

- In 29 trials that evaluated length of stay, only amiodarone and pacing shortened the average length of stay
- In 25 trials that reported on the incidence of postoperative stroke, the risk of stroke was decreased with treatment. Amiodarone was the only single intervention that significantly lowered the risk of stroke compared to placebo.

Approach to Prevention

Preventive therapy to reduce the incidence of postoperative AF is recommended, especially in patients at high risk of its development. While the evidence is not robust, prevention of AF may lead to a lowering of the risk of in-hospital stroke and a shortened length of stay. In addition, successful prevention of AF will prevent the need for anticoagulation in some patients. Beta-blockers, sotalol, amiodarone, and atrial pacing are significantly more effective than placebo in lowering the rate of postoperative AF.^{10,13} There is some evidence to support the use of antioxidant vitamins for this purpose. Beta-blockers are preferred to amiodarone or sotalol due to lower cost and lower risk of potential side effects and to pacing because of its relative complexity and cost. Amiodarone or sotalol is a reasonable alternative in patients who cannot tolerate β -blockade. If possible, β -blockers should be started before CABG.

MANAGEMENT

While prevention with β -blockers, amiodarone, sotalol, or pacing lowers the risk of postoperative AF, many patients still develop AF. There is uncertainty as to the optimal management of these patients, because it is not known whether postoperative AF has similar natural history in terms of future adverse events as AF occurring without cardiac surgery. The initial management should include correction of predisposing factors such as hypoxemia, electrolyte abnormalities, and hemodynamic instability as well as pain management and withdrawal of stimulating factors such as inotropic agents. Subsequent management relates to the issues of rate control versus rhythm control, cardioversion, and anticoagulation.

Rate Control

Given the transient nature of the arrhythmia, initial control of the ventricular response rate is an effective and relatively safe strategy in many patients who develop postoperative AF.⁶ Rate control is most commonly achieved with β -blockers. Intravenous esmolol, a β -blocker with a short half-life, can be given for acute rate control if there is a concern for bradyarrhythmias, hypotension, or bronchospasm. Slowing of the ventricular rate in many AF patients receiving inotropic agents postoperatively can be achieved by lowering the dose or discontinuation of these agents.

The optimal rate goal for patients with AF after cardiac surgery has not been determined. As these patients vary widely in many clinical features (comorbidities, need for rapid ventricular rate, etc.), the optimal ventricular rate should be determined on a case by case basis. In many patients, a ventricular rate of less than 110 beats/minute will prevent symptoms such as palpitations and allow for optimal cardiac performance. Calcium channel blockers and digoxin are the other atrioventricular (AV) nodal blockers that can control the ventricular rate in AF, but they are not more effective than β -blockers. In patients in whom alternate agents have not been successful in rate control, intravenous amiodarone can be used to slow the ventricular response. Ivabradine is not effective, as it does not have any effect on AV node conduction.

Rhythm Control

Restoration of sinus rhythm from well-tolerated postoperative AF is usually not necessary but occasionally can be beneficial. Restoration of sinus rhythm is indicated in symptomatic patients or in those when rate control is difficult to achieve. An attempt at the restoration of sinus rhythm can be beneficial in patients with a low ejection fraction. In addition, cardioversion in asymptomatic patients may be reasonable when well-tolerated AF occurs near the time of anticipated hospital discharge or when it does not spontaneously terminate within 24 hours, so that oral anticoagulation can be avoided; especially in patients at high risk of bleeding.

An attempt at cardioversion with either electrical or pharmacologic therapy is reasonable. The choice between the two should be made on local practice and patient conditions. Electrical therapy of AF involves direct current external transthoracic cardioversion and it is effective in approximately 95% cases.²⁶ For patients where transthoracic cardioversion fails or is not feasible, pharmacologic therapy with intravenous sotalol or amiodarone is reasonable. The efficacy of antiarrhythmic drugs for reversion of postoperative AF is similar to that in AF not related to surgery.²⁷

Rate Versus Rhythm Control

For patients who do not spontaneously revert to sinus rhythm within a few hours, rate control, and rhythm control (with or without electrical cardioversion) appear to be comparable strategies.⁷ Advantages of a rate control strategy include the absence of side effects from drug therapy; disadvantages include a slower resolution of AF, thereby leading to a potentially greater need for anticoagulation at discharge.

ANTICOAGULATION

Patients on Long-term Anticoagulant

For AF patients on warfarin or direct oral anticoagulants, anticoagulation is stopped at least 3 days before surgery and restarted 3–5 days after surgery. Bridging with heparin therapy for patients at high risk of an embolic complication while off oral anticoagulant, must be balanced against increased bleeding risk.

Patients not Taking Anticoagulant Prior to Cardiac Surgery

Patients with AF or atrial flutter, regardless of the setting, are at risk for thromboembolic events. Thromboembolic risk is primarily limited to AF or atrial flutter of more than 48 hours duration and is greater in patients with certain high-risk features (rheumatic mitral valve disease, previous thromboembolism, hypertension, or heart failure, etc.).²⁷

Patients who develop AF after cardiac surgery are at risk of thromboembolic events, including in-hospital stroke. However, in the individual postsurgical patient with an embolic event, the cause may be unclear, as underlying comorbidities are often responsible for such strokes, rather than the arrhythmia itself.¹⁰ It is reasonable to believe that such therapy will lead to fewer embolic events in patients with postoperative AF but a reduction of events with anticoagulant therapy in this population has never been well studied.

The complications of anticoagulation were seen in observational studies of patients who were treated with intravenous heparin or oral anticoagulants.²⁸ When closely monitored, complication rates appear to be low. However, one report found a significant increase in large pericardial effusions and tamponade in patients treated with warfarin, particularly when the international normalized ratio (INR) was above the therapeutic target.²⁸ Thus, when anticoagulation is initiated, the patient must be monitored carefully. Similarly, the optimal duration of anticoagulation after hospital discharge is unknown. Among patients with new-onset AF after cardiac surgery, many will revert to and maintain sinus rhythm.^{1,7}

As their therapeutic effect is not easily reversed, newer oral anticoagulants are not in routine clinical use in the early postoperative period. There are limited data at present, but this is an evolving strategy that may gain support as our understanding evolves.²⁹

Evidence is emerging that the left atrial appendage may play a major role in the development of stroke and interventional/surgical elimination may obviate the need for anticoagulation. However, there are insufficient data at this time to support routine surgical elimination.

Approach to Postoperative Anticoagulation

Among patients who develop AF following cardiac surgery, the following approach to anticoagulation may be considered. For patients with multiple episodes of AF or one episode that lasts more than 24–48 hours, oral anticoagulant therapy should be started, but only if bleeding risks are considered acceptable. As the role of direct thrombin and factor Xa inhibitors has not been established for patients with postoperative AF, warfarin should be chosen for most patients (INR 2.0–3.0).

Anticoagulation should be continued for at least 4 weeks after return to sinus rhythm, particularly if the patient has risk factors for thromboembolism. Longer duration of anticoagulation is recommended by some in patients with

high CHADS-VASc scores, at low-risk for bleeding based on the HAS-BLED score, or at high-risk of AF recurrence. Long-term anticoagulation should be considered for patients who remain in AF or who have paroxysmal AF at 4 weeks. Oral anticoagulation should be continued in patients in which a concomitant Cox-Maze procedure has been performed for at least 3 months, regardless of no postoperative atrial arrhythmias. After 3 months with no AF recurrence, anticoagulation may be interrupted, considering the patient risk profile for stroke by the CHADS-VASc score.³⁰

In most cases, intravenous heparin is not used as a bridge to full oral anticoagulation, as the risk of postoperative bleeding outweighs the small benefit from stroke prevention. For patients with prior systemic or pulmonary embolization or those with a mechanical valve, bridging anticoagulation with heparin may be reasonable. Both intravenous and oral anticoagulation should be monitored closely, as bleeding complications, including pericardial effusion and tamponade increase with excessive anticoagulation.

Managing Antithrombotics after Percutaneous Coronary Intervention in Atrial Fibrillation: Current Recommendations

Sundeep Mishra

INTRODUCTION

The management of patients who have undergone percutaneous coronary intervention (PCI) and already have atrial fibrillation (AF) is a challenging problem but is quite common. Broadly, there are three issues in the management paradigm; risk of stent thrombosis (ST) poststent implantation, risk of ischemic stroke due to embolization of clot (formed commonly in left atrial appendage) as a result of irregular rate alterations in AF and risk of bleeding consequent to use of antiplatelets or anticoagulants. Optimal therapy in this group comprises of striking a balance between these three concerns (Fig. 1). These risks can vary depending on patient's condition, lesion condition, and time after procedure and thus therapy may require to be individualized according to individual patients and temporal profile. AF

is the most common arrhythmia and nearly one-third of patients of AF have coronary artery disease (CAD) and nearly one-tenth of all AF patients undergo PCI.¹ On the other hand, it has been estimated that approximately 5–7% of patients undergoing PCI also have AF or other indications for chronic oral anticoagulant (OAC) therapy.^{2–5} Thus the matter is not trivial but requires a careful consideration. The crux of the matter is that post PCI with stenting patients require dual antiplatelet therapy (DAPT) to prevent ST but those having AF require anticoagulation to prevent stroke and other thromboembolic events. Thus triple antithrombotic (TAT) is a logical outcome. However, TAT is associated with a significant bleeding risk. Thus the issue at hand is whether TAT is necessary? If necessary which anticoagulant to use; vitamin K antagonist (VKA) or nonvitamin K oral anticoagulant (NOAC)? Which antiplatelet to use aspirin (ASA), clopidogrel, prasugrel, or ticagrelor or a combination of them? If combination, which combination? Finally, how long should TAT be continued, and what next?

AF, atrial fibrillation; PCI, percutaneous coronary intervention; ST, stent thrombosis.

FIG. 1: Issues at stake in patients with atrial fibrillation undergoing percutaneous coronary intervention.

WHY RISK OF THROMBOSIS AFTER PERCUTANEOUS CORONARY INTERVENTION?

Currently PCI is invariably associated with stent or scaffold deployment. During the course of stent deployment, significant trauma and damage to the endothelium can occur during the procedure. Subsequently, struts of the stent or scaffold are exposed to flowing blood in the coronary artery promoting platelet activation and aggregation and thus contributing to a milieu of arterial thrombosis, the risk persisting till the time endothelialization of exposed struts happen. Finally, PCI is often carried out in the context of acute coronary syndrome or acute myocardial infarction (AMI), conditions per se which can increase risk of arterial thrombosis (Box 1).

BOX 1**Risk of vascular thrombosis after percutaneous coronary intervention**

Risk of thrombosis associated with percutaneous coronary intervention

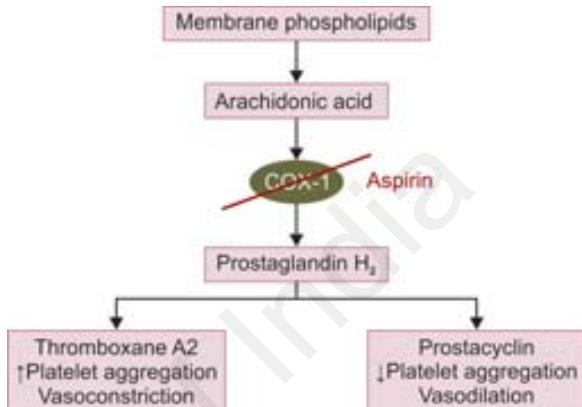

- Acute arterial vessel injury during percutaneous coronary intervention procedure
- Risk of stent thrombosis after procedure
- Risk of arterial thrombosis associated with accompanying acute coronary syndrome

WHY RISK OF STROKE AFTER ONSET OF ATRIAL FIBRILLATION?

Blood flow is usually sluggish in the venous chambers and top chambers of the heart (atrial part) which can lead to formation of blood clots, particularly in left atrial appendage. During onset of AF or with change in heart rate associated with AF, a piece of a clot can break off. This clot commonly travels to the brain to cause a stroke, but it can travel to other organs in body as well.

HOW TO PREVENT THROMBOSIS IN PATIENT UNDERGOING PERCUTANEOUS CORONARY INTERVENTION?

Potent antiplatelets are required to prevent ST. ASA (ASA) can inhibit both platelet activation and aggregation, the mechanism primarily involves irreversible inhibition of the platelet-dependent enzyme cyclooxygenase (COX). One of the isoenzymes COX-1 (inhibited by ASA) is a powerful inhibitor of thromboxane A2 (Tx A2). Tx A2 promotes platelet aggregation and vasoconstriction. During platelet activation, the hydrolysis of membrane phospholipids yields arachidonic acid, which is converted to prostaglandin H₂ by the catalytic activity of the COX enzyme prostaglandin G/H synthase. By the selective and irreversible acetylation of a single serine residue within prostaglandin G/H synthase, ASA causes the inactivation of COX activity (Flowchart 1). In coronary tree platelet activation and aggregation lead to activation of clotting cascade contributing to acute vascular closure and myocardial infarction (MI). Besides inhibition of Tx A2, ASA may act by many other favorable mechanisms as well; inhibition of COX-dependent vasoconstrictors, inhibition of endothelial dysfunction, inhibition of the production of endothelial-produced prostacyclin (a vasodilator and inhibitor of platelet aggregation), inhibition of inflammation and even inhibition of Tx A2 biosynthesis (Box 2).⁶ Unlike platelets, endothelial cells recover their ability to synthesize prostacyclin within a couple of hours. As a result of its potent action ASA has been widely accepted as a cornerstone therapy in reducing ischemic complications after balloon angioplasty or stent implantation. The therapy should be initiated before the advent of procedure and continued lifelong (preferably) after the procedure.⁷⁻¹² Regarding the optimal dose of ASA for prevention of MI, stroke, or vascular death following PCI, a narrow range of 75–160 mg/day seems enough as nearly

FLOWCHART 1: Mechanism of action of aspirin.

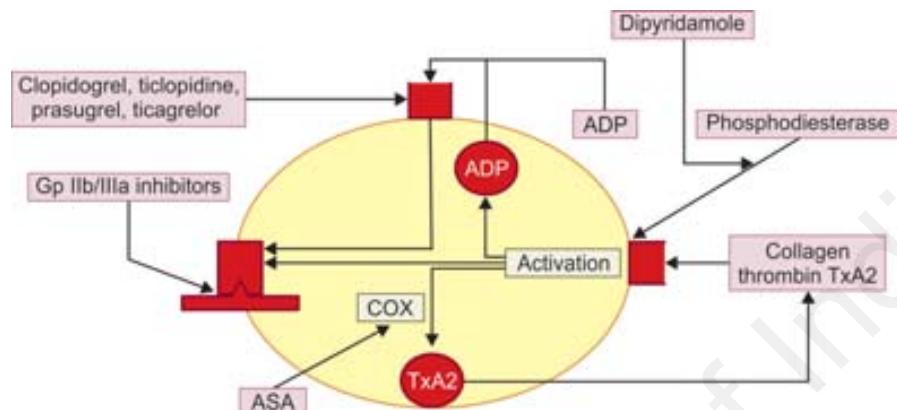

BOX 2**Mechanism of action of aspirin in preventing coronary ischemia**

Mechanism of action of aspirin

- Inhibiting COX-1 mediated activation of Tx A2 and thus inhibiting platelet aggregation
- Inhibiting COX mediated vasoconstrictors, reducing endothelial dysfunction
- Inhibition of the production of endothelial-produced prostacyclin (a vasodilator and inhibitor of platelet aggregation)
- Inhibition of inflammation
- Inhibiting Tx A2 biosynthesis

COX, cyclooxygenase; Tx A2, thromboxane A2.

complete inhibition of COX-1 can occur at this dose.^{13,14} During PCI, platelet activation leads to platelet aggregation which can lead to activation of coagulation cascade. ASA inhibits platelet aggregation by inhibiting the production of Tx A2. However, there could be other mechanisms of platelet aggregation besides COX dependant pathway; particularly adenosine diphosphate (ADP)-mediated pathways (Fig. 2). ASA alone has no effect on this pathway and thus platelet aggregation may still happen despite optimal ASA therapy. Furthermore, in certain instances inability of ASA to reduce TXA2 production culminating in inability to prolong bleeding time, or producing typical in vitro effects on platelet function resulting in lack of protection against thrombotic events, an effect known as ASA resistance.^{15,16} The prevalence of ASA resistance is highly variable (5–60%) depending on the population studied, the clinical situation and the method employed for testing.¹⁵⁻¹⁷ Several mechanisms have been implicated in development of ASA resistance; genetic polymorphisms of COX 1, enhanced platelet turnover, genetic polymorphism of other genes involved in Tx biosynthesis, up-regulation of nonplatelet sources of Tx, and drug interactions (Box 3).^{15,18,19} Thus it is clear that there is a requirement of other inhibitors of platelet function to achieve optimal antithrombotic effect. Dipyridamole interferes with platelet-stimulating factors like collagen through various mechanisms including the inhibition of phosphodiesterase and inhibition of cellular uptake of adenosine. However, its benefit in context

of PCI is not established. Cochrane review of 29 randomized trials involving 23,019 patients could demonstrate no benefit for the combination of ASA with dipyridamole in context of CAD.²⁰ Cilostazol is another agent (2-oxoquinoline derivative) which possesses vasodilatory and antithrombotic effects as well as antiproliferative properties, useful in reducing smooth

muscle cell proliferation and neointimal hyperplasia after endothelial injury. However, no large scale study is available demonstrating its usefulness in the current context. On the other hand, the P2Y₁₂ receptor antagonists (clopidogrel, prasugrel, and ticagrelor) which bind and inhibit ADP receptors on platelets, thereby, inhibiting glycoprotein IIb/IIIa-receptor activation and subsequent platelet aggregation (Fig. 3). Ticlopidine was the first generation thienopyridine but its use was seriously limited as a result of bone marrow toxicity and was largely replaced by clopidogrel which till recently had become standard of care in patients undergoing PCI.²¹ The level of platelet aggregation inhibition (via ADP-induced pathway), by usual doses of clopidogrel (50–100 mg), when steady state is reached is around 50–60% but this state is achieved only after 4–7 days. The clinical benefit of a combination of ASA and clopidogrel over ASA alone has been confirmed in various clinical situations after PCI; clopidogrel for the reduction of events during observation

FIG. 3: Mechanism of action of P2Y₁₂ receptor antagonists.

(CREDO), clopidogrel and metoprolol myocardial infarction trial (COMMIT) [within 12 hours of ST-elevation myocardial infarction (STEMI)], and clopidogrel as adjunctive reperfusion therapy (CLARITY) trial (within 24 hours of STEMI).²²⁻²⁴ However, clopidogrel itself has its own set of limitations. One of them is slow onset of action. There is some evidence that use of a 600-mg rather than a 300-mg loading dose of clopidogrel would lead to a more rapid onset of action and greater platelet inhibition and reduce the rate of ST albeit at the cost of some increase in major bleeding.^{25,26} Another limitation of clopidogrel therapy is high on-treatment platelet reactivity or platelet resistance. It is known to occur in nearly one-third of patients and has been associated with 1.5–5 times increased risk of ST. The prevalence varies according to presence of comorbidities (dyslipidemias, diabetes mellitus, etc.), use of proton pump inhibitors (omeprazole), and concomitant therapies (atorvastatin, calcium channel blockers, etc.). The mechanism of this resistance could be insufficient active metabolite generation (clopidogrel being a prodrug) particularly from effect on CYP450 isoenzymes (2C19, 1A2, 2B6, 2C9, 3A4), either extraneous influences or genetic polymorphisms.²⁷⁻²⁹ Indeed in a meta-analysis of nine studies [9,685 patients with acute coronary syndrome (ACS) or undergoing PCI], Mega and co-worker demonstrated a 55% increase in risk of MI, stroke, or cardiovascular death in carriers with one loss of function CYP2C19 allele and an increase of 76% with two loss of function alleles, both statistically significant compared to noncarriers. Overall, more than 7/10 subjects were noncarriers, more than 1/4 had one reduced-function CYP2C19 allele, and more than 2% had two reduced-function CYP2C19 alleles.³⁰

These limitations of clopidogrel therapy have led to an ongoing search for a better thienopyridine; more efficacious, faster onset of action and more predictable response. Prasugrel, another prodrug of the same group, has a more rapid onset of action, a complete inhibition of ADP-induced platelet aggregation and has a more consistent response compared with clopidogrel.^{31,32} Prasugrel has been found efficacious and safe in clinical studies as well. The trial to assess improvement in therapeutic outcomes by optimizing platelet inhibition with prasugrel-thrombolysis in myocardial infarction 38 (TRITON-TIMI 38) demonstrated that there was a 19% reduction in the composite primary outcome of MI, stroke, or cardiovascular death [9.9% vs. 12.1%; 95% confidence interval (CI): 0.73–0.90] as well as a significant reduction of ST (1.1% vs. 2.4%, p = 0.001) without an increase in major, life-threatening, or fatal bleeding with prasugrel therapy compared with standard clopidogrel therapy (300 mg loading dose followed by 75 mg/day).³³ Interestingly this study revealed a greater benefit of this therapy in patients undergoing primary PCI, a context where rapid and complete inhibition of platelets is of vital importance, also highlighting the limitation of clopidogrel in this setting. Another situation where prasugrel is remarkably effective vis-à-vis clopidogrel is diabetes mellitus, a context of high clopidogrel resistance as well as one where complete platelet inhibition is required. This drug is associated with increase of minor bleeding but is contraindicated in patients with active bleeding or history

of stroke or transient ischemic attack (TIA) and used with caution in older (>75 years age) or thinner individuals (<60 kg weight).

Ticagrelor is the newest kid on the block among the thienopyridines. It scores in many ways above clopidogrel: it is an active drug (does not require biotransformation to be active); it has a significantly shorter delay of action (requiring only an hour to achieve maximal platelet reactivity inhibition vis-à-vis 6–12 hours with clopidogrel; it is a more potent inhibitor, has a very-low interpatient variability (ticagrelor resistance is ~3% only), has vasodilatory effects (mediated via increased ADP) and has a shorter duration of action (inhibition being reversible). The shorter duration of action (3 days vs. 5 days with clopidogrel) can be useful when the patient is due for emergency surgery or those experiencing bleeding.³⁴⁻³⁷ In the Platelet Inhibition and Patient Outcomes (PLATO) trial testing efficacy of ticagrelor with clopidogrel standard therapy in patients of ACS and STEMI ticagrelor was associated with a significant reduction in ischemic events (MI, ST, and total mortality). Interestingly mortality reduction was to the tune of 22% (p <0.01), a first by any thienopyridine. However, the only limitation with ticagrelor Rx was increased rate of non-CABG-related major bleeding (2.8 vs. 2.2%; p = 0.03) although the overall rate of major bleeding remained same.³⁸ In another landmark trial, prevention of cardiovascular events in patients with prior heart attack using ticagrelor compared to placebo on a background of ASA (PEGASUS) trial the effect of different doses of ticagrelor (60 mg, 90 mg) was compared with placebo (the other drug in all arms being ASA) in a subset of patients with a higher risk. Over nearly 3 years of follow-up, both doses of ticagrelor (combined with ASA) were superior to ASA alone in preventing ischemic complications (MI, stroke, or death) over a prolonged duration of DAPT Rx. Expectedly, risk of nonCABG TIMI bleed was higher in ticagrelor groups but interestingly, the lower dose of ticagrelor had similar ischemic benefit but a reduced risk of bleeding.^{39,40} This raises the possibility of prolonged use of DAPT with low-dose ticagrelor in patients with higher ischemic risk.

HOW TO PREVENT STROKE IN A PATIENT WITH ATRIAL FIBRILLATION?

Atrial fibrillation is the most common arrhythmia afflicting mankind (up to 2% of world suffers from it and after age of 40 years nearly one-fourth of the population will develop it).^{41,42} It is also one of the most important risk factor for stroke, which happens to be one of the leading causes of cerebrovascular mortality worldwide.⁴³ It is a common knowledge that the stroke rate among patients with nonvalvular AF is 5% per annum (with valvular AF particularly in context of severe mitral stenosis it is much higher) but what is not that well known is the fact that nearly 50% of patients with AF-related stroke die within 1-year.⁴⁴ Even if they survive, stroke has a devastating effect on patients, their families and careers and a significant financial impact on the national economy. Costs of this disease escalate far beyond mere cost of medication; cost of long-term care for the living and the financial impact of lost productivity. However, the

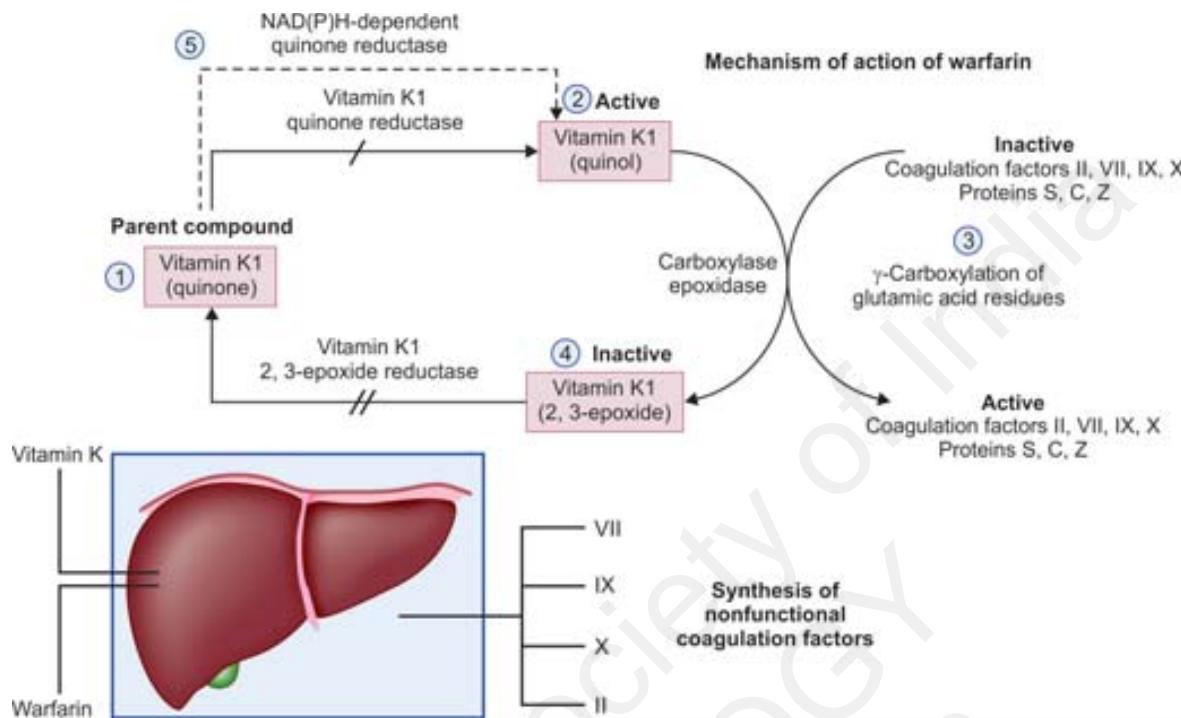

FIG. 4: Mechanism of action of vitamin K antagonists.

risk of stroke varies between different patient subgroups and associated comorbidities. Likewise the bleeding risk also varies among the patient groups and disease situations. The crux of optimal therapy is striking the right balance between ischemic risk of stroke and the underlying bleeding risk.

Vitamin K antagonists have remained the cornerstone of therapy for stroke prevention in AF till recently. They act by depleting the active form of the vitamin by inhibiting reversibly the enzyme vitamin K epoxide reductase and thus the recycling of the inactive vitamin K epoxide back to the active reduced form of vitamin K. Vitamin K is required for the carboxylation of clotting proteins II (carboxylate-specific glutamic acid residues on prothrombin), VII, IX, and X. Without adequate levels of vitamin K, the liver produces partially carboxylated and decarboxylated clotting proteins, which have reduced procoagulant activity. Vitamin K is required for the synthesis of certain proteins. Without these carboxylated residues, the protein will not form the appropriate conformation of thrombin (and other components of the pathway), an essential component of blood clotting process. Thus, no fibrin monomers will form that are polymerized to form blood clots (Fig. 4).⁴⁵ Being reversible (competitive inhibition) in nature, the action of this class of anticoagulants may be reversed by administering vitamin K for the duration of the anticoagulant's residence in the body, and the daily dose needed for reversal is the same for all drugs in the class. Coumarins or coumadins (more accurately 4-hydroxycoumarins) are the most commonly used VKAs, and warfarin is the most commonly used coumarin. Numerous trials have shown benefit of warfarin in stroke prevention in AF (SPAF) and a recent meta-analysis involving six randomized controlled trials (RCTs) of both primary and

secondary patients, enrolling more than 2,500 individuals; atrial fibrillation ASA and anticoagulation (AFASAK), Boston area anticoagulation trial for atrial fibrillation (BAATAF), Canadian atrial fibrillation anticoagulation (CAFA), stroke prevention in atrial fibrillation (SPAF) I, stroke prevention in nonrheumatic atrial fibrillation (SPINAF), and European atrial fibrillation trial (EAFT) confirm the same. Overall, with use VKA the risk of nonfatal stroke was reduced by two-thirds and mortality by one-fourth (vs. no treatment).⁴⁶⁻⁵² However, since VKAs also increase the risk of bleeding, particularly major, nonfatal, noncranial bleeding its use in patients with low risk [CHADS₂ score (congestive heart failure, hypertension, age ≥75 years, diabetes mellitus, stroke) 0], may not be mandated. Acenocoumarol is another coumarin group of drugs available in some countries like India. It may have some pharmacokinetic and pharmacodynamic benefits over warfarin (Box 4).

Antiplatelets acts by inhibiting platelet aggregation, a step in coagulation cascade, active after formation of fibrin clots. Thus it is not surprising that several RCTs

BOX 4 Difference of acenocoumarol compared with warfarin

Acenocoumarol (acitrom)

Same as warfarin with following differences:

- Shorter half life 10–16 h
- More rapid onset of action on PT
- Shorter duration of action (2 days)
- Causes gastrointestinal disturbances, oral ulcerations, and dermatitis
- Total 4 mg on day one, 4–8 mg on the day 2nd then maintenance dose 1–8 mg according to response by PT test

have demonstrated that antiplatelet monotherapy could contribute to one-fifth reduction in risk of nonfatal stroke (vs. No Rx).^{46,49,51,53-57} However, data from analysis of six primary prevention trials and a meta-analysis of 60 secondary prevention trials, enrolling nearly 200,000 patients have revealed that ASA increases the risk of nonfatal, noncranial bleeding by 50%.^{58,59} On the other hand, adjusted-dose warfarin may be far superior to ASA for the prevention of stroke in patients with AF but at the same time is likely to be associated with a greater bleeding risk. A meta-analysis involving 11 RCTs and 6,526 patients (comparing adjusted-dose VKA therapy to antiplatelet monotherapy) has revealed that VKA therapy led to reduction in risk of stroke by half although it simultaneously increased risk of major bleeding 2-2.5-fold.⁶⁰⁻⁷⁰ Thus, if ischemic risk is higher; CHADS₂ above 0, VKA may be preferred. On the other hand, if risk is low (CHADS₂ = 0), ASA may be preferred.

Use of DAPT in AF can be considered in patients who are unsuitable for oral anticoagulant therapy. A combination of ASA and clopidogrel (DAPT) versus ASA alone, in the atrial fibrillation clopidogrel trial with irbesartan for prevention of vascular events (ACTIVE) A trial enrolling 7,554 patients has revealed that DAPT is more effective in reducing the risk of nonfatal stroke, albeit with increased risk of nonfatal, noncranial major bleeding.⁷¹

Vitamin K antagonists are fairly effective in stroke prevention; however, there are many serious downsides to this therapy. The standard risk of major bleeding with this therapy is 1-4% per year (in ambulatory pts. 4-9% per year),

with an intracranial bleeding (IC bleed) rate of 0.2-0.5% per year. Further, the bleeding risk increases dramatically when the international normalized ratio (INR) exceeds 4.0 and as a matter of fact warfarin-induced out-of-range INR is the most important risk factor for IC bleeds, thus entailing the need for frequent monitoring of INR. Thus VKAs are beset with so many serious issues that it is under use worldwide is not surprising and its use is considered "a disease in itself" by some physicians.

As a result anticoagulant therapy for AF is evolving rapidly with the development of newer oral anticoagulants that mechanistically directly target different levels of the coagulation pathway but at the same time have a more predictable efficacy, thus not requiring INR monitoring. These drugs directly act at a specific target on coagulation cascade and therefore have a much more predictable outcome (Fig. 5). Currently the following drugs are available:

- Direct thrombin inhibitors (dabigatran)
- Direct factor Xa inhibitors (apixaban, rivaroxaban, and edoxaban).

Direct thrombin inhibitor, dabigatran was found useful in the randomized evaluation of long-term anticoagulation therapy (RE-LY) trial (basically a meta-analysis of three RCTs enrolling >18,000 patients and testing two doses of dabigatran; 110 mg and 150 mg) compared with dose-adjusted warfarin (target INR 2.0-3.0). Data revealed that it was high-dose dabigatran (150 mg) which was associated with one-third reduction in nonfatal stroke with no increase in nonfatal, noncranial bleeding. Interestingly, there was even a trend

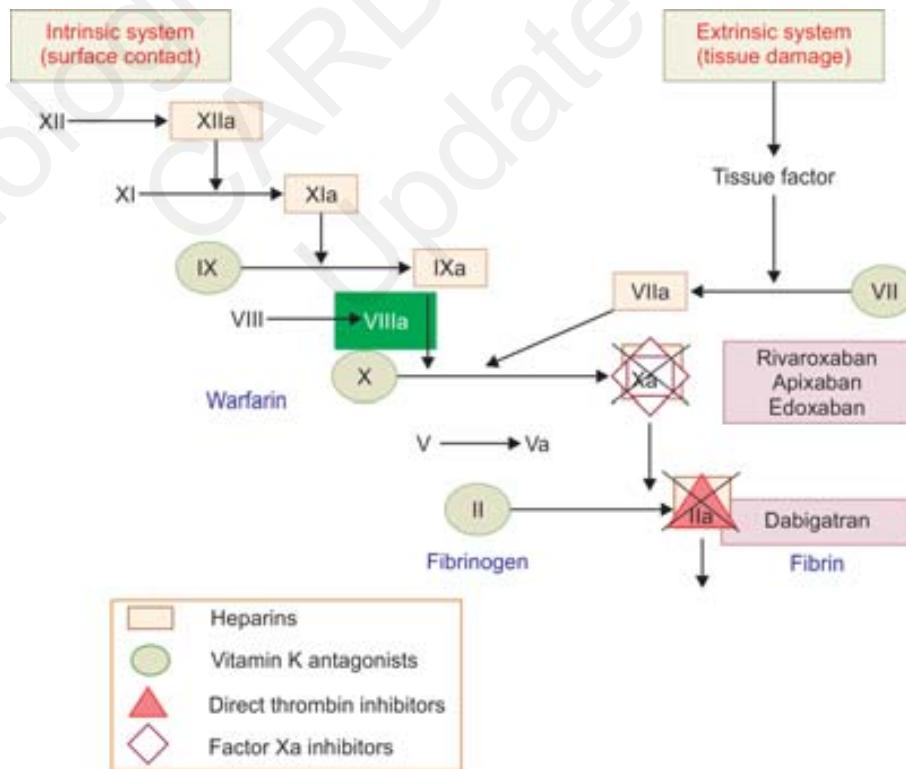

FIG. 5: Mechanism of action of anticoagulant drugs.

toward mortality reduction (11%) in these patients.⁷² Likewise, apixaban for the prevention of stroke in subjects with atrial fibrillation (ARISTOTLE) trial, a double-blind, double-dummy RCT, enrolling >18,000 patients with AF, and comparing 10 mg daily apixaban to warfarin (target INR 2.0–3.0) revealed that a use of apixaban led to 21% reduction in risk of ischemic or hemorrhagic stroke but also 31% reduction in risk of major bleeding (vs. warfarin). Furthermore all-cause mortality was 11% lower with apixaban.⁷³ On the other hand, the rivaroxaban once daily oral direct factor Xa inhibition compared with vitamin K antagonism for prevention of stroke and embolism trial in atrial fibrillation (ROCKET-AF), a double-blind RCT, enrolling >14,000 was not superior to warfarin (INR 2–3) with an increased risk of major GI bleeding (3.2% and 2.2%, respectively, $p < 0.001$), although overall major bleeding was no different. There was no effect on mortality.⁷⁴ However, in all the three trials use of newer nonvitamin K oral coagulants versus warfarin, the rate of IC-hemorrhage was lower.^{72–76}

HOW TO BALANCE RISKS AND BENEFITS IN PATIENT OF ATRIAL FIBRILLATION UNDERGOING PERCUTANEOUS CORONARY INTERVENTION

Since antiplatelet drugs have some anticoagulant effect and anticoagulant drugs have some antiplatelet effects, theoretically it might be reasonable to assume that using one class of

drug may be sufficient for both activities (Fig. 6). However, it has to be understood that antithrombotic drugs act predominantly in reducing arterial thrombosis (consequent upon PCI) whereas anticoagulants are predominantly effective in reducing venous thrombosis [precursor of stroke and thromboembolic events (TE) complications of AF]. The effect of one therapeutic modality on the other one is very weak at best. It is thus clear that a combination of both agents would be required to appropriately address risk of this complex situation.^{77,78} Indeed, early guidelines suggested TAT strategy for patient of AF undergoing PCI with stent implantation.^{79,80} However, TAT, while vary efficacious for ischemic and thromboembolic complications, carries a nearly 3-fold increase in risk of bleeding. Indeed, several trials and later network meta-analysis revealed that risk of bleeding from TAT was the highest.^{81–97} Analysis of RCTs in this area also revealed same general findings.^{98–101}

It is clear that a combination will be required which will balance all the risks associated with arterial thrombosis, venous thrombosis and bleeding risks. Thus, it is important to understand the risk benefits associated with individual drugs; antiplatelet or anticoagulants. The comparison of these drugs for various risks (from highest to least) is as follows.

Anti-ischemic Risk

The anti-ischemic risk is as follows ASA > NOACs > VKA > clopidogrel > ticagrelor > prasugrel (Table 1 and Fig. 7).

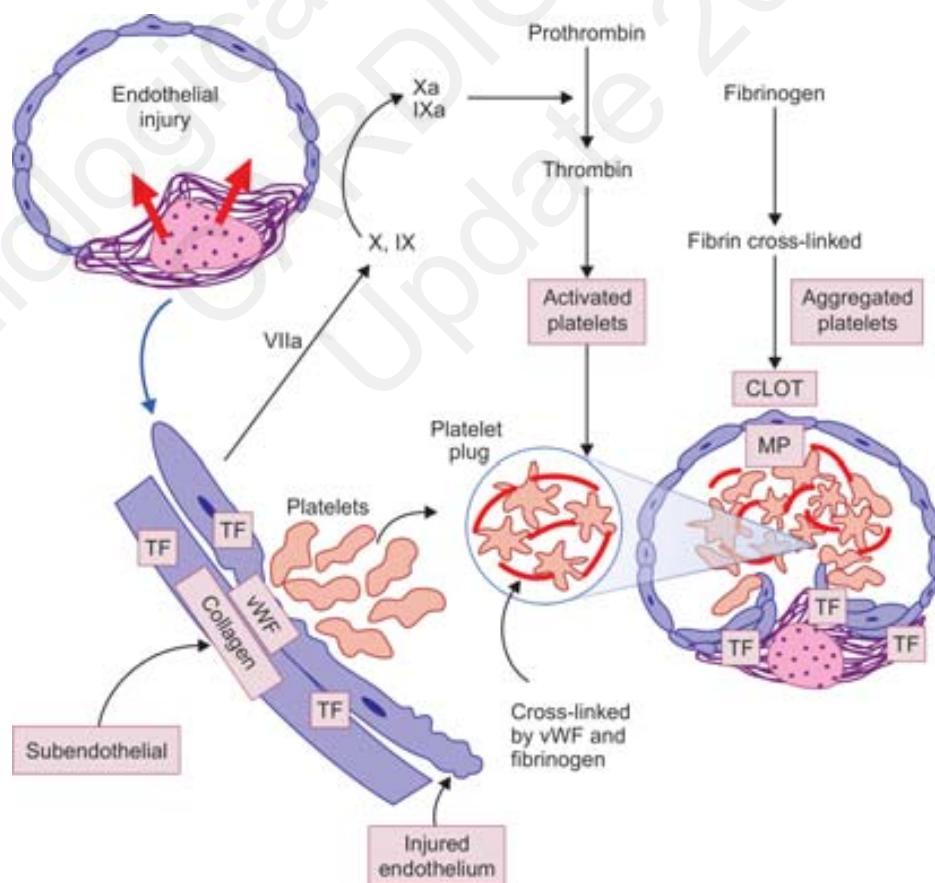

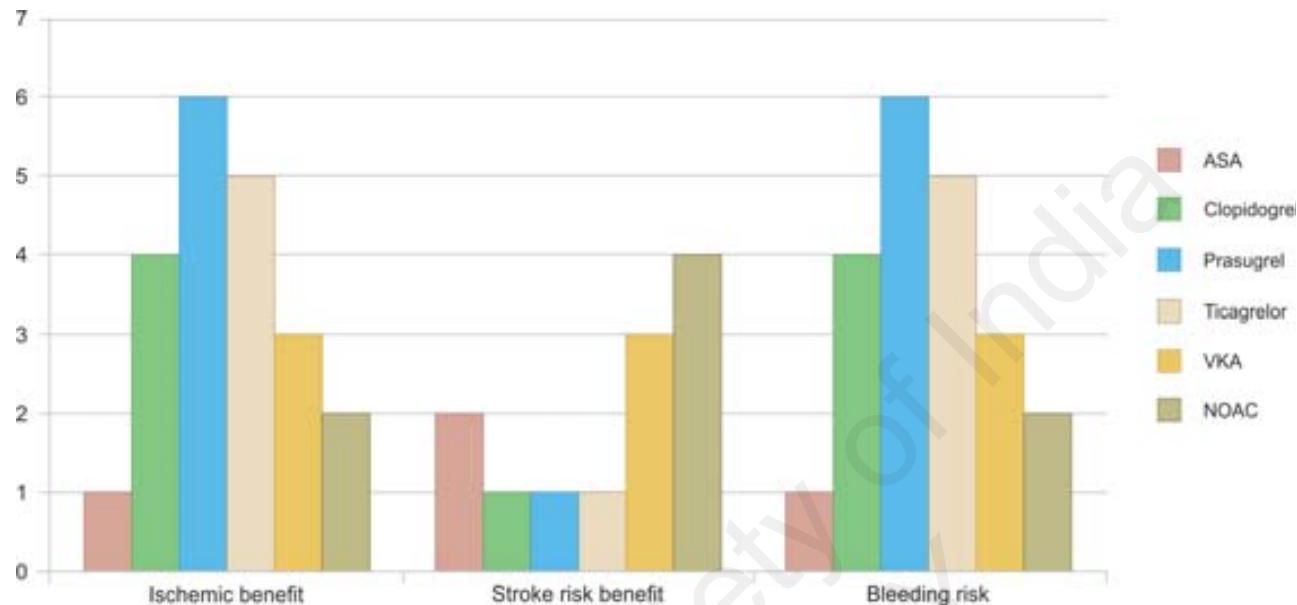

FIG. 6: Mechanism of formation of blood clot.

ASA, aspirin; NOAC, nonvitamin K oral anticoagulant; VKA, vitamin K antagonist.

FIG. 7: Risk and benefits of individual antiplatelet and anticoagulant agents.

TABLE 1: Risk and benefits of individual antiplatelet and anti-coagulant agents

Drugs	Ischemic benefit	Thromboembolic benefit	Bleeding risk
Aspirin	+	++	+
Clopidogrel	++++	+	++++
Prasugrel	+++++	+	+ + + +
Ticagrelor	++++	+	++++
VKA	+++	+++	+++
NOAC	++	++++	++

VKA, vitamin K antagonist; NOAC, nonvitamin K antagonist oral anticoagulants.

Antithromboembolic Risk

The stroke risk and other thromboembolic risk as follows: clopidogrel, ticagrelor, prasugrel > VKA > NOAC (Fig. 7).

Bleeding Risk

The bleeding risk is as follows: prasugrel > ticagrelor > clopidogrel > VKA > NOAC (Fig. 7).

While risk benefit profile of individual antiplatelet and anticoagulant may be useful in predicting the profile of their combinations, there could be some variations. For example, while TATs should be possessing most efficacy, in reality their efficacy can be lower than a combination of DAPT and low-dose NOAC. The reason could be that because of increased bleeding risk, during the time of bleeding, effective antithrombotic therapy may be discontinued contributing to increased ischemic risk. The anti-ischemic benefit and bleeding risk (from least to highest) are as follows.

Thrombotic Risk

The antithrombotic benefit (ST + stroke) is as follows:

DAPT < TAT < VKA + P2Y12 inhibitor < DAPT + low dose NOAC < NOAC (full dose) + P2Y12 inhibitor.

Bleeding Risk

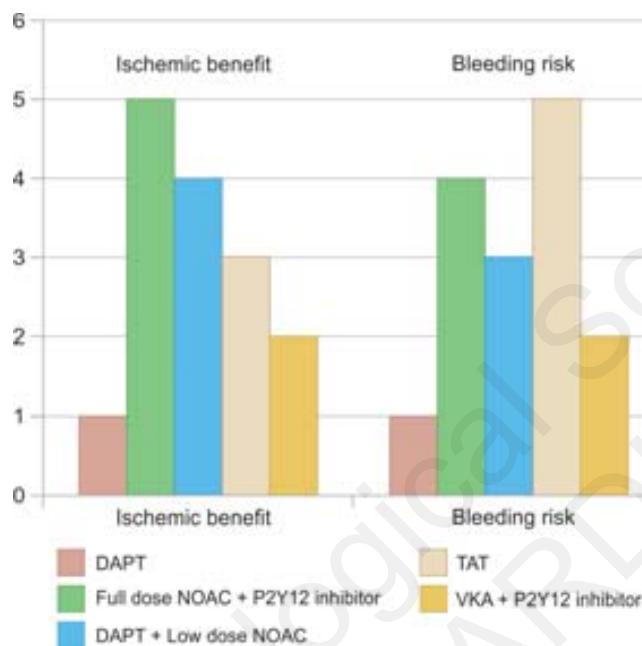

The bleeding risk is as follows: DAPT < VKA + P2Y12 inhibitor < DAPT + low dose NOAC < NOAC (full dose) + P2Y12 inhibitor < TAT (Table 2 and Fig. 8).

It is clear from the above discussion that DAPT has the least antithrombotic efficacy (particularly low against stroke) and TAT has the highest bleeding risk (at least 50% more than any dual combination). As such both are not suitable for this complex subset. Full dose NOAC + P2Y12 inhibitor has a high bleeding risk as well (although this combination has the highest thrombotic efficacy). Low dose NOAC with DAPT has higher antithrombotic efficacy compared to VKA + P2Y12 inhibitor but it has higher bleeding risk as well. Thus a clinician has generally two options: If the risk of ST is high; left main disease, bifurcation disease, ACS, diabetes mellitus etc., low dose NOAC with DAPT may be chosen. On the other hand in a garden variety of PCI, VKA + P2Y12 inhibitor therapy may be chosen.^{98,99} It has to be understood that as far as bleeding is concerned, VKA + P2Y12 inhibitor therapy only decreases risk of minor bleeding, so unless background bleeding risk is high low-dose NOAC with DAPT still remains a reasonable alternative in this group as well. On the other hand if risk of ST is inordinately high; left main bifurcation or bioresorbable scaffold or primary PCI in diabetic but bleeding risk is not inadvertently high a therapy of full dose NOAC + P2Y12 inhibitor may be chosen. The only difference in approach

TABLE 2: The risk and benefits of various antithrombotic combinations

Combination	Ischemic benefit	Bleeding risk
DAPT	+	+
NOAC (full dose) + P2Y12 Inhibitor	+++++	++++
DAPT+ low dose NOAC	++++	+++
TAT	++	+++++
VKA + P2Y12 Inhibitor	+++	++

DAPT, dual antiplatelet therapy; NOAC, nonvitamin K antagonist oral anticoagulants; TAT, triple antithrombotic; VKA, vitamin K antagonist.

DAPT, dual antiplatelet therapy; NOAC, nonvitamin K oral anticoagulants; TAT, triple antithrombotic.

FIG. 8: The risk and benefits of various antithrombotic combinations.

would be that this combination therapy could be limited to 6 weeks or 6 months as the risk may be. The main limitation of low-dose NOAC with DAPT is a higher bleeding risk (vis-à-vis VKA + P2Y12 inhibitor). If instead of DAPT, only clopidogrel is used it may strike the right balance; sufficient efficacy with less bleeding risk (vis-à-vis DAPT or even prasugrel or ticagrelor). Thus a combination of clopidogrel with low-dose NOAC may be the ideal combination for the regular PCI.

A number of points can be made regarding the combination therapy:¹⁰⁰

- Where NOAC is used along with clopidogrel or other P2Y12 inhibitors, a lower dose should be used
- In setting of ACS, dabigatran increases the risk of GI bleeding
- Rivaroxaban in very-low-doses (2.5 mg BD) possesses anti-ischemic properties although it may not be useful in stroke prevention at this dose.

- NOACs are associated with significantly lower intracranial bleeding versus VKA
- Newer P2Y12 inhibitors like prasugrel or ticagrelor should not be used with NOACs because of increased bleeding risk. There is especially a drug interaction between dabigatran and ticagrelor. Here is especially a drug interaction between dabigatran and ticagrelor

Treatment of Atrial Fibrillation in Heart Failure: Is It Any Different?

Rajesh A Dhopeshwarkar

INTRODUCTION

Atrial fibrillation (AF) is a very common arrhythmia and is seen in a myriad of conditions.

Heart failure (HF) and AF have a hand in glove relationship with one frequently perpetuating the other. Besides numerous conditions are common for both of them.

Atrial fibrillation increases both morbidity and mortality by increasing thromboembolic risk and worsening HF. In a large database analysis of all patients admitted with AF and HF between 2001 and 2011, patients with HF and AF had greater in-hospital mortality compared with those without AF (4.6% vs. 3.3%, respectively, $p < 0.0001$). Additionally, black, Hispanic, Asian, and white patients with HF and AF had a 24%, 17%, 13%, and 6% higher mortality, respectively, than if they did not have AF.¹

GOALS OF TREATMENT IN ATRIAL FIBRILLATION

Symptom Control

Most of the symptoms due to AF are a result of fast ventricular rate. However, in patients with HF, loss of atrial kick also significantly contributes to symptoms and progression of HF (Flowchart 1).

Managing Heart Failure and Progression of Heart Failure

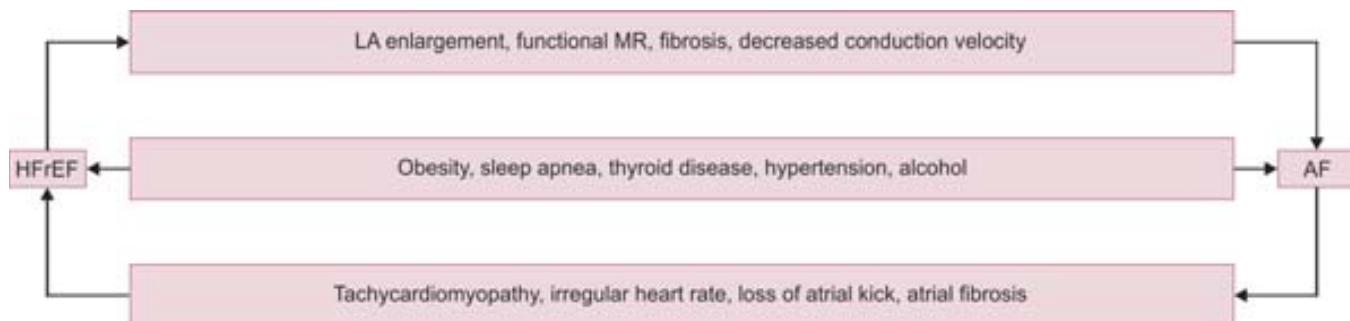

Atrial fibrillation significantly contributes to worsening of HF onset of a potent poor prognosis in HF patients where, management of HF fundamentally remains the same. AF causes significant challenges and needs meticulous understanding of disease processes and more aggressive approach in treating both (Flowchart 2).

Stroke Prevention

Presence of HF increases stroke risk in AF. Anticoagulation remains the mainstay in treatment. Associated organ dysfunction may imply modification of drug dosing. Besides, presence of intracavitary clot may preclude use of newer oral anticoagulants and may necessitate use of vitamin K antagonist (VKA).

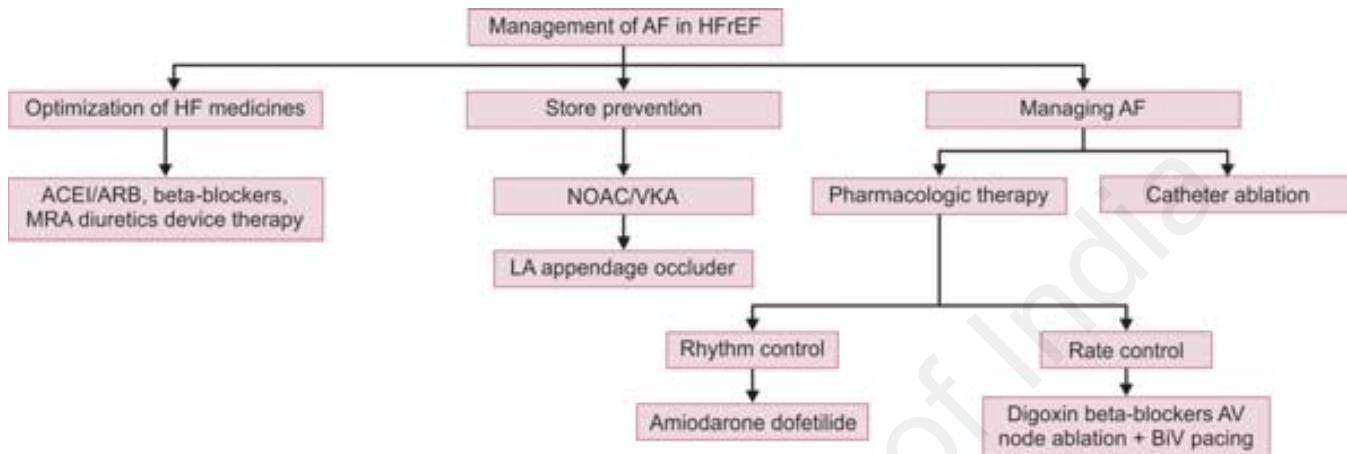

Rate Control

Aggressive rhythm control strategy remains the mainstay for managing AF with congestive HF. Patients with permanent AF and congestive HF rate control may be attempted. Digoxin is a frontline drug in rate control strategy in HF with reduced ejection fraction (HFrEF) patients given its

LA, Left Atrium; MR, mitral regurgitation; HFrEF, heart failure with reduced ejection fraction; AF, atrial fibrillation.

FLOWCHART 1: Mechanisms and pathways of progression of heart failure and atrial fibrillation.

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; AV, atrioventricular; AF, atrial fibrillation; BiV, biventricular; HFrEF, heart failure with reduced ejection fraction; LA, Left Atrium; MRA, mineralocorticoid receptor antagonist; VKA, vitamin K antagonist.

FLOWCHART 2: Management of atrial fibrillation in heart failure with reduced ejection fraction.

atrioventricular (AV) nodal blocking properties with positive inotropic action. There is no randomized controlled trial (RCT) evidence of benefit with Digoxin in the setting of AF.

All other AV nodal blocking agents have a potentially negative inotropic action. Calcium blockers like verapamil and diltiazem are relatively contraindicated in HF. Amiodarone, though a drug used to maintain sinus rhythm, is also used for rate control strategy in combination with other drugs. Appropriate anticoagulation is essential given the potential conversion to sinus rhythm with amiodarone. Patients on long-term amiodarone for rate or rhythm control in HFrEF who develop fast ventricular response should be screened for amiodarone-induced thyrotoxicosis.

Beta-blockers remain the mainstay of rate control in HFrEF. Various trials have proven efficacy of beta-blockers in HFrEF in terms of morbidity and mortality reduction. Hypotension remains a limiting factor in titrating dose of beta-blockers. Very frequently a combination therapy may be necessary.

In a meta-analysis of 11 trials of beta-blockers in HFrEF, Kotecha et al.² found that regardless of pretreatment heart rate, beta-blockers reduce mortality in patients with HF with reduced ejection fraction in sinus rhythm. However, lowering ventricular rate with beta-blockers did not appear to be a predictor of outcomes in patients with HF and AF. The mechanism of this is still unclear. Therefore, although indicated and useful for rate control, beta-blockers have little prognostic impact as compared to patients of HF who are in sinus rhythm.

Patients presenting with decompensated HF and AF with fast ventricular rate should not be initiated on beta-blockers. Rate control can be achieved to reach a goal of 85 per minute at rest and 110 per minute during exercise.

Lenient Rate Control

Lenient rate control with target heart rate of less than 110 per minute at rest is much easier to achieve and in the Rate

Control Efficacy in Permanent Atrial Fibrillation (RACE) 2 trial³ has been found to have similar outcomes. However, RACE 2 patients were mostly in New York Health Association (NYHA) CL 1-2 and very few patients had HFrEF. Hence, these results may not apply to HFrEF patients.

Adequate rate control is even more important in HFrEF patients. Besides, fast ventricular response may lead to tachycardiomyopathy.

Nonpharmacological Rate Control: Pace and Ablate

Atrioventricular node ablation remains the last resort in patients who have failed drug therapy. Both European⁴ and American⁵ guidelines state that AV junction ablation and pacing is reasonable in patients with AF where rhythm control by drugs or ablation is not achievable and where rate control with drugs has failed. Choice of right ventricular pacing versus biventricular (BiV) pacing must be judiciously done ideally based on baseline left ventricular (LV) ejection fraction. His bundle pacing is now being considered increasingly in patients with AV block and LV dysfunction who will need long-term ventricular pacing.

Patients who have received a BiV device and now develop AF frequently leads to loss of BiV pacing. Achieving BiV pacing in excess of 90% is of paramount importance. This is achieved by uptitrating drugs that control ventricular rates. However, AV node ablation is now considered a superior strategy. In a systematic review, Ganesan et al.⁶ found AV node ablation was associated with better overall and cardiovascular mortality and better functional class.

Rhythm Control

Whenever possible establishing and maintaining sinus rhythm remains the long-standing goal in patients with AF and HFrEF. This is accomplished by pharmacologic therapy, electrical cardioversion, and catheter ablation.

Pharmacology Therapy

Maintaining sinus rhythm is challenging in the setting of AF and HF due to limited availability of drugs that can be used and poor efficacy.

In multiple RCTs, rhythm control strategy has not been proven to be superior to rate control. In the atrial fibrillation and congestive heart failure (AF-CHF) trial⁷, patients were randomized to aggressive rhythm control strategy using electrical cardioversion with amiodarone and if necessary, sotalol or dofetilide. Over a 3-year period, there was no difference in cardiovascular mortality between the two arms.

Therefore, rate control strategy was equally effective in terms of hard endpoints.

Amiodarone

It remains the mainstay in managing AF in patients with HFrEF. This is due to its almost no risk of proarrhythmia-like torsades. Two major drawbacks of amiodarone are relative lack of efficacy and significant systemic side effects often necessitating withdrawal. Intravenous amiodarone is known to have a conversion rate to sinus rhythm of around 30%. It does increase the chance of maintaining sinus rhythm when administered in long run. However, 30% of patients on long-term amiodarone do not tolerate and hence discontinue the medicine. Common systemic side effect is hypothyroidism; however, rarely hyperthyroidism is also known to occur. Besides liver and pulmonary toxicity also need monitoring. While administering amiodarone, close monitoring of international normalized ratio (INR) is necessary in patients anticoagulated with VKA due to its potentiation of VKA.

Sotalol

It is a class III antiarrhythmic drug that has been used in patients with coronary artery disease and AF. It should be used with caution in patients with severe LV dysfunction or with renal dysfunction. QT prolongation must be monitored as it is known to precipitate torsades. Implantable cardioverter defibrillator (ICD) implant is necessary before sotalol is used. Dofetilide: It is a class III antiarrhythmic drug. Patients are initiated on dofetilide as an inpatient with serial QT monitoring and doses are adjusted according to creatinine clearance. In the Danish Investigations of Arrhythmia and Mortality on Dofetilide in congestive heart failure (DIAMOND CHF)⁸ and DIAMOND substudy⁹ trials, patients with HFrEF and AF were administered dofetilide. Rate of conversion to sinus rhythm was significantly higher (57% vs. 34%) than placebo. Probability of maintaining sinus rhythm was greater with dofetilide (79% vs. 42%). There was no survival benefit with dofetilide. Torsades De pointes was the most important side effect that was observed in 3.3% patients most of them happening in first 3 days of initiation of dofetilide. Due to its proarrhythmic effect ICD implantation prior to administration of drug is useful. Dofetilide is currently unavailable in India.

Electrical Cardioversion

Hemodynamic instability in the setting of AF and HF warrants urgent electrical cardioversion. Before electrical or pharmacologic cardioversion, achieving optimal

anticoagulation is necessary. If there is a necessity to cardiovert early, intracardiac clot must be ruled out with a transesophageal echocardiogram. Unless pretreated with antiarrhythmic drugs a high proportion of patients who undergo electrical cardioversion will revert to AF. Preferably, patient should be initiated on amiodarone or other antiarrhythmic drug prior to cardioversion that increases the likelihood of long-term success. Any intercurrent illness like pneumonia will make long-term maintenance of sinus rhythm unlikely. In such scenario, rate control strategy may be appropriate. Attempt to achieve and maintain sinus rhythm must be done for every patient with HFrEF and AF.

Catheter Ablation

Catheter ablation remains second line of management of AF in patients with normal heart. Current guidelines recommend catheter ablation in patients symptomatic despite drug therapy or those who decline drug therapy. However, AF in patients with HFrEF remains a challenge due to limited options of drug. In a landmark study, the CASTLE AF study,¹⁰ patients with AF and HF were randomly assigned to catheter ablation or medical therapy. At 3 years, there was a significant reduction of the combined endpoint of death and hospitalization in patients undergoing catheter ablation (28.5% vs. 44.6%). At the end of 60 months, 66% of catheter ablation patients were in sinus rhythm as compared to only 22% in the medical therapy arm. LV ejection fraction improved by 8% in the ablation arm as compared to 0.2% in the medical therapy arm. In a meta-analysis¹¹ of 26 RCTs, significant improvement of LV ejection fraction was observed with catheter ablation.

In the recently presented catheter ablation vs. antiarrhythmic drug therapy in atrial fibrillation (CABANA)¹² trial, ablation was not superior to drug therapy for cardiovascular outcomes at 5 years among patients with new-onset or untreated AF that required therapy. However, this happened due to lot of crossover between the treatment arms. In those patients who did receive catheter ablation, there was significant reduction in the primary composite endpoint. About 15% of patients in CABANA had HF.

Stroke Prevention

Fundamentally all patients with AF and HFrEF need anticoagulation. Current guidelines have no role of Aspirin for stroke prevention in this setting. Other than patients with mechanical valves or moderate to severe mitral stenosis, all other patients can receive direct oral anticoagulant (DOAC) in preference to VKA.

Direct Oral Anticoagulant or Vitamin K Antagonist

Direct oral anticoagulants have been proven to be non-inferior to VKA in terms of preventing stroke. Some of them have been even superior to VKA. A large meta-analysis¹³ of four RCTs found DOAC use to be as safe and effective as VKA in the setting of AF and HF. Use of DOAC was associated with a 41% lesser risk of intracranial bleed as compared to VKA.

Renal dysfunction is a frequent association with HFrEF. None of the DOAC has been tried with creatinine clearance less than 30 mL/min. They can be used safely with appropriate dose modification in the rest.

Role of Left Atrial Appendage Occluder

Long-term anticoagulation with VKA is associated with narrow therapeutic range as well as increased bleeding risk. Most of the cardioembolic strokes in AF arise from the left atrial appendage (LAA). Occluding or clamping the LAA has been tried in various studies. These devices are currently approved for use in patients who have relative contraindications to long-term anticoagulation. In the percutaneous left atrial appendage closure versus warfarin for atrial fibrillation (PROTECT-AF)¹⁴ study, the WATCHMAN LAA occluder was found to reduce the composite endpoint of stroke, systemic embolism, and cardiovascular death by an absolute value of 1.5%. This was driven mainly by decreased incidence of hemorrhagic stroke in the device arm.

CHALLENGES IN DEVICE MANAGEMENT IN PATIENTS WITH ATRIAL FIBRILLATION AND HEART FAILURE

Device-detected Atrial Fibrillation

Device-detected atrial high rate episodes (AHRE) pose a new question of stroke risk associated with such episodes and whether such patients will benefit from anticoagulation. In a meta-analysis¹⁵ of 11 trials, device-detected or subclinical AF was associated with more clinical AF. Such episodes were also associated with elevated stroke risk although it was lower than those with clinical AF. Studies are underway to define indications for anticoagulation in patients with device-detected AF. Currently, patients with AHRE on device logs undergo further testing with ambulatory ECG and external loop recorders to document AF.

Inappropriate Shocks

Atrial fibrillation and other supraventricular tachycardias are responsible for most of the inappropriate shocks. Appropriate device discriminators have to be programmed in such patients. Aggressive management of AF with pharmacologic therapy and if necessary catheter ablation is necessary.

CONCLUSION

Atrial fibrillation and HF frequently coexist and perpetuate each other. Onset of AF adds to challenges in the management of HF. AF, therefore, needs to be treated aggressively to prevent progression of HF as well as prevent development of structural changes that make AF permanent. Pharmacologic

therapy whether aiming rate control or rhythm control is highly inadequate. Catheter ablation is an effective alternative that is now proven in RCT to reduce hard endpoints of HF hospitalizations and mortality. Catheter ablation is now being increasingly used in preference to pharmacologic therapy. DOAC have definite advantage over VKA both in terms of safety and efficacy. LAA occlusion with devices is an evolving therapy that is currently approved for use in patients where long-term use of anticoagulation is contraindicated. Managing comorbidities by lifestyle changes and risk factor modification are of paramount importance. Besides, optimization of HF with guideline-directed medical therapy is essential. A multidisciplinary approach with electrophysiologists and HF specialists will provide optimal patient care in this challenging situation.

Managing Atrial Fibrillation in Acute Myocardial Infarction

Jayagopal P Balagopalan, Sarjun Basha

INTRODUCTION

Atrial fibrillation (AF) often complicates acute myocardial infarction (AMI) with an incidence between 6% and 21%. AF may be pre-existing, first time detected, or of new onset. ST-segment elevation myocardial infarction (STEMI) patients with documented AF have worse short and long-term prognosis when compared with patients in sinus rhythm.¹ Presence of AF is associated with a higher reinfarction rate, higher stroke rate, higher risk for heart failure, and increased risk for sudden cardiac death.²⁻⁴

PREDICTORS OF ATRIAL FIBRILLATION IN ACUTE MYOCARDIAL INFARCTION

Increased age, presence of heart failure symptoms, high heart rates at admission, and left ventricular dysfunction are the major predictors.

MANAGEMENT OF ATRIAL FIBRILLATION IN ACUTE MYOCARDIAL INFARCTION

Management includes:

- Rate control
- Rhythm control
- Prevention of thromboembolism.

Rate Control

High ventricular rates associated with AF may further impair hemodynamics in patients with AMI by increasing myocardial oxygen demand. Thus adequate rate control represents the first therapeutic approach. In patients with AF and rapid ventricular rate, acute heart rate (HR) control is usually achieved with intravenous (IV) medication namely IV beta-blocker, IV amiodarone, and IV digoxin (Table 1). IV beta-blocker is indicated when there are no clinical signs of acute heart failure or hypotension.^{2,5} IV amiodarone is indicated in the presence of concomitant acute heart

TABLE 1: Atrial fibrillation acute rate control—common medication dosage.

Beta-blockers	Intravenous administration	Usual oral maintenance dose
Metoprolol tartrate	2.5–5.0 mg IV bolus over 2 minutes; up to 3 doses	25–100 mg bid
Esmolol	500 µg/kg IV bolus over 1 minute, then 50–300 µg/kg/min IV	N/A
Digoxin	0.25 mg IV with repeat dosing to a maximum of 1.5 mg over 24 hours	0.125–0.25 mg od
Amiodarone	300 mg IV over 1 hour, then 10–50 mg/h over 24 hours	100–200 mg od

bid, twice daily; IV, intravenous; N/A, not applicable; od, once daily.

failure without hypotension.⁶ IV digitalis is indicated in the presence of acute heart failure and hypotension.⁷ When coadministering IV digoxin and amiodarone, close monitoring for digoxin toxicity is necessary as digoxin serum concentration may rise.

However, electrical cardioversion is considered when adequate rate control is not achieved with pharmacological agents, there is ongoing ischemia, severe hemodynamic compromise or heart failure. Even though electrical cardioversion effectively reverts AF, early recurrence is frequent after successful cardioversion particularly in patients who need catecholamine therapy for circulatory support. IV amiodarone promotes electrical cardioversion and also decreases risk for early recurrence, more so in recent onset AF.

Rhythm Control

There is scarce information indicating preferences for rate control over rhythm control for AF in AMI situation.⁸ According to European Society of Cardiology (ESC) 2016 guidelines on AF, IV amiodarone is indicated for conversion to sinus rhythm in stable patients with recent onset AF and

structural heart disease. Digoxin, calcium channel blockers, and beta-blockers, including sotalol are ineffective in converting recent onset AF to sinus rhythm.^{9,10}

Prevention of Thromboembolism

Prevention of thromboembolism stroke is the most important aspect of management of AF. Reversion of AF to sinus rhythm does not eliminate the stroke risk in patients who do not have a pre-existing left atrial thrombus, as the atria remain stunned for several weeks after cardioversion. The risk of thromboembolism is evaluated by CHA2DS2-VASc score. The risk of bleeding should always be assessed before initiation of anticoagulation. This assessment is done using the HAS-BLED (Hypertension, Abnormal renal and liver function, Stroke, Bleeding Labile INR, Elderly, Drugs or alcohol) score.

Postcardioversion Anticoagulation

In patient with AF less than 48 hours from a definite onset, a bolus of UFH (5,000 units) or low-molecular-weight heparin (1 mg/kg IV) is given. If AF has occurred for more than 48 hours transesophageal echocardiography is necessary to exclude left atrial thrombus. Following cardioversion, further anticoagulation may be needed depending on underlying risk factor assessed by CHA2DS2-VASc score. For patients with CHA2DS2-VASc score 0 for males (or) 1 for female, no oral anticoagulation (OAC) is needed after cardioversion. In patient with AF more than 48 hours (or) risk factors for thromboembolism, heparin is continued together with warfarin targeting a lower international normalized ratio (INR) 2–2.5. Thereafter, anticoagulation is continued for 4 weeks and then further anticoagulation depends on the presence of risk factors. When AF cannot be cardioverted or cardioversion is contraindicated (presence of left atrial thrombus) acute rate control by IV medication alone is used.

Anticoagulation and Antiplatelets in Acute Myocardial Infarction

According to ESC 2017 guidelines on STEMI, in patients with clear indication for OAC that is AF with CHA2DS2-VACs score more than 2, and OAC is used in addition to antiplatelet therapy (Class IC).

For Patients Treated with Fibrinolysis

Consider triple therapy (aspirin, clopidogrel, and vitamin K antagonist to keep INR 2–2.5) for 14 days followed by a vitamin K antagonist plus a single antiplatelet agent (2013 ACC/AHA guidelines for management of STEMI).

For Patients Treated with Primary Percutaneous Coronary Intervention

After an ACS in patients with AF with stent implantation combination triple therapy with aspirin, clopidogrel and an OAC is recommended for 1–6 months (ACC/AHA 2013 guidelines on STEMI and 2016 update on duration of dual antiplatelet therapy). However without stent implantation

dual treatment with an OAC and aspirin or clopidogrel is advised for up to 12 months.¹¹ If patient requires triple antithrombotic therapy combining dual antiplatelet therapy (DAPT) and OAC, duration of DAPT should be minimized to reduce bleeding risk (class IB). Triple therapy is required for at least 1 month. There is new data showing efficacy and safety of novel oral anticoagulants in this scenario. Dabigatran along with newer antiplatelets have been shown to be safe and efficacious in the recently published RE-DUAL study.¹² PIONEER-AF data¹³ showed in selected patients who receive aspirin and clopidogrel, low-dose rivaroxaban (2.5 mg twice daily) can be used if the patient is at low bleeding risk. Gastric protection with a proton pump inhibitor is used for the duration of DAPT therapy in patients at high risk of bleeding (Class IC).

CONCLUSION

Atrial fibrillation is a common arrhythmia that complicates myocardial infarction early in the disease. AF in AMI is an independent predictor of short- and long-term unfavorable outcome irrespective of reperfusion strategy. A comprehensive approach which includes rate and rhythm control and TE episode prevention are the main aspects of management. Treatment of underlying cardiovascular causes and heart failure, the most common mode of death post-AMI, should be targeted as a priority.

Ventricular Arrhythmias

Ventricular Arrhythmias in Acute Myocardial Infarction

Rajesh A Dhopeshwarkar, Rakesh Yadav, Kewal C Goswami

INTRODUCTION

Sustained ventricular arrhythmias (VA) in the setting of acute myocardial infarction (AMI) remains a predominant cause of mortality both early and late after myocardial infarction (MI). A dynamic and changing cellular and intercellular milieu is responsible for the genesis of these arrhythmias. The true incidence of these arrhythmias in AMI occurring in the community is not clearly known as many sudden deaths that happen before the patient reaches the hospital are due to serious VA. Underlying genetic predisposition also contributes to this risk for VA. The incidence of VA is higher in patients with ST segment elevation MI (STEMI) than in patients with a non-ST elevation AMI. Management of VA in this setting is often challenging with limited effectiveness of current pharmacological therapy and frequently needing adjuvant treatment such as autonomic modulation, hemodynamics support, and rarely ablation.

TYPES OF VENTRICULAR ARRHYTHMIAS

Isolated ventricular premature beats (VPBs) is the most common arrhythmia seen in the setting of AMI with a reported frequency of 10–93%. More serious VAs are seen less frequently. Among patients with STEMI incidence of ventricular fibrillation (VF) is 3.7–6.7%.¹ In the GUSTO-1 trial,² the incidence of sustained ventricular tachycardia (VT) or VF was 10.2% with majority of these occurring in the first 48 hours of MI. In the current era of primary percutaneous coronary intervention (PCI) and pharmacotherapy using β-blockers and angiotensin-converting enzyme (ACE) inhibitors, the incidence of VA is markedly reduced.

MECHANISM AND PATHOGENESIS OF VENTRICULAR ARRHYTHMIAS AFTER ACUTE MYOCARDIAL INFARCTION

Acute myocardial infarction is an evolving dynamic state where multiple mechanisms are responsible for genesis of VA

that are time-dependent. Various mechanisms are summarized in flowchart 1. Temporal distributions of VA during AMI are conventionally classified as early (<48 h) and late (>48 h). Patients with early (<48 h) VAs are classified as very early (Phase 1) within 30 minutes of occlusion of infarct-related artery (IRA) and (Phase 2) 1.5–72 hours of occlusion of IRA.

Phase 1 is a reversible phase where reperfusion can lead to complete salvage of myocardium. Phase 2 starts at 1.5 hours where there could be onset of irreversible myocardial injury.

Accompanying the loss of mechanical function with the occlusion of IRA are significant biochemical changes. These biochemical changes and associated myocyte edema and altered electrophysiologic properties of infarcting myocardium giving rise to areas of slow conduction, altered refractoriness, and altered excitability. Purkinje fibers are relatively resistant to ischemia and surviving Purkinje fibers exhibit shortened action potentials with depolarized membrane potential. These surviving and irritable Purkinje fibers have been proposed as the main cause for generating VA during Phase 2.

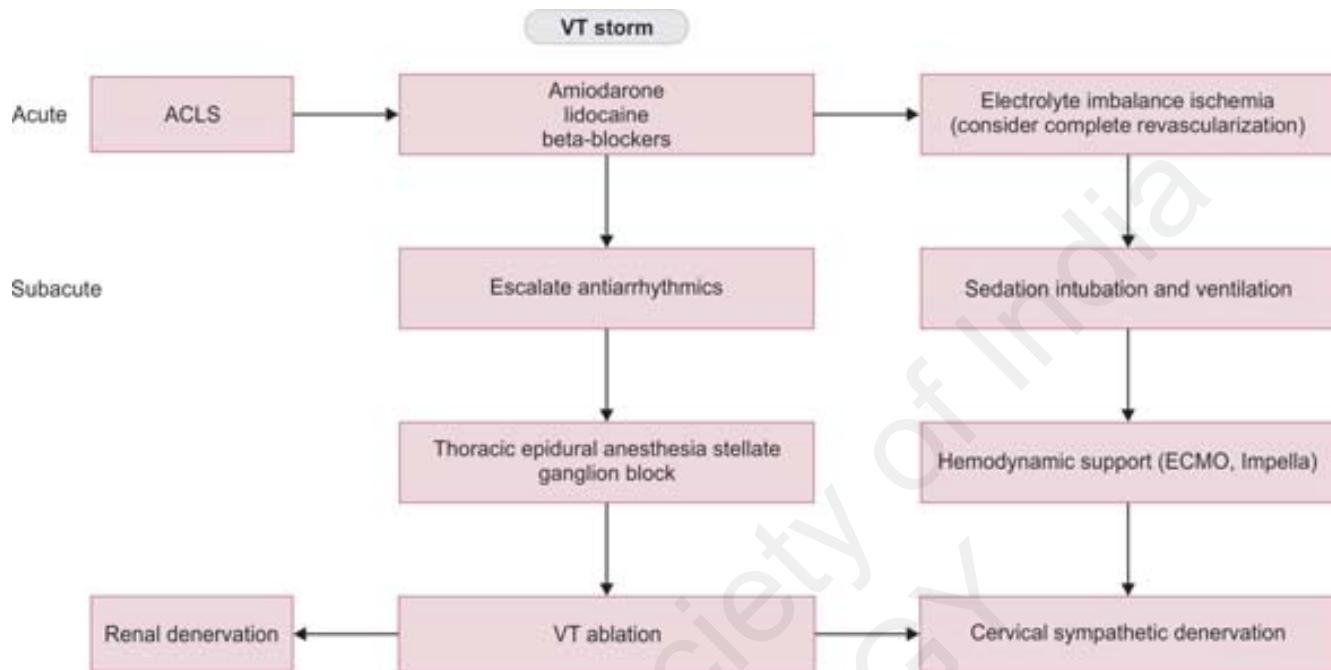

A multitude of biochemical and electrophysiological changes contribute to genesis of VA and are responsible for sudden cardiac death in AMI rather than an isolated mechanism or event. Particular interest is genetic predisposition that increases susceptibility to VA as identified in recent studies.

PREDICTORS OF SUSTAINED VENTRICULAR TACHYCARDIA AND VENTRICULAR FIBRILLATION

There are some factors that predispose a patient for VA after AMI. Patients with larger infarcts, low-ejection fraction, late presenters, or inability to achieve adequate perfusion all endow increased risk for VA, especially sustained VA. In addition, large peri-infarct border zone and extensive scar on magnetic resonance imaging (MRI) are potential risk factors.

Ventricular Arrhythmias

ACLS, advanced cardiac life support; ECMO, extracorporeal membrane oxygenator; VF, ventricular fibrillation; VT, ventricular tachycardia.

FLOWCHART 1: Algorithm for management of VT storm.

VF, ventricular fibrillation; VT, ventricular tachycardia; EAD, Early Afterdepolarization; DAD Delayed after depolarization.

FLOWCHART 2: Mechanisms of VT/VF in acute myocardial infarction.

DETERMINE³ is a current large randomized trial looking into prophylactic implantable cardioverter defibrillator (ICD) therapy based on MRI-determined scar burden.

Programmed electrical stimulation has been used to assess the benefits of ICD therapy in patients late after AMI in the MADIT study. However, inducibility of sustained VT has

low sensitivity in predicting future arrhythmic events. Other repolarization abnormalities, such as QT variability and dispersion, T-wave alternans, and measures of autonomic tone, such as heart rate variability and heart rate turbulence as well as baroreflex sensitivity, have been assessed as predictors.

However, they have not been proven to be beneficial. Higher prevalence of early repolarization has been observed in patients with VA and AMI in small studies.⁴

MANAGEMENT OF VENTRICULAR ARRHYTHMIAS

Ventricular Premature Beats

Isolated VPBs do not adversely affect prognosis after AMI. However, patients having complex ectopy, couplets, and multiform ectopics have a 3-fold increase in sudden deaths and 2-fold increase in all-cause mortalities.⁵ In the GISSI-2 trial,⁶ patients receiving thrombolytic therapy and having increased frequency of ventricular ectopy had higher mortality rate. In the CAMI study,⁷ cardiac mortality was increased with increase in frequency of VPBs, but VPBs did not have an independent predictive value in multivariate analysis. With the advent of primary PCI, the absolute burden on VPBs in patients after AMI has been reduced. There is no evidence to support antiarrhythmic therapy to suppress VPBs. In fact there is evidence that drugs such as Encainide and Flecainide may increase mortality.⁸

Nonsustained Ventricular Tachycardia

With mechanism similar to sustained VT, nonsustained ventricular tachycardia (NSVT) is also seen in 12.7% patients following AMI. There is no evidence to treat asymptomatic episodes of NSVT with antiarrhythmic therapy other than β -blockers. However, frequent and hemodynamically unstable NSVT may need treatment with amiodarone.

Accelerated Idioventricular Rhythm

Accelerated idioventricular rhythm (AIVR) or slow VT is a ventricular rhythm with the heart rate between 50 and 100 beats/minute. Either an escape rhythm or an abnormal ectopic focus may be responsible for AIVR. AIVR is seen in up to 50% patients with AMI. Although seen post reperfusion, it is neither a sensitive nor a specific marker for successful reperfusion. AIVR is usually transient and needs no treatment.

Sustained Monomorphic Ventricular Tachycardia

Sustained monomorphic VT (SMVT) is observed in 2–3% of patients with STEMI and less than 1% of patients with non-ST elevation myocardial infarction (NSTEMI).² SMVT is less common than VF in the first few hours after AMI as the reentrant circuit needed for a SMVT is not established by then. SMVT occurring in the first 48 hours is generally due to enhanced automaticity or due to a prior infarct. SMVT occurring beyond 48 hours is usually due to structural changes leading to reentrant circuits. Scar from an old infarct may also be responsible for SMVT. While late SMVT is associated with a higher chance of recurrence of clinical VA, the clinical significance of early SMVT is still unclear as it may

reflect presence of substrate for recurrence of VT. Available clinical data seems to suggest that patients who have SMVT in the post-MI period have a worse outcome than patients who have NSVT or VF.

Polymorphic Ventricular Tachycardia

Polymorphic VT is a rare arrhythmia following AMI (0.3%).⁹ Coronary ischemia is the most common trigger for this arrhythmia. SMVT, within 48 hours of AMI, is associated with higher in-hospital mortality. However, its impact on long-term outcomes is unclear.² In a study¹⁰ of 9,015 patients who had undergone PCI for AMI, sustained VT/VF was seen in 5.2% of the population and was associated with 4-fold increase in in-hospital mortality.

Late VT beyond 48 hours in the absence of ongoing ischemia is often due to arrhythmogenic substrate during healing of infarct. Patients with SMVT occurring beyond 48 hours have a worse in-hospital and 1-year mortality.²

Ventricular Fibrillation

The incidence of VF in the fibrinolytic era has ranged from 3% to 7% in various studies. Most of the episodes of VF are seen in the first 48–72 hours. They are usually due to ischemia and lack of perfusion.² VF is classified as primary when there is no ischemia or heart failure precipitating. VF due to recurrent ischemia or due to heart failure is classified as nonprimary VF.

Management of Sustained Ventricular Tachycardia/Ventricular Fibrillation¹¹

Acute management of hemodynamically unstable sustained VT or VF is done as per ACLS guidelines. Prompt defibrillation is extremely important. Recurrent sustained VA could be due to residual ischemia or recurrence of acute ischemia. Prompt revascularization is important in eliminating it. This is especially true for polymorphic VT and VF. Patients with hemodynamically tolerated SMVT are treated with intravenous amiodarone. Use of other antiarrhythmic drugs in acute coronary syndrome such as Procainamide or Flecainide is not recommended.

Correction of acid-base balance and electrolytes are important adjuncts to the management. Patients with recurrent VT/VF should be promptly sedated and, if necessary, ventilated. SMVT that is recurrent and refractory to therapy is a challenging subset. Overdrive pacing can be used in these patients. Catheter ablation is a challenging but useful therapy in this subset of patients. Hemodynamic support with percutaneous left ventricular assist device (LVAD)¹² and extracorporeal membrane oxygenator (ECMO)-assisted primary PCI are extremely useful therapies in patients with refractory VA and cardiogenic shock.

In a study¹³ comparing ECMO and intra-aortic balloon pump (IABP), 69.23% of patients on ECMO could be weaned as against only 12.5% with IABP. IABP is therefore not recommended.

Pharmacologic Therapy

Beta-blockers

Beta-blocker therapy remains the crux of management of patients with AMI. Multiple trials have proven reduction in sudden death and total mortality with β -blocker use in AMI.

Amiodarone

Amiodarone remains the drug of choice for managing sustained VT/VF after AMI. Amiodarone was found superior to lidocaine in patients with out-of-hospital cardiac arrest. However, amiodarone use has not been found to be associated with any long-term survival benefit. Lidocaine, mexiletine, and phenytoin have also been used in patients with incessant VA in the setting of AMI.

Catheter Ablation of Recurrent Sustained Ventricular Tachycardia and Electrical Storm

Three or more distinct episodes of VT or VF occurring within 24 hours of AMI is defined as electrical storm. Incessant VT and VF after AMI carries high mortality. It is often difficult to control with antiarrhythmic treatment alone. Recurrent VT or VF arise frequently from Purkinje fiber irritability in the infarct border zones. When it persists despite revascularization and adequate pharmacologic treatment, catheter ablation should be considered. These incessant VT and VF are due to macro-reentrant circuits that develop early in the infarct border zone and due to triggering premature ventricular beats from irritable Purkinje fibers. Both can be targeted by ablation. Three-dimensional mapping and ablation using irrigated catheters is performed in this setting. Identifying and targeting late potentials, fragmented electrograms, channel ablation, and scar homogenization has been described in context to substrate-based ablation.¹⁴ Activation mapping of VPBs that trigger VT and VF can be done provided they are frequent enough. Purkinje potentials before the VPBs are also identified in the infarct border zone.¹⁵

Noninducibility of VT/VF is a good marker for long-term success and survival.¹⁶ Periprocedural mortality of up to 3% due to intractable VT and long-term mortality of 18% due to both VT and heart failure have been reported.¹⁷

Implantable Cardioverter Defibrillator

Patients who develop VT/VF within 48 hours of AMI have not been evaluated systematically. Current guidelines do not recommend ICD implantation in these patients. Patients developing sustained VT/VF beyond 48 hours without a correctable cause are candidates for ICD therapy.

Wearable Cardiac Defibrillator

Substantial mortality exists early after AMI. Two trials, DINAMIT and IRIS, have found the futility of primary prevention ICD within 40 days of AMI. To address this early period, VEST prevention of early sudden death trial, the VEST trial¹⁸ was designed. Contrary to expectations wearable cardiac defibrillator (WCD) did not reduce sudden cardiac death (SCD) for up to 90 days after AMI. Surprisingly, all-cause

mortality was significantly less in the WCD arm. Current ESC guidelines¹¹ recommend WCD (Cl IIb LOE C) in patients who are at high-risk for SCD for a limited time. They are likely to be modified in the setting of AMI after the VEST trial.

Autonomic Modulation for Management of Refractory Ventricular Tachycardia/Ventricular Fibrillation in the Setting of Electrical Storm¹⁹

Autonomic nervous system plays an important role in the genesis of VT and VF. AMI is frequently associated with sympathetic activation. Electrical storm with multiple ICD shocks is associated with high mortality. Thoracic epidural anesthesia (TEA) and percutaneous stellate ganglion block are two promising bedside interventions. Cervical sympathetic denervation (CSD), especially bilateral CSD, has been tried in patients with structural heart disease and electrical storm. In a small group of patients with refractory VA,²⁰ TEA was associated with 80% reduction and CSD with 50% reduction in arrhythmia burden. In an international multicenter study, CSD, especially bilateral CSD, was associated with 88% reduction in ICD shocks and 50% freedom from ICD shocks, transplant, or death.²¹ Other neuromodulatory therapies, such as spinal cord stimulation, percutaneous stellate ganglion block, and renal denervation are also being evaluated for managing refractory VA.

CONCLUSION

Ventricular arrhythmias have been reported after STEMI and NSTEMI with varying frequency and severity. Setting of STEMI is dynamic and evolving with changing arrhythmia substrate and mechanisms responsible for arrhythmogenesis. Both early and late VAs, especially sustained VAs, are associated with worse prognosis after STEMI. Management of VA, especially refractory VA, after STEMI, remains challenging and involves drugs, hemodynamic and ventilatory support, as well as autonomic modulation and ablation.

Ventricular arrhythmias, especially sustained VT/VF, impart a substantial increase in mortality in patients after AMI. Prompt revascularization is of utmost importance not only in limiting the myocardial damage but also in reducing the incidence of VA. Management of VA in this setting is confounded by limited pharmacologic therapy at disposal. Management of associated electrolyte abnormalities and hemodynamic support is of use in patients with low cardiac output and cardiogenic shock. Heightened sympathetic tone and autonomic imbalance also contribute. Newer investigational therapies are being tried to address this. Catheter ablation is challenging and of high risk but offers reasonable options in an otherwise hopeless situation of drug refractory and incessant VT/VF.

Ventricular Arrhythmias and Sudden Death: Problems and Opportunities in Clinical Practice

Kapil Kumawat

INTRODUCTION

Sudden cardiac death (SCD) accounts for 50% of all cardiovascular deaths,¹ and approximately 50% of cardiac disorders are first clinically recognized when patient unfortunately presents with SCD.² Ventricular arrhythmias (VAs) constitute the major underlying mechanism in SCD, especially in older age group. In out-of-hospital cardiac arrest, VAs constitute 30–70% of the initially observed rhythm,^{3,4} though the exact rhythm would depend upon the time from actual event to evaluation of rhythm, with early observation leading to more VAs being observed and later evaluation leading to more asystole and pulseless electrical activity. Not all VAs lead to sudden death. VAs can range from being completely asymptomatic, as in ventricular premature beats (VPBs) to the most devastating ventricular fibrillation (VF) leading to sudden cardiac arrest (SCA) and SCD. Vast majority of sudden death by VA is seen in patients with underlying structural heart disease, especially coronary artery disease (CAD). Monomorphic ventricular tachycardia (VT) occurring in absence of underlying heart disease is called idiopathic VT and usually does not lead to SCD. The structural heart disease is either known before the SCD or is discovered after the event as postmortem analysis or in the clinical evaluation of the lucky few who are successfully resuscitated from SCA.

MECHANISMS OF VENTRICULAR ARRHYTHMIAS AND SUDDEN CARDIAC DEATH

Mechanisms of VA include: (1) enhanced normal automaticity or abnormal automaticity; (2) triggered activity induced by early or late afterdepolarizations; and (3) reentry. The initiation and progression of VA involves a complex interplay between substrate, triggers, and modifiers. The substrate may be structural changes secondary to an underlying disease process, and often includes a scar caused by prior myocardial infarction (MI) or surgical repair, or patchy fibrosis in the

setting of cardiomyopathy or hypertrophy. With advancement in imaging like cardiac magnetic resonance (CMR), underlying structural changes are being elucidated in more and more diseases. Changes in ion channels, transporter proteins and other cell membrane proteins, cell-to-cell connections and coupling protein may be the underlying substrate in patients with so called structurally normal heart as these cannot be picked up by any clinical imaging modality.

The electrophysiological substrate is dynamically influenced by a variety of factors including electrolytes, cardiac metabolism, mechanical stretch, signaling pathways, and autonomic effects. Cardiac innervation and autonomic inputs (parasympathetic and sympathetic) are increasingly being recognized as significant modifying (sometimes initiating) factors in VAs and SCD and various new therapeutic modalities affecting cardiac nervous system are being developed and tested to prevent and treat VA and decrease SCD.

Most sustained VAs in the presence of structural heart disease are caused by reentry as underlying mechanism.⁵ Reentry may occur around a fixed anatomical obstacle, such as scar after an MI or surgically repaired congenital heart disease. Reentry can also be functional reentry around areas of functional block without anatomical obstacles. There are two main proposed complex models of functional reentry to explain mechanism of VF.^{6,7} The “leading circle model” has a functionally refractory core and no excitable gap. “Spiral wave reentry” is driven by a rotor with a curved waveform and wavetail pivoting around an excitable but unexcited core. Phase 2 reentry can occur due to heterogeneity of repolarization between various areas of heart (e.g., between endocardium and epicardium). Phase 2 reentry may be one of the mechanisms of VT or VF in Brugada syndrome and during acute ischemia.⁷

Abnormal automaticity is one of the causes of VAs in acute ischemia and is caused by decreased transmembrane potential (due to increased extracellular potassium) nearing the activation potential of calcium channels.^{5,7} Enhanced normal automaticity in Purkinje cells in ischemic zone may

also trigger VA during acute coronary syndrome (ACS). Early afterdepolarizations (during late phase 2 or early phase 3 of action potential) are the trigger for torsades de pointes VT associated with QT prolongation (acquired or genetic channelopathies). Delayed afterdepolarizations occur after complete membrane repolarization, and develop under conditions of intracellular calcium overload caused by tachycardia, catecholamines, hypokalemia, digoxin toxicity, cardiac hypertrophy, and heart failure (HF).^{8,9} Increased sarcoplasmic calcium and ryanodine receptor over activity can lead to activation of calcium-sodium currents leading to triggered action potential. Delayed afterdepolarizations are the underlying mechanism for VT in the setting of digoxin toxicity, catecholaminergic polymorphic VT, and idiopathic outflow tract VA, VAs in HF and some Purkinje fiber mediated VAs.

EPIDEMIOLOGY

By far the most common underlying disease in patient dying because of VA is CAD. The incidence of CAD in patients with SCD is pegged to be about 80% in patients above 35 years of age in western world.¹⁰ The next most common cause of VA and SCD is cardiomyopathies [including dilated cardiomyopathy and hypertrophic cardiomyopathy (HCM)] accounting for 10–20% of SCD cases. Less than 5% of VA and SCD are caused by miscellaneous disorders like valvular heart disease, inflammatory and infiltrative heart disease. The infiltrative heart diseases like sarcoidosis are more and more being recognized as cause of VAs, but they still account for small numbers of SCD in general population. The genetic arrhythmia syndromes like channelopathies play a minor role numerically in general population above 35 years of age but are important cause of VAs and SCD. In younger age group of adolescents and young adults, myocarditis and congenital structural heart disease are responsible for majority of cases of VA and SCD. The age group 25–35 years is transition zone where CAD and cardiomyopathy increase as cause of SCD.¹⁰ More men than women have SCD, especially with advancing age, due to increasing prevalence of CAD.¹¹

It is a major exercise to determine in cause or mechanism of SCD, and the required tools like molecular autopsy and genetic analysis may not be readily available, especially in country like India. Even after autopsy and extensive post-mortem evaluation up to 50% SCD may remain unexplained.¹²

THERAPIES FOR VENTRICULAR ARRHYTHMIAS AND SUDDEN CARDIAC DEATH

Treatment of VAs (and prevention of SCD) begins with management of underlying diseases and comorbidities to prevent formation or progression of substrate, and to prevent triggers leading to VA and SCD. The therapies involve medications, nonpharmacological medical management, and use of devices especially defibrillators (in various forms), catheter ablation and surgery. A lot of progress has been made

in management of underlying disorders since the seminal trials of drugs and implantable cardioverter defibrillators (ICDs) were done and it is unlikely that any such new trials would be done. So we need to extrapolate the findings of these trials to the modern context.¹³ An important aspect of treatment is discontinuation of proarrhythmic medications like those causing prolonged QT.

Antiarrhythmic Drugs

Of all the available antiarrhythmic medications, only β -blockers have shown to improve survival in randomized trials in VAs. A few trials have shown benefits with amiodarone.^{14,15} All drugs have a significant potential for causing adverse events, including proarrhythmia. However, the use of these medications is essential in some patients to control arrhythmias and improve symptoms. Drugs can induce sinus bradycardia and atrioventricular (AV) block, impair His-Purkinje conduction and produce AV or bundle branch block, or prolong ventricular repolarization and the QT interval.

Beta-Blockers

Beta-blockers act by decreasing sympathetic activity by competitively blocking beta-adrenoceptors, decreasing sinus rate and by decreasing calcium release by ryanodine receptor channel.¹⁶ They are usually the first line of therapy in a large spectrum of disorders with or without HF.^{17,18} Beta-blockers reduce all-cause mortality and SCD in patients with HF with reduced ejection fraction (HFrEF).^{19–21} In the setting of polymorphic VT after MI, β -blockers reduce mortality.²² Beta-blockers (e.g., nadolol, propranolol) are also first-line therapy for some cardiac channelopathies [e.g., long QT syndrome (LQTS), catecholaminergic polymorphic VT].

Amiodarone

Amiodarone is multichannel blocker and blocks adrenergic receptors and sodium, potassium, and calcium channels. Effect of amiodarone on SCD is controversial. A few studies and a meta-analysis of several large studies have shown a reduction in SCD using amiodarone in patients with left ventricular (LV) dysfunction due to prior MI and nonischemic cardiomyopathy (NICM).^{23–25} The SCD in Heart Failure Trial (SCD-HeFT) did not show any survival benefit with amiodarone versus placebo in patients with left ventricular ejection fraction (LVEF) less than 35%.²⁶ In fact, a secondary analysis of the SCD-HeFT showed increased risk of mortality with amiodarone in patients with New York Heart Association (NYHA) class III symptoms.²⁷ A meta-analysis in high-risk patients (LVEF <40%, with or without coronary disease), concluded that, for primary prevention, amiodarone decreased the risk of SCD [risk ratio 0.76; 95% confidence interval (CI) 0.66–0.88] and all-cause mortality (risk ratio: 0.88; 95% CI 0.78–1.00). The same systematic review suggested no significant benefit or harm in secondary prevention.²⁸ Intravenous amiodarone is used to reduce recurrent VT or VF during resuscitation.²⁹ Long-term administration of amiodarone has adverse effects on multiple systems including thyroid, lungs, liver, eyes, skin, and nerves.

These adverse effects are dependent on dose and duration of use and require discontinuation in significant number of patients. Hence, chronic treatment of young patients with amiodarone should be reserved as a bridge to more definitive treatment options such as catheter ablation.³⁰

Sotalol

Sotalol is a blocker of delayed rectifier potassium channels with β -blocker properties. It has some efficacy in suppressing VA, but it has significant proarrhythmic effects and has not been shown to improve survival in a study of 146 patients with CAD and ICD.³¹ D-sotalol was shown in the SWORD (Survival with Oral D-Sotalol) trial to increase the risk of death in patients with HF.³² Sotalol may lead to HF decompensation, and so its use in patients with an LVEF less than 20% is generally avoided. Sotalol can be used safely in patients with CAD who do not have decompensated HF. The use of sotalol requires careful monitoring using electrocardiogram (ECG, QTc), especially in patients with a low body mass index or impaired renal function.

Sodium Channel Blockers

Class IA (e.g., quinidine, disopyramide) antiarrhythmic drugs that block the sodium current also block the rapid component of the delayed rectifier potassium current and may therefore prolong the QT interval. The CAST (Cardiac Arrhythmia Suppression Trial),³³ showed an increased mortality or nonfatal cardiac arrest rate (7.7%) among post-MI patients treated with encainide or flecainide. Hence, the use of class IC sodium channel blockers after MI has been contraindicated. The contraindication has been extended to other class I antiarrhythmic agents, because even if they do not increase mortality in post-MI patients they fail to reduce mortality.

Intravenous lidocaine can be used in cases of refractory VT or witnessed cardiac arrest²⁹ (most of the times along with amiodarone). Oral mexiletine is useful in congenital LQTS and quinidine is useful in Brugada syndrome patients.³⁴ Flecainide is used in catecholaminergic polymorphic VT patients not responding to β -blockers.³⁵

Ranolazine, developed as antianginal agent, is a late sodium channel current blocking agent and has small blocking action on phase 3 repolarizing potassium current (Ik_r). In small clinical studies, it has shown to decrease VTs, but not SCD.³⁶

Others

In patients with HF with reduced EF (HFrEF), many HF medications have shown to decrease SCD. Angiotensin-converting enzyme inhibitors reduce mortality and SCD³⁷ in HFrEF patients. Mineralocorticoid-receptor antagonists, spironolactone, and eplerenone also reduce SCD along with overall mortality in this group of patients.^{38,39} Recently published studies with the angiotensin receptor neprilysin inhibitor (sacubitril or valsartan) have shown a reduction in SCD along with cardiac mortality.⁴⁰

Intravenous magnesium is first-line therapy in torsades de pointes VT.⁴¹ It is recommended to keep the potassium

level between 4.5 mmol/L and 5 mmol/L to prevent VA,^{42,43} especially in high-risk conditions like acute myocardial infarction (AMI).

Combination Therapy

This should be reserved for patient with refractory VAs as it can be highly proarrhythmic. Combinations of sodium channel blockers and potassium channel blockers (e.g., amiodarone and flecainide/propafenone or mexiletine and sotalol) have been used in patients with frequent VT recurrences who have a defibrillator in place. Combination of β -blockers and amiodarone reduces the number of ICD shocks, however, side effects result in drug discontinuation in a significant number of patients.⁴⁴ Ranolazine has recently been tried in combined with other antiarrhythmic agents in cases of refractory VT, and has shown mixed results.⁴⁵

DEVICES FOR TREATMENT OF VENTRICULAR ARRHYTHMIAS AND SUDDEN CARDIAC DEATH

Defibrillation is highly effective in terminating life-threatening VA. There are various forms of defibrillators: transvenous ICD; a subcutaneous ICD; a wearable cardioverter-defibrillator (WCD); or an external defibrillator.

Implantable Cardioverter Defibrillator

Implantable defibrillators have now been in use for last 30 years. Many high-quality randomized controlled trials (RCTs) support its use in various patient populations including survivors of cardiac arrest, patients with VT and structural heart disease, and patients with significant LV dysfunction. ICD therapy has been shown to prevent SCD and prolong life in patients at high-risk of sudden arrhythmic death, and is recommended in high-risk patients if the patient does not suffer from other conditions that limit life expectancy to less than 1-2 years.⁴⁶ However, ICD use may be associated with complications like infection and inappropriate shocks, which are especially frequent in children.⁴⁷ A retrospective analyses of 3,000 patients with ICD or cardiac resynchronization therapy defibrillator (CRT-D) showed a significant incidence of adverse events over a 12-year period: 20% inappropriate shocks, 6% device-related infections, and 17% lead failures.⁴⁸ Hence, careful selection of patients for ICD is very important. In spite of compelling evidence in favor of ICD, its utilization lags significantly in many countries like India. The major limiting factor being the high cost of ICDs.

A meta-analysis of the three major secondary prophylaxis ICD trials [Antiarrhythmics Versus Implantable Defibrillators (AVID), Cardiac Arrest Study Hamburg (CASH) and Canadian Implantable defibrillator study (CIDS)] demonstrated that ICD therapy was associated with a 50% ($p = 0.0001$) reduction in mortality by arrhythmia and a 28% ($p = 0.006$) reduction in total mortality in patients who have survived a cardiac arrest or life-threatening VA (hemodynamically unstable VA or VT with syncope) compared to antiarrhythmic drugs (predominantly amiodarone).⁴⁹

Subcutaneous Cardioverter Defibrillator

The subcutaneous implantable cardioverter defibrillator does not require venous access and hence avoid complications of transvenous lead implantation including pneumothorax, hemothorax, and cardiac tamponade. Studies (mostly nonrandomized) have shown that the subcutaneous implantable cardioverter defibrillator can reliably detect and treat VF during defibrillation threshold testing at time of implantation and successfully terminate spontaneous clinical sustained VT and VF occurring during follow-up.⁵⁰ They are especially useful in patients who do not require anti-tachycardia pacing (or pacing in general) and patients with no venous access.

Wearable Cardioverter Defibrillator

The wearable cardioverter defibrillator is a vest to be worn under clothing, in contact with chest. The electrodes in this vest continuously monitor the heart rhythm and automatically deliver defibrillation shock when VF or VT is detected. The WCD has been approved in the United States by the US Food and Drug Administration for patients who are “at risk for SCA and are not candidates for or refuse an implantable defibrillator”, e.g., patients having an LVEF of 35% or less within 40 days from MI or revascularization within the past 90 days (hence not yet a candidate for ICD), patients awaiting cardiac transplant, or patients with newly diagnosed NICM, myocarditis or secondary cardiomyopathy. A recently presented trial (Vest Prevention of Early Sudden Death Trial—VEST)⁵¹ surprisingly showed that WCD does not reduce SCD (but reduces all-cause mortality) among patients with moderate-to-severe LV dysfunction immediately post-MI up to 90 days.

Automated Cardioverter Defibrillator

External defibrillation reduces mortality when delivered within minutes of onset of life-threatening VA including VF. The automated cardioverter defibrillator (AED) can be safely used by first responders including lay persons to deliver defibrillation to patients having out-of-hospital cardiac arrest.⁵² Efforts should be made to popularize placement and use of AEDs at public places like airports, railway and bus stations, schools, sports facilities, etc.

Catheter Ablation

Catheter ablation is an important treatment option for patients with VA when antiarrhythmic medications are ineffective, not tolerated, or not desired by the patient. Whether catheter ablation can replace ICD therapy in well-tolerated sustained monomorphic VT in patients with an LVEF less than 40% requires further evaluation. Till then, ICD implantation is recommended in survivors of MI and other disorders with structural and molecular heart diseases suffering from sustained VT or VF, even if they undergo successful catheter ablation.¹⁴ At present, there is no evidence that catheter ablation reduces mortality. It plays very useful role in decreasing ICD shocks, which have been shown to increase mortality.⁵³

PREVENTION, PREDICTION, AND TREATMENT OF VAS AND SCD IN SPECIFIC DISORDERS

Coronary Artery Disease

Ischemic heart disease (IHD) due to CAD, recognized or unrecognized, remains the overwhelmingly largest underlying cause of VA and SCD. When VF is the first identified rhythm in a patient of out-of-hospital cardiac arrest, AMI is discovered in about half the patients and significant coronary stenosis was found in more than 50% patient of out-of-hospital cardiac arrest when they were subjected to coronary angiography immediately after resuscitation.⁵⁴ The mechanism of VA differs in the acute and chronic phases of IHD. In chronic phase it is the macroreentry around the scar which leads to VT which can then degenerate into VF leading to SCD. The mechanisms of VAs in acute phase of IHD are less well understood, but include heterogeneity of depolarization and repolarization due to ischemic damage to cell membranes, and abnormal or enhanced automaticity in Purkinje fibers. VA in acute phase is usually polymorphic VT or VF.

A large number of SCD events occur in patients of ACS even before they reach hospital. Hence, to reduce incidence of SCD in general population it is important to screen for patients at high risk of SCD. The incidence of VA in ACS undergoing treatment in hospital has declined in recent years, mainly due to early and intense revascularization, including primary angioplasty and also due to availability and adequate use of specific pharmacological treatment. However, in spite of adequate modern management in ACS, up to 6% of patients develop VT or VF within the first 48 hours after the onset of symptoms, most often before or during reperfusion.¹³

Acute Coronary Syndrome

Beta-blockers reduce VT or VF in ACS and are therefore recommended to be used early in ACS in patients who are hemodynamically stable.⁵⁵ Intravenous amiodarone should be considered only if episodes of VT or VF are frequent and cannot be controlled by repeated electrical cardioversion or defibrillation.¹³ Intravenous lidocaine can be used in resistant cases of recurrent sustained VT or VF not responding to β-blockers and/or amiodarone. Some patients with recurrent VT or VF which is shown to be triggered by premature ventricular complex (PVC) arising from partially injured Purkinje fibers can be successfully treated by catheter ablation of initiating ventricular premature contraction.¹³

Immediate Post ACS

Sudden cardiac death is an important cause of death after AMI and is often due to recurrent infarction and not just because of VAs. Early ICD implantation after ACS has not been shown to improve prognosis, probably due to prevalence of nonrhythmic causes of death, like reinfarction and cardiac rupture. Hence, it is recommended that LVEF be reassessed 6–12 weeks after MI in stable patients on optimized HF medications to assess for a primary preventive ICD implantation.^{13,30}

Risk Stratification Post ACS

The LVEF is the most commonly used marker for the assessment of risk of SCD in IHD, and many studies have conclusively proved that ICDs reduce risk of SCD in patients with low LVEF. An LVEF of less than 30–35% is widely used as cut-off for ICD implantation. However, LVEF is not a very robust parameter to assess risk of SCD. When a LVEF of less than 35% is used as cut-off, 80% of cases of SCD will be missed. In the primary prevention population, only 5% of patients with ICDs for LVEF less than 35% will experience VT or VF per year.²⁶ In secondary prevention population, up to 50% of patients received ICD therapy in 1 year. SCD risk is highest in the immediate post-MI phase; however, the ICDs in Acute Myocardial Infarction Trial (DINAMIT) showed no mortality benefit with early placement of ICDs (at 6–40 days after MI).

In patients' history of MI and preserved LVEF, none of noninvasive risk stratification techniques were found to have sufficient specificity and sensitivity for clinical use. Many markers have been evaluated: microvolt T-wave alternans; QRS duration; signal-averaged ECG; ventricular ectopy; indicators of autonomic tone, such as heart rate variability, heart rate turbulence and baroreflex sensitivity.⁵⁶ However, in spite of initial promise, none of these were found to be superior to LVEF for SCD risk stratification and selection of patients for ICD implantation. QRS fragmentation seen in 12-lead ECG is due to conduction delays in different portions of heart. Some studies have shown usefulness of QRS fragmentation for prediction of VAs. However, assessment of this parameter is highly subjective and it can be seen as a normal variant. Hence, QRS fragmentation was never found to be sensitive or specific enough to predict SCD. More studies are needed to more accurately define relevant ECG morphologies to make it part of clinical decision making.^{57–61}

More recently, late gadolinium enhancement cardiac magnetic resonance (LGE-CMR) has gained acceptance as gold standard for assessing myocardial fibrosis. The extent of myocardial fibrosis, especially in peri-infarct zone, as assessed by LGE-CMR appears to correlate with risk of SCD. However, routine use of LGE-CMR is limited in many centers due to its high cost, lack of expert radiologists, duration of study, and the need for potentially toxic contrast.^{62–64}

Reduced right ventricular ejection fraction (RVEF) has also emerged as a useful parameter for assessing SCD risk: a strong correlation between RVEF less than 45% and SCD was documented in patients with LVEF greater than 35%.⁶⁵ Myocardial iodine-123 meta-iodobenzylguanidine imaging and (11)C-meta-hydroxyephedrine positron emission tomography (PET) have been used to demonstrate reduced sympathetic innervation of the heart and can predict an increased risk of SCD.^{66,67}

Nonischemic Cardiomyopathy

Patients with NICM should be on adequate guidelines based medical treatment for HF for at least 3 months before a primary prevention ICD is considered.³⁰ LVEF is still the

most robust measure for stratifying risk of SCD in NICM. Doubts have been raised about usefulness of ICD in primary prevention of SCD in NICM patients. A meta-analysis of the five primary prevention ICD trials (1,854 patients with nonischemic dilated cardiomyopathy) showed that in NICM, ICD reduce all-cause mortality by a significant 31% relative to medical therapy (risk ratio: 0.69; 95% CI 0.55–0.87, $p = 0.002$).⁶⁸ Recently published DANISH (the Danish Study to Assess the Efficiency of ICDs in Patients with Non-ischemic Systolic Heart Failure on Mortality) trial has stoked the controversy again.⁶⁹ DANISH trial showed that prophylactic ICD implantation in symptomatic NICM led to 50% reduction in SCD at 8 years compared with "usual clinical care". However, all-cause mortality was not significantly lowered. In DANISH study, CRT (either ICD or pacemaker) was used in 58% of patients in both the ICD and medical therapy arms. Therefore, the results of DANISH cannot be generalized to patients with NICM who are ineligible for CRT.³⁰

Syncope in patients of NICM has shown to be associated with high mortality and appropriate ICD shocks in non-randomized studies and hence ICD was recommended in such patients.^{70–72} However conflicting data has emerged, which challenges the assumption that syncope in NICM is due to malignant VAs. In a subgroup analysis of SCD-HeFT patients with NICM and syncope, ICD did not lead to decreased mortality.⁷³ Similarly, in a subgroup analysis of the MADIT-RIT (Multicenter Automatic Defibrillator Implantation Trial-Reduce Inappropriate Therapy) trial, syncope was found to be due to VAs in only 39% of patients.⁷⁴

A meta-analysis of 29 studies regarding the use of LGE-CMR for risk stratification in NICM, suggested that it could be a significant predictor of SCD risk.⁷⁵ The distribution of fibrosis in LGE-CMR is of incremental value, mid-wall fibrosis appears to be associated with increased risk of VAs and SCD.^{76,77}

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is considered to be the most common identifiable cause of SCD in individuals less than 40 years of age.⁷⁸ HCM patients who have survived SCA, VF, or sustained VT resulting in syncope or hemodynamic compromise are indicated to have ICD implantation.³⁰ Risk of SCD in HCM is estimated to be 1% per year. Decision regarding ICD implantation in patients apart from the above group of patients can be very difficult and requires substantial workup. ICD risk stratification needs to be performed every 1–3 years even when initial workup denotes low-risk. Box 1 gives the risk factors associated with SCD in HCM.³⁰

Late gadolinium enhancement CMR is fast emerging as an important and reliable marker for assessing SCD risk in HCM. However, studies of LGE-CMR in HCM have not been conclusive so far. One study found LGE to be an independent risk factor for SCD on univariate analysis, but the effect was lost on multivariate analysis.⁷⁹ T1 mapping in CMR appears to be promising in future evaluation of HCM, because it

BOX 1	Risk factors associated with increased sudden cardiac death in patients with hypertrophic cardiomyopathy
	Established risk factors:
	<ul style="list-style-type: none"> • Survival from a cardiac arrest due to VT or VF • Spontaneous sustained VT causing syncope or hemodynamic compromise • Family history of SCD associated with HCM • LV wall thickness ≥ 30 mm • Unexplained syncope within 6 months • NSVT ≥ 3 beats • Abnormal blood pressure response during exercise
	Potential risk modifiers:
	<ul style="list-style-type: none"> • Age <30 years • LGE on cardiac MRI • Severe LVOT obstruction • Syncope >5 years ago
	High-risk subsets:
	<ul style="list-style-type: none"> • LV apical aneurysm • LVEF $<50\%$

assesses general expansion of the extracellular space, and hence better in detecting diffuse myocardial fibrosis.⁸⁰

Syncope in HCM poses significant clinical dilemma. Syncope in HCM can be neurally mediated (vasovagal), medication related, due to LV outflow obstruction, as well as due to VA. Hence, cause of syncope should be carefully evaluated before considering it to be associated with increased SCD risk. In one study, syncope that was unexplained or thought not to be neurally mediated was associated with SCD risk only when it occurred within previous 6 months but not if most episodes occurred more than 5 years previously.⁸¹

Nonsustained ventricular tachycardia (NSVT) is not considered to be an independent risk factor for SCD in patients with HCM if present alone. However, the risk of SCD increases if risk modifiers are present along with NSVT, especially in patients less than 30 years of age.⁸² Electrophysiology study (EPS) and programmed ventricular stimulation is not recommended in patients with HCM as it has low predictive value.³⁰

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a genetically determined heritable disorder associated with replacement of right ventricular (and sometimes LV) myocardium by fibro-fatty tissue. ARVC is an important cause of SCD in young people and athletes. ARVC was found in 5–20% cases of undiagnosed SCD in patients of less than 35 years age.^{83,84} A recent observational study of 301 ARVC patients suggested that rate of life-threatening VAs is ranging

between 1.5 and 4.0 per 100 person-years; with the risk distributed from adolescence to later life and peaking at the ages of 21–40 years.⁸⁵

Competitive sports increase the risk for VT or SCD in patients with ARVC and hence they are advised to limit exercise intensity and duration to less than 650 metabolic equivalents hours (MET-Hr) per year, or 12.5 MET-Hr per week.³² Asymptomatic patients of ARVC (usually diagnosed by family screening) with no VA or ventricular dysfunction are generally observed without antiarrhythmic therapy other than β -blockers. Periodic reassessment is recommended in these patients to look for development of arrhythmias or ventricular dysfunction.³⁰ Atenolol was shown in one study to reduce VA in ARVC patients.⁸⁶

There is no clear value of electrophysiological study in asymptomatic ARVC patients (a small subgroup) with preserved ventricular function in predicting SCD risk and hence is not recommended.⁸⁷ In experienced centers, use of epicardial and endocardial mapping and ablation is associated with decrease in VA incidence in ARVC. However, successful VT ablation does not eliminate the need for an ICD in appropriate candidates. Box 2 enumerates the major and minor risk factors for SCD in ARVC.

Cardiac Channelopathies

Brugada Syndrome

Brugada syndrome is a genetically mediated heritable ion channel disorder resulting in an increased risk of SCD, despite an apparently structurally normal heart. It is characterized by coved ST elevation in leads V1 or V2 (positioned in the second, third, or fourth intercostal space) either spontaneously or induced by a sodium channel blocking drug, in the absence of other causes of ST elevation. Brugada syndrome is associated with syncope or SCA due to VF, seen predominantly in young males, although it can occur in all age groups. In Brugada syndrome-related SCD, short-coupled VPBs evolve into polymorphic VT and finally degenerate to VF.

Recently, imaging studies, specifically cardiac magnetic resonance imaging (MRI), have pointed toward potential anatomic substrate for arrhythmogenesis in Brugada syndrome.

Right ventricular outflow tract (RVOT) and upper RV anterior wall have been shown to be involved in the generation of VF and sudden death in Brugada syndrome, and studies have detected structural abnormalities like epicardial fibrosis in these regions.⁸⁸⁻⁹² Ablation of abnormal areas of late activation in the epicardial RVOT has been shown to suppress or eliminate VAs in small group of patients.⁹² In these studies, the spontaneous type 1 Brugada pattern on ECG was eliminated in more than 75% of patients and recurrences of VT or VF were significantly reduced.^{88,92-94}

After initial presentation, the SCD risk in Brugada syndrome is approximately 10% in first 4 years. Risk of arrhythmia is much lower in asymptomatic Brugada syndrome "patients", about 0.5% per year.^{95,96} The only treatment which can reduce the risk of SCD in Brugada syndrome is the ICD implantation, therefore, the device is recommended in patients with documented VT or VF and in patients presenting with a spontaneous type 1 ECG and a history of syncope.¹³ Inducibility of VT or VF on EPS has been debated to be of any value as a risk marker and most clinical studies have been inconclusive.¹³ Certain ECG changes like QRS fragmentation and presence of a wide or large S-wave in lead I in spontaneous type I pattern patients (suggestive of RVOT conduction delay), appear to be associated with increased SCD risk.^{97,98} Family history of SCD is not considered to increase risk of SCD in index patient.

Quinidine can suppress VF storm and suppress arrhythmia in Brugada patients. Some anesthetic agents, certain psychotropic medicines, cocaine, excessive alcohol intake, heavy meals, and fever (www.brugadadrugs.org) have been shown to trigger VF and SCA in Brugada syndrome. These agents and conditions should be avoided and fever should be aggressively treated to reduce temperature.³⁰ SCD in Brugada syndrome mostly occurs at rest or during sleep.

Long QT Syndrome

Long QT syndrome is characterized by a prolonged QT interval at some or all the times in patient (Table 1)⁹⁹ and is associated with VAs, usually triggered by increased sympathetic stimulation. LQTS presents at a young age with mean age of presentation being 14 years. Rate of SCD in untreated LQTS is estimated to be between 0.33 and 0.9% per annum, whereas rate for syncope is estimated to be about 5% per annum.^{100,101} Assessment of SCD risk in an individual of LQTS requires evaluation of genetic parameters along with clinical and ECG features. Cardiac arrest survivors have a high risk of recurrence of malignant VAs, even when receiving β -blockers (14% within 5 years on therapy) and hence, ICD is indicated in all survivors of cardiac arrest with LQTS.¹³ Left cardiac sympathetic denervation has been shown to reduce number of appropriate ICD shocks and VA burden in LQTS. In LQTS type 3, ranolazine, mexiletine, and flecainide can be used as they have been shown to shorten the QTc and can reduce recurrent arrhythmias.¹⁰²⁻¹⁰⁴

Implantable cardioverter defibrillator for primary prophylaxis may be considered in certain high-risk patients

TABLE 1: Scoring system for diagnosis of LQTS

Criteria		Points
ECG		
QTc (Bazett's formula)	≥ 480 ms	3
	460–479 ms	2
	450–459 ms (males)	1
	≥ 480 ms during 4 th minute of recovery from exercise stress test	1
Torsade de pointes (mutually exclusive of syncope)		2
T-wave alternans		1
Notched T wave in 3 leads		1
Low heart rate for age (<2 nd percentile for age at rest)		0.5
Clinical History		
Syncope (mutually exclusive of Torsades)	With stress	2
	Without stress	1
Family History (one family member to be counted once)		
Family member(s) with definite LQTS		1
Unexplained SCD at age <30 years in immediate family		0.5
<i>Scoring:</i>		
≤ 1.0 point = low probability of LQTS		
1.5–3.0 points = intermediate probability of LQTS		
≥ 3.5 points = high probability of LQTS		

ECG, electrocardiogram; LQTS, long QT syndrome; SCD: sudden cardiac death.

such as women with LQTS type 2 and QTc more than 500 ms, patients with QTc more than 500 ms and signs of electrical instability and in patients with high-risk genetic profiles (carriers of two mutations, including Jervell and Lange-Nielsen syndrome or Timothy syndrome). Invasive EPS in patients with LQTS for risk stratification is of no use.

Beta-blockers consistently reduce adverse cardiac events in patients of LQTS type 1 (>95%), type 2 (>75%), and females with LQTS type 3 by more than 60%. However, efficacy of β -blockers in males with LQTS type 3 is not very well proven.³⁰ There is some difference in efficacy of individual β -blockers and propranolol, atenolol, and nadolol have been found to be more effective than metoprolol.¹⁰⁵

Medications which prolong QT (www.crediblemeds.org) should not be used in patients with LQTS unless there is no suitable alternative. Normal potassium and magnesium balance should be maintained in all LQTS patients to prevent VAs.

Electrocardiography Clues in a Sudden Cardiac Death Survivor

Ranjan Modi, Aparna Jaswal

INTRODUCTION

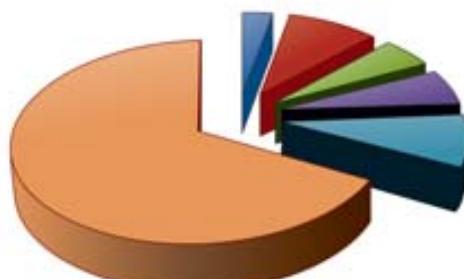

There have been numerous papers published on electrocardiography (ECG) and cardiac diseases. The literature has established the profound correlation between ECG and sudden cardiac death (SCD) with most SCD attributed to cardiac diseases. Studies on SCD survivors indicate that 5–10% of cases occur in the absence of any apparent cardiac disease.¹ Primary electrical disorders resulting from channelopathies are believed to play a role in such patients. ECG provides important clues to the differential diagnosis of these entities. The ECG clues in these conditions may be broadly classified in table 1.

In a study in Korea for distribution of underlying cardiac diseases in SCD survivors, ECG abnormalities in structural heart disease and nonstructural heart disease were identified and respective underlying diseases prevalence noted (Fig. 1).

FIG. 1: Prevalence of underlying cardiac diseases in sudden cardiac death.

Recently various clinical entities such as Brugada syndrome (BS), long QT syndrome (LQTS), short QT syndrome (SQTS), arrhythmogenic right ventricular dysplasia (ARVD) and early repolarization syndrome (ERS) have gained importance in SCD survivors.

STRUCTURAL HEART DISEASE

Hypertrophic Cardiomyopathy

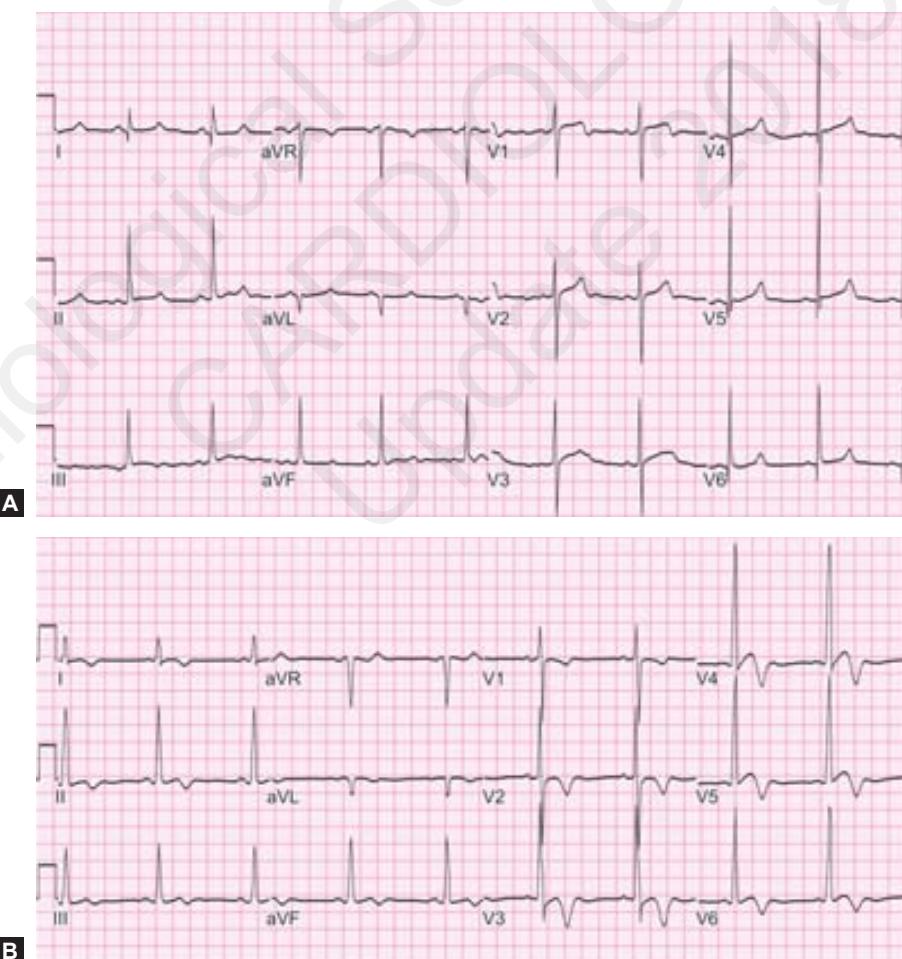

- Hypertrophic cardiomyopathy (HCM) is one of the most common inherited cardiac disorders; it affects almost 1 in 500 people and is the number one cause of SCD in young athletes.
- The mortality in HCM is estimated at 1–2% annually.
- It is produced by mutations in multiple genes coding for sarcomeric proteins (e.g., beta-myosin heavy chain, troponin T)
- It is an autosomal dominant disease.
- The chief abnormality is left ventricular hypertrophy (LVH), occurring in the absence of any stimulus such as hypertension or aortic stenosis
- The most common pattern is asymmetrical thickening of the anterior interventricular septum. It is associated with

systolic anterior motion (SAM) of the mitral valve and dynamic left ventricular outflow tract (LVOT) obstruction. In the majority of cases almost 75%, HCM is not associated with LVOT obstruction

- Other patterns of LVH include concentric hypertrophy (20% of cases) and apical hypertrophy (10%), which are less common.

Electrocardiographic Features of Hypertrophic Cardiomyopathy

- Left atrial enlargement
- Left ventricular hypertrophy with associated ST/T abnormalities
- Deep, narrow (“dagger-like”) Q waves in the lateral more than the inferior leads
- Giant precordial T-wave inversions which are mainly seen in apical HCM
- Short PR and delta wave which are signs suggestive of Wolff-Parkinson-White syndrome
- It is estimated that 5–10% of patient with HCM have ventricular pre-excitation²
- *Dysrhythmias:* Atrial fibrillation, supraventricular tachycardia (Fig. 2).

aVF, augmented vector foot; aVL, augmented vector left; aVR, augmented vector right.

FIG. 2: Electrocardiography features of hypertrophic cardiomyopathy.

Classic HCM pattern with asymmetrical septal hypertrophy (Fig. 2A):

- Voltage criteria for LVH.
- Deep narrow Q waves less than or equal to 40 ms wide in the lateral leads I, augmented vector left, and V5-6.

Figure 2B ECG shows the typical pattern of apical HCM:

- Large precordial voltages
- Giant T wave inversions in the precordial leads
- Inverted T waves are also seen in the inferior and lateral leads.

Arrhythmogenic Right Ventricular Dysplasia

- It is an autosomal dominant inherited myocardial disease
- It is characterized by fibro-fatty replacement of the right ventricular myocardium on pathology
- It is second most common cause of SCD in the young (after HCM)
- It is reported to cause 20% of SCDs in patients less than 35 years of age
- More common in men than women (3:1)
- It approximately affects 1 in 5,000.

Electrocardiographic Features

Arrhythmogenic right ventricular dysplasia is associated with characteristic ECG abnormalities:

- Epsilon wave (most specific finding, seen in 30% of patients)
- T-wave inversions in V₁-V₃ seen in 85% of patients.
- Prolonged S-wave upstroke of 55 ms in V₁-V₃ (95% of patients)
- Localized QRS widening of 110 ms in V₁-V₃
- Paroxysmal episodes of ventricular tachycardia with left bundle branch block (LBBB) morphology (Fig. 3).

ISCHEMIC HEART DISEASE

Ischemic heart disease (IHD) accounts for majority of cases of SCD. Presence of q waves in the ECG suggest old evolved

myocardial infarction, such patients may have scarred myocardium resulting in scar ventricular tachycardia (VT)/ventricular fibrillation (VF). These patients may also have severe left ventricular dysfunction which may lead to predisposition of VT/VF and may result in SCD. Many articles and numerous literatures' have discussed the diagnosis, management, and complications of IHD (Fig. 4).³

NONSTRUCTURAL HEART DISEASE: INHERITED

Brugada Syndrome

Brugada syndrome is an autosomal dominant inherited arrhythmic disorder characterized by ST elevation with successive negative T wave in the right precordial leads without structural cardiac abnormalities.⁴⁻⁶ Patients are at risk for VF which may lead to SCD. The ECG pattern similar to coved-type ST-segment elevation was reported as a normal variant in the healthy population or related to VF with structural abnormality,^{7,8} but as a distinct entity, Brugada and Brugada⁵ were the first to report eight patients with VF, right bundle branch block (BBB), and ST-segment elevation on 12-lead ECG.⁹ Later, structural changes were reported.¹⁰⁻¹²

Genetic Background

The first causal mutations were found in SCNSA in 1998, which encodes for the α -subunit of the sodium channel.¹³ Ever since, more than 100 SCNSA mutations have been reported in BS and currently represent the most common genotype, which is inherited as an autosomal-dominant trait with incomplete penetrance. The other mutations reported are missense mutation, nonsense mutation, nucleotide insertion/deletion, and splice site mutation.¹⁴

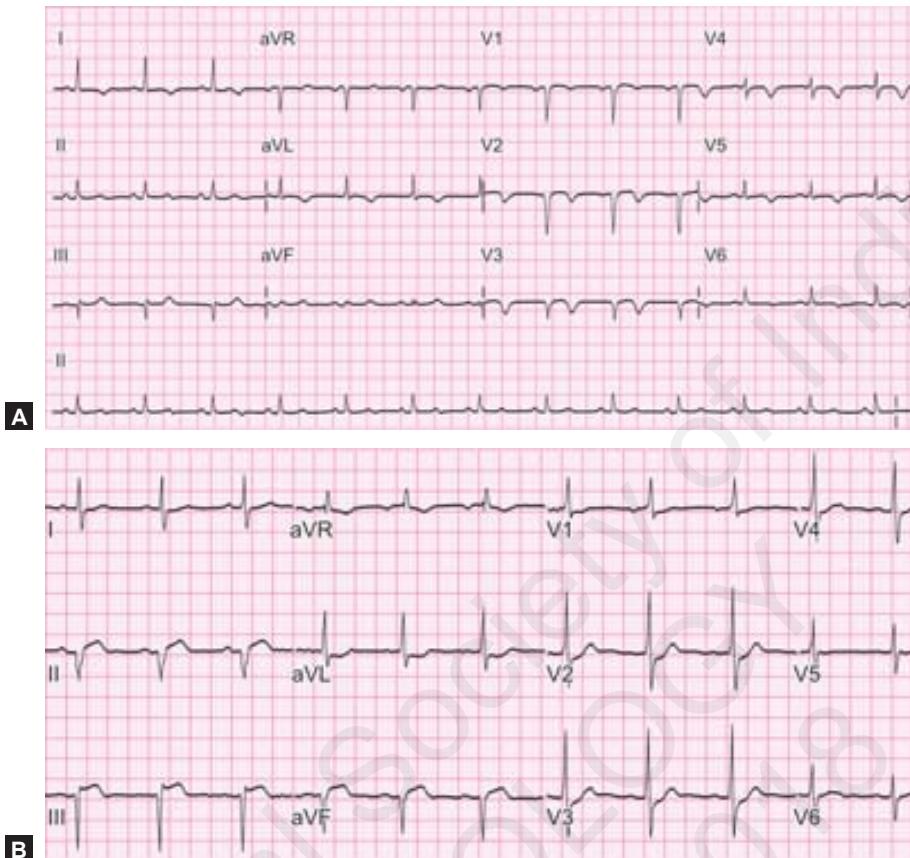

The SCNSA mutations not only may cause BS, but also may lead to other diseases. SCNSA mutations can also be seen in LQTS type 3, progressive cardiac conduction disease, sick sinus syndrome, or combinations of these,¹⁵⁻¹⁷ congenital atrial standstill; or dilated cardiomyopathy (Fig. 5).¹⁸⁻²¹

Brugada syndrome is more common in males and has a variable penetrance.^{22,23} Symptoms include syncope and seizures. ECG remains the cornerstone of diagnosis of BS.²⁴

aVF, augmented vector foot; aVL, augmented vector left; aVR, augmented vector right.

FIG. 4: Electrocardiography of ischemic heart disease.

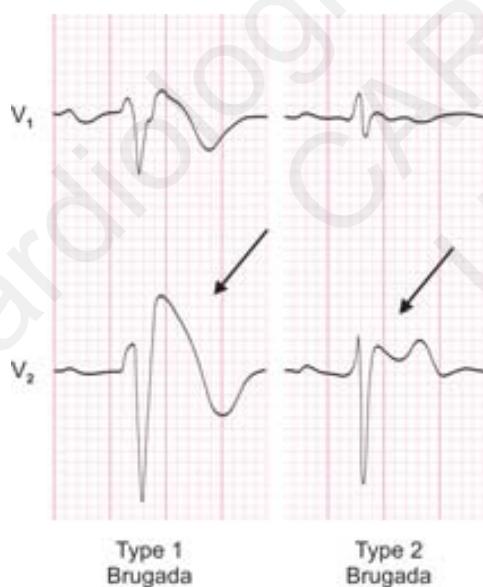

FIG. 5: Electrocardiography of Brugada syndrome.

Provocation of Brugada ECG feature by sodium-channel blocker is a specific marker for BS and the J-point is augmented by sodium-channel blockers in the right precordial leads in patients with a Brugada ECG.

A pitfall in the ECG diagnosis of BS is the so-called “masked” BS. In patients with BBB, the BS-type ST changes may be buried within the wide QRS complex, being unmasked only when the BBB is relieved. Therefore, in patients with cardiac arrest and right BBB, the possibility of masked BS should be considered in the differential diagnosis.²⁴⁻²⁷

The consensus for the management of BS is mentioned in figure 6.

Early Repolarization Syndrome

Early repolarization (ER), also recognized as “J-waves” or “f-point elevation”, is an electrocardiographic abnormality consistent with elevation of the junction at the end of the QRS complex and the beginning of the ST segment in two contiguous leads.^{28,29} Grant et al.³⁰ are considered to be the first who used the term ER to describe ST-segment deviations and related T-wave inversion. It was assumed that premature repolarization was the underlying etiology. The so-called “ERS” was regarded as “normal”, a “normal variant”, or a “benign ER” until 2000.³¹ However, numerous reports have suggested a relationship between ER and an increased risk of death from cardiac arrhythmias.^{32,33} ERS is an ECG finding which is characterized by J-point elevation manifested as either QRS slurring or notching, ST-segment elevation with upper concavity and prominent T waves in at least two contiguous leads (Fig. 7).³⁴

SECTION 16

Ventricular Arrhythmias

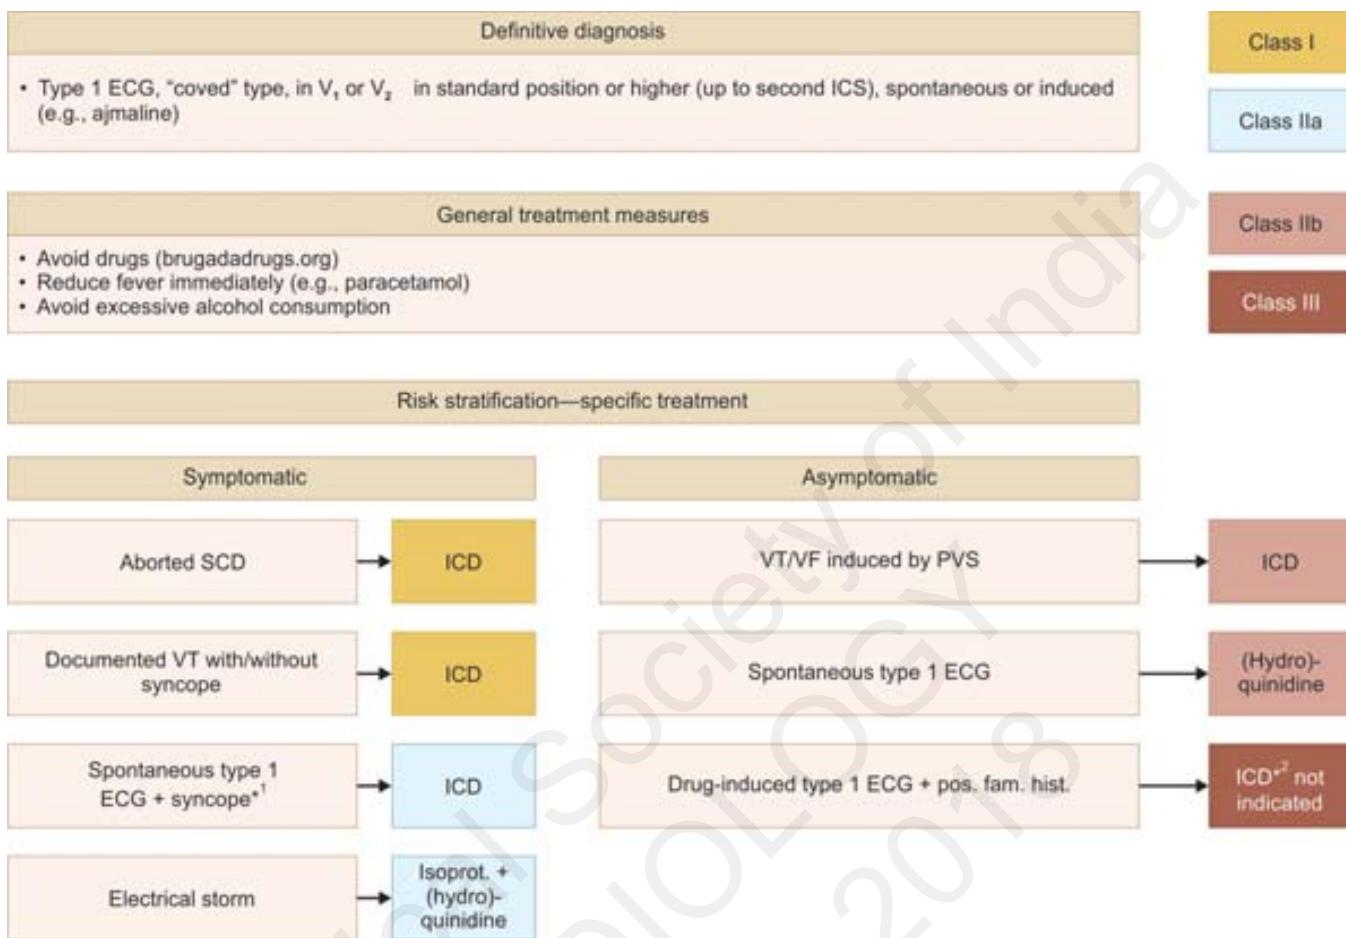

FIG. 6: The Heart Rhythm Society/European Heart Rhythm Association/Asia Pacific Heart Rhythm Society (HRS/EHRA/APHRS) Expert consensus statement on the diagnosis and management of patients with inherited primary arrhythmia syndromes of Brugada syndrome.

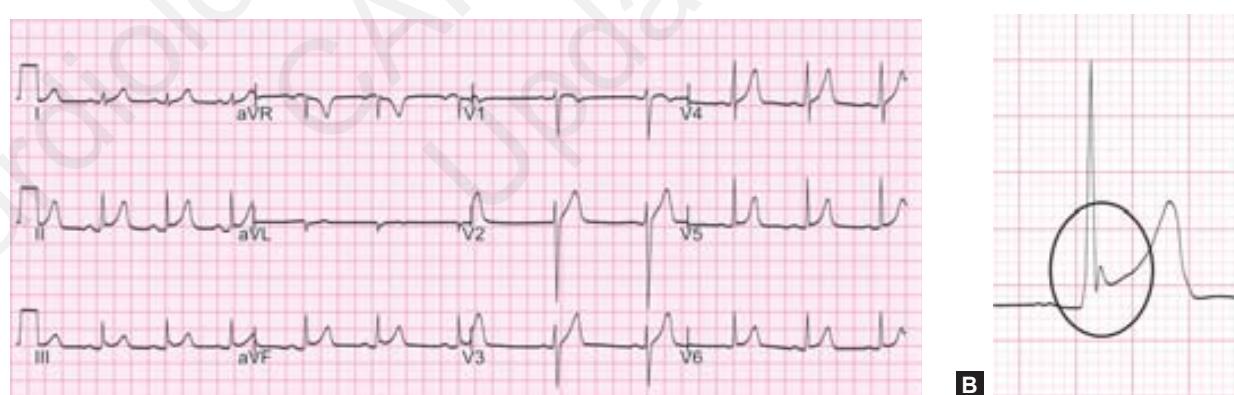

FIG. 7: Electrocardiography of early repolarization syndrome.

The ERS is usually seen in athletes, cocaine users, hypertrophic obstructive cardiomyopathy and defects, and/or hypertrophy of interventricular septal defects.^{35,36} ERS have a prevalence of 3–24% in the general population. Young individuals, males, African Americans, and athletes are known to have a higher prevalence of ERS.^{34–37}

The pathophysiologic basis of the ER, the most common hypothesis, says that this may be related to either an increased susceptibility or vulnerability to cardiac arrest in critical ischemic conditions such as acute coronary syndromes, or to subtle changes in the cardiac action potential (AP).^{38,39} ER occurs in early phase of the cardiac AP. It is caused by the

TABLE 2: The Heart Rhythm Society/European Heart Rhythm Association/Asia Pacific Heart Rhythm Society (HRS/EHRA/APHRS) consensus statement on the diagnosis and management of primary inherited arrhythmia syndromes recommendation for therapeutic intervention in early repolarization syndrome⁴⁴: Expert consensus recommendations on early repolarization therapeutic interventions

Class I	1	ICD implementation is recommended in patients with a diagnosis of ER syndrome who have survived a cardiac arrest
Class IIa	2	Isoproterenol infusion can be useful in suppressing electrical storms in patients with a diagnosis of ER syndrome
	3	Quinidine in addition to an ICD can be useful for secondary prevention of VF in patients with a diagnosis of ER syndrome.
Class IIb	4	ICD implantation may be considered in symptomatic family members of ER syndrome patients with a history of syncope in the presence of ST-segment elevation >1 mm in 2 or more inferior or lateral leads
	5	ICD implantation may be considered in asymptomatic individuals who demonstrate a high-risk ER ECG pattern (high J-wave amplitude, horizontal/descending ST-segment) in the presence of a strong family history of juvenile unexplained sudden death with or without a pathogenic mutation
Class III	6	ICD implantation is not recommended in asymptomatic patients with an isolated BR BCG pattern

ER, early repolarization; ICD, implantable cardioverter defibrillator; VF, ventricular fibrillation.

cardiac transient outward potassium current (I_{to}). In some situations the density of the I channels in endocardium is reduced compared to myocardium and epicardium.⁴⁰ At such situations a large I_{to} current can occur that results in ECG ER and large voltage gradients that may generate J-wave elevation (Fig. 6). These have the propensity to initiate life-threatening arrhythmias.^{39,40} Another hypothesis regarding the mechanism causing ER suggests an association of localized depolarization abnormalities with repolarization anomalies, as it happens in type1 BS.⁴¹

The gene mutations involved in the syndrome include the *KCNJ8* gene (responsible for the ATP sensitive potassium channel $K_{ir}6.1$ -IKATP current), *CACNAIC*, *CACNB2*, *CACNA2D1* genes (responsible for the cardiac L-type calcium channel- I_{CaL} current), and the *SCNSA* gene (responsible for the sodium channel- I_{Na} current).⁴² All these genes increase the imbalance between the underlying inward-outward currents and are responsible for accelerated epicardial repolarization.⁴³

Electrocardiography Diagnosis

The ECG hallmark of ERS is elevation (>1 mm above baseline) of the QRS-ST junction manifested as either QRS slurring or notching, ST-segment elevation with upper concavity, and prominent T-waves in two or more contiguous inferior and/or lateral leads in a patient resuscitated from otherwise unexplained ventricular arrhythmia.³⁴ Recent studies have omitted ST-segment elevation from the definition of ERS, and say that the J point changes are sufficient to diagnose ERS. Although, the inclusion or exclusion of right precordial leads is also an area for debate.

Antzelevitch et al.⁴¹ described three subtypes of ERS, and highlighted the risk profile.

Type 1: It shows ER in the lateral precordial leads that is seen in healthy male athletes and has the lowest risk of malignant arrhythmias.

Type 2: It shows ER in the inferior and inferolateral leads and is associated with a greater risk of malignant arrhythmias.

Type 3: It shows ER pattern in all ECG leads and has the highest risk of malignant arrhythmias and electrical storms.

The Heart Rhythm Society/European Heart Rhythm Association/Asia Pacific Heart Rhythm Society (HRS/EHRA/APHRS) consensus statement on the diagnosis and management of primary inherited arrhythmia syndromes recommended criteria for the diagnosis of ER is shown in table 2.⁴⁴

Tikkanen et al. again identified a subgroup of patients with ER who show a benign long-term prognosis.⁴⁵ If the ST segment after the J wave is ascending, the long-term mortality is not significantly different from the general population, whereas subjects with a J wave and horizontal or descending ST segment changes are at higher risk of arrhythmic death.⁴⁵⁻⁴⁷

Long QT Syndrome

The congenital LQTS is a cardiac arrhythmia syndrome that represents one of the most leading causes of sudden death in the young. LQTS is typically characterized by a prolongation of the QT interval on the ECG and by the occurrence of syncope or cardiac arrest, mainly precipitated by emotional or physical stress.

Since ages,⁴⁶ hereditary variants, the Romano-Ward (RW) syndrome^{47,48} and the extremely severe Jervell and Lange-Nielsen (JLN) syndrome,^{49,50} which are associated with congenital deafness, have been included under the comprehensive name of LQTS. The usual mode of inheritance for RW is autosomal dominant, whereas JLN shows autosomal recessive inheritance.

Several reasons make LQTS an important disease. Symptomatic patients left without therapy are known to have a high mortality rate, 21% within 1 year from the first syncope.⁵¹ However, with proper treatment, mortality is now almost 1% during a 15-year follow-up.⁵²

Genetics of Long QT Syndrome

The QT interval represents the depolarization and repolarization phases of the cardiac AP. The combined interaction of these several ion channels determine the AP duration. A decrease in repolarizing outward K^+ current or increase in depolarizing inward sodium or calcium current can

lead to prolongation of the QT interval, thus representing a pathophysiological substrate for LQTS.

The *KCNQ1* (LQT1), *KCNH2* (LQT2), and *SCNSA* (LQT3) are mostly 90% of the times the common genes accounted for in LQTS.^{53,54}

Electrocardiography Presentation

The ventricular tachyarrhythmia that potentiates the cardiac events of LQTS is torsades de pointes (TdP), a type of ventricular tachycardia that may be self-limiting, produces transient syncope but can also lead into VF causing cardiac arrest or sudden death.⁵⁵

Short QT Syndrome

Introduction

Short QT (SQT) refers to the ECG manifestation of accelerated cardiac repolarization. Its association with atrial and VF was suggested by Gussak et al.⁵⁶ Various articles have confirmed the familial nature and arrhythmogenic potential of SQT.⁵⁷ The most common cause is the acquired disease which results from electrolyte disturbances or drugs, in addition to hypercalcemia, hyperkalemia, and acidosis; SQT also manifests with drugs like digoxin, androgen use, increased vagal tone, and after VF.⁵⁸⁻⁶⁰ SQTS is autosomal dominant and can manifest with atrial and ventricular arrhythmias leading to SCD.⁶¹ Cardiac arrest can be the presenting symptom in up to 40% of the cases.⁶²

Molecular Basis and Genetics

The manifestation can be attributed to mutations in potassium (*KCNH2*, *KCNQ1*, *KCNJ2*) and calcium (*CACNA1C*, *CACNB2*, *CACNA2D1*) channels (Table 3). Calcium-channel mutations also lead to a correlation with diseases, such as BS or ERS. Recently carnitine deficiency has also been linked to ECG manifestations of SQT.^{63,64}

Gain of function mutations in the potassium channels have been shown to hasten earlier repolarizing currents, this decreases the AP causing lower threshold for arrhythmias. Calcium channel mutations cause loss of function in the slow inward calcium channel or L-type channel.^{65,66} Mouse models of carnitine deficiency showed response to carnitine supplementation with reduction in ventricular arrhythmias, linking indirect effect of long-chain fatty acid on the regulation of the potassium channels.

Diagnosis

According to the HRS/EHRA/APHRS expert consensus statement on the diagnosis and management of patients with inherited primary arrhythmia syndromes, SQTS is diagnosed in the presence of a QTc less than or equal to 330 ms. It can also be diagnosed in combination with the presence of a QTc less than 360 ms and one of the following: a pathogenic mutation, family history of SQTS, family history of sudden death at age less than or equal to 40, or survival of a VT/VF episode in the absence of heart disease (Fig. 8).⁶⁷

TABLE 3: Diagnostic criteria of long QT syndrome⁵⁵

Electrocardiographic findings*		Points
A	QTc.	
	≥480 ms	3
	460–479	2
	450–459 (men)	1
B	QTc. t 4 th minute of recovery from exercise stress test ≥480 ms	1
C	Torsades de pointes	2
D	T-wave alternans	1
	Notched T wave in 3 leads	1
	Low heart rate for age	0.5

	With stress	2
	Without stress	1
B	Congenital deafness	0.5
Family history		
A	Family members with definite LQT	1
B	Unexplained sudden cardiac death younger than age 30 among immediate family members	0.5

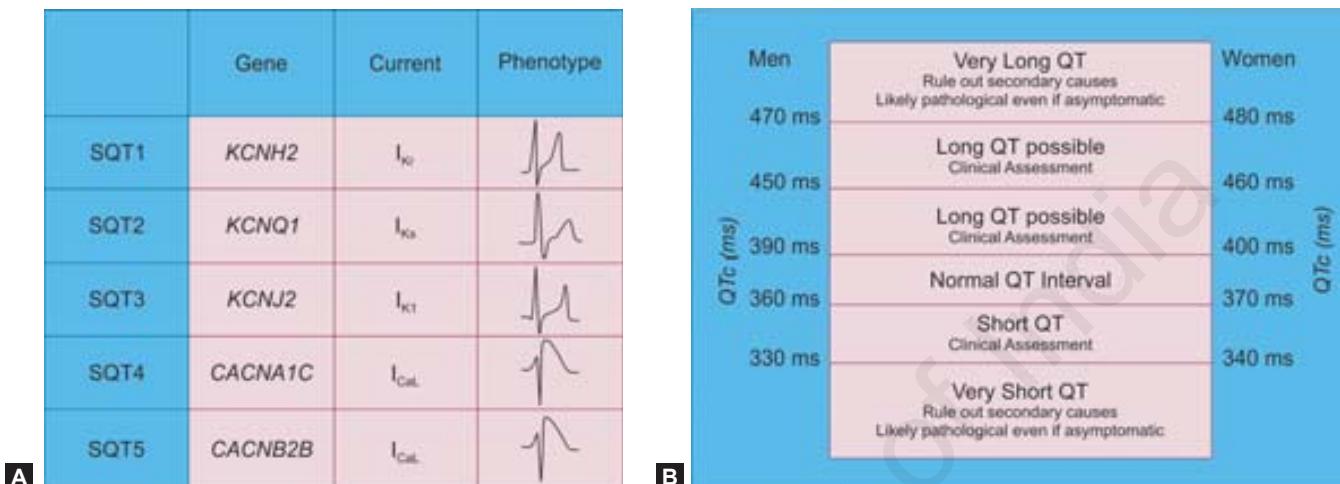

In 2011, A diagnostic criteria was proposed for the assessment of patients with suspected SQTS⁶⁸ (Table 4). The criteria included ECG findings as well a family history, clinical history, and genotyping.⁶⁹ An overall score of 4 or more was considered to indicate a high probability diagnosis of SQTS.

The QTc generally is fixed and short in relation to changing heart rate (HR) of patients with SQTS.⁶⁹ This failure of adaptation to a faster HR has allowed more specific identification of subjects with QTc intervals between 340 ms and 360 ms, and a QT/HR slope under -0.9 ms/beat/min.^{70,71}

Another ECG finding noted in SQTS is the high prevalence of early repolarization patterns (ERP). A study depicted that the presence of ERP in patients with SQTS is associated with higher arrhythmic events. The study looked at the uncorrected J point-T peak interval (JT_p) and found that patients with symptomatic SQTS had shorter uncorrected JT_p (<150 ms), shorter uncorrected J point-T end interval (JT_e; <230 ms), and a high rate-corrected Tpeak-Tend c/QTc ratio.

J Wave Syndromes

Brugada syndrome and ERS share many ECG and clinical features, and have been collectively grouped as J wave syndrome (JWS). The concept has now expanded to include other structural heart diseases such as acute myocardial infarction, variant angina, and even some forms of cardiomyopathy.^{3,4} This emphasizes the possibility that J waves may be even more important than previously recognized and may serve as a common mechanism of VF in various clinical settings (Box 1).

J Wave-related Syndrome in Patients with Structural Heart Disease or Other Conditions

The J wave phenomenon can be observed both in structurally normal hearts and in patients with structural heart diseases. The pathogenic role of the epicardial notch and phase 2 re-entry in the early stages of acute myocardial ischemia was demonstrated by Yan et al.⁷² who showed that acute regional myocardial ischemia results in heterogeneous loss of the epicardial AP dome across the ischemic border zone, leading to phase 2 re-entry and R-on-T extra-systoles inducing VFs. Although direct evidence is lacking, as the J wave is an

BOX 1 Conditions with J waves

Conditions with predominant J waves

- Hypothermia
- Hypercalcemia
- Hyperkalemia
- Vasospastic angina
- Brugada syndrome
- Early repolarization syndrome
- Short QT syndrome
- Hypoxia
- Acidosis
- Pulmonary embolism
- Arrhythmogenic right ventricular cardiomyopathy
- Subarachnoid hemorrhage

electrocardiographic marker of vulnerability to phase 2 re-entry, its presence in the setting of acute myocardial ischemia is presumed to cause a higher likelihood of VF and SCD (Table 5).

Electrophysiological mechanism and the concept of the “Dome Reserve”

The J wave is known to arise and originate from the heterogeneous distribution of a transient outward current-mediated spike and, dome morphology of the AP across the ventricular wall. The presence of a prominent AP notch in the epicardium, but not the endocardium, provides a voltage gradient that manifests as J (Osborn) wave or elevated J point in the ECG.^{73,74} The unique features of the AP shape in the epicardium have rendered epicardial repolarization more susceptible to changes in response to drive cycle lengths, extra stimulation, drugs or ischemia.^{75,76} The heterogeneous loss of the AP dome by ischemia, the sodium channel blocker, flecainide, or acetylcholine results in the development of marked prolongation of AP duration. This is followed by local re-excitation (phase 2 re-entry) due to AP propagating from sites where it was maintained to ones where it was abolished. Thus, the ECG J wave, a clinical marker of the AP notch, represents the vulnerability of the epicardial AP to an all-or-none repolarization, and susceptibility to fatal ventricular tachyarrhythmias. It is presumed that individuals with prominent J waves are thought to have the potential to lose their AP dome by extrinsic factors such as vagal stimulation, sodium channel blocker or ischemia. This ability of the ventricular myocardium to preserve this AP dome may be called “dome reserve”, and the lack of this reserve may simply be expressed by the electrocardiographic J waves. A study proposed the concept of a “repolarization reserve” in which normal hearts have multiple repolarization currents during the physiologic repolarization process.^{77,78} Defects in one of these multiple mechanisms may not produce the full-blown electrocardiographic features of LQTS. When multiple subclinical lesions are already present in the repolarization process that superimposition of an I_{Kr} -blocking drug can produce marked AP prolongation, resulting in TdP.

NONSTRUCTURAL HEART DISEASE: NONINHERITED

Acquired Long QT Syndrome

Acquired LQTS is defined as a disorder of cardiac repolarization mostly due to specific drugs, hypokalemia, or hypomagnesemia that may precipitate TdP and cause SCD. Selzer and Wray first reported QT prolongation and VF as a response to a drug which was quinidine in 1964 (Box 2).⁷⁹

The QT interval on the surface electrocardiogram represents the summation of AP. QT prolongation entails AP prolongation, which results from an increase in inward current (through sodium or calcium channels) or a decrease in outward current (through potassium channels). Myocardial repolarization is primarily mediated by efflux of potassium ions. The two subtypes of the delayed rectifier I_{to} , I_{Kr} (rapid) and I_{Ks} (slow), are predominantly responsible for repolarization. These two currents have different activation, inactivation, and deactivation characteristics, different sensitivities to blocking drugs,⁸⁰⁻⁸² different rate, and

BOX 2 Risk factors for drug-induced torsade de pointes

- Female sex
- Hypokalemia
- Bradycardia
- Recent conversion from atrial fibrillation
- Congestive heart failure
- Left ventricular hypertrophy
- High drug concentration
- Infusion with a QT prolonging drug
- Base line QT prolongation
- Subclinical long QT syndrome
- Ion channel polymorphism
- Severe hypomagnesemia

Miscellaneous medications	Methadone

catecholamine sensitivity^{83,84} and are also result of expression of different genes.^{85,86}

The hallmark mechanism of acquired LQTS and TdP is the blockade of I_{Kr} by specific drugs.⁸⁷ I_{Kr} current proteins are encoded by the *HERG* gene (now termed *KCNH2*) (Table 6).⁸⁸

The I_{Kr} blockade results in a delay in phase 3 rapid repolarization of the AP, which is reflected by QT prolongation. Prolonged repolarization can cause early after depolarization (EADs) due to activation of inward depolarizing currents (L-type calcium channels or sodium-calcium exchange current).⁸⁹ These EADs that reach threshold voltage can result in a ventricular extrasystole preceded by a long QT interval on the surface ECG.

ELECTROCARDIOGRAPHY-BASED TESTS

The 12-lead electrocardiogram (ECG) is a widely available, inexpensive, noninvasive tool, used and familiar to all clinicians. As a time tested modality reflecting the electrical activity of the heart, it seems to be the one to contribute significantly to identifying risk of SCD, which may be the result of electrical disturbances in the heart (Table 7).

COMMON FORMS OF SUDDEN CARDIAC DEATH

Most SCD in the general population is associated with coronary artery disease (CAD),⁹⁰ while a smaller proportion is due to other cardiomyopathies. Assessment of SCD risk is complex since it represents a combination of multiple processes acting together.⁹¹

TABLE 7: Electrocardiography-based tests

ECC-based test	Advantages	Disadvantages/Limitations	Practical value for risk stratification
12-lead ECG	Cheap, quick and easy to perform; can be obtained serially at each follow-up visit to reassess risk; large databases can be generated and analyzed retrospectively/prospectively	Many abnormal parameters are markers of increased mortality, rather than specifically SCD; low positive predictive and negative predictive accuracies; subject to interobserver variability (unless automated software is used); considerable overlap in some parameters between healthy subjects and patients	Remains a standard investigation in patients with CAD; low positive and negative predictive accuracies for SCD limit its practical use in (risk stratification and selection of ICD candidates
Signal-averaged ECG	Easy and quick to perform; high negative predictive accuracy; can be used in patients with AF	Low positive predictive accuracy; numerous negative studies, especially in current era of interventional cardiology; better at predicting risk of VT than VF; normal standards for patients with bundle branch block or paced rhythm have not been established	Improved risk stratification when used in combination with other tests: probably more useful in identifying low-risk patients; not useful alone for risk stratification
Standard 24-hour Holter	Provides information on other arrhythmias in patients with CAD (e.g., AF, heart block); standard test, easy to perform; can be used in patients in AF or paced rhythms	Low sensitivity and specificity	Most promising use is in combination with other parameters (e.g., HRV and HRD obtained from Holter recordings; not useful alone for risk stratification
Heart rate variability	Can be automatically recorded with standard Holter (using additional software); short (2–30 min) and longer (24 h) measurements are possible	Cannot be reliably assessed in patients with AF or frequent PVCs Influenced by a number of factors (e.g., age, medication); may be affected by functional state of sinus node; short-term measurements in risk prediction have not been well tested; no consensus on which parameters of HRV or method of assessment is best	Current practical use for risk stratification is limited as a consensus opinion on which parameters of HRV to record and which method of assessing HRV is required
Heart rate turbulence	Value in risk prediction post-AMI supported by several recent large-scale prospective studies; provides prognostic information in patients with normal and impaired LVEF	Optimal time post-AMI to perform the test has not been established; can only be performed in patients in SR with a significant number of PVCs: use in patients with CAD and no history of AMI not well established	A promising test for risk prediction that can be used with other Holter-based measurements; limited practical use at present in the absence of clear guidelines for risk stratification
T-wave alternans	Easy to perform; can use existing equipment or modification of equipment; high negative predictive accuracy	Can only be used in patients in SR; "clean" ECG trace required (difficult to obtain during exercise); indeterminate result if target heart rate not achieved during exercise; low positive predictive accuracy	Useful in risk stratifying patients with impaired and preserved LVEF; useful role in determining which patients are unlikely to benefit from ICD insertion; improved risk stratification when used in combination with other tests: dear guidelines awaited for practical use for risk stratification

AF, atrial fibrillation; AMI, acute myocardial infarction; CAD, coronary artery disease; HRD, heart rate detection; HRV, heart rate variability; ICD, implantable cardioverter defibrillators; LVEF, left ventricular ejection fraction; PVC, premature ventricular contraction; SCD, sudden cardiac death; VF, ventricular fibrillation; VT, ventricular tachycardia; ECG, electrocardiography.

Resting Heart Rate

A higher resting HR has been linked to SCD risk in several studies. In the Paris Prospective Study, subjects with an HR more than 75 beats/min had an almost 4-fold risk of SCD compared with those with a HR less than 65.^{92,93} HR is linked to autonomic tone which influences the risk of arrhythmia.⁹⁴ However, there has been some concern that HR may be a nonspecific marker,⁹⁵ furthermore, it is influenced by several factors of which drugs are the most common.

Abnormalities of Depolarization

Various abnormalities related to the QRS complex, which reflects ventricular depolarization, can help evaluate SCD risk. Q waves, representing loss of myocardium and possibly LV dysfunction and scar, have been associated with an increased risk.⁹⁶ Various QRS scores have been calculated and shown to correlate with ventricular arrhythmic events.⁹⁷⁻⁹⁹

A longer QRS duration (QRSD) has been shown to be associated with the risk of SCD irrespective of the presence of BBB.^{100,101} A study showed a 27% increase in SCD risk for every 10 ms increase in the QRSD.¹⁰² Also dynamic prolongation of QRSD has been shown to occur in acute myocardial ischemia.¹⁰³ While prolonged QRSD has been well studied as a risk factor for SCD, there is very less data on the relevance of QRS morphologies. A large population-based study reported that intraventricular conduction delay was associated with arrhythmic death, it may also be weakly associated with LBBB, while right BBB has not been correlated.¹⁰⁴ Fragmentation of the QRS (fQRS) is defined as the presence of various RSR patterns. This results from disrupted electrical conduction in areas of diseased or fibrosed myocardium;¹⁰⁵ thus, it can be related to re-entrant arrhythmias. A study¹⁰⁶ demonstrated that fQRS was better than Q waves in detecting myocardial scar. Subsequent studies have shown that fQRS is related to SCD as well as implantable cardioverter defibrillator (ICD) shocks.^{107,108} The evidence for fQRS as a prognostic marker in patients with beyond CAD, such as in arrhythmogenic right ventricular cardiomyopathy¹⁰⁹ and cardiac amyloidosis,¹¹⁰ suggests that it may be a useful risk marker for SCD risk.¹¹¹ Another often overlooked risk factor in the context of SCD is the presence of LVH on the ECG. While ECG-LVH has been shown to be associated with SCD risk,¹¹² it has been associated as an indicator of increased LV mass.^{113,114} A subsequent study demonstrated diagnoses of LVH with respect to the risk of developing new atrial fibrillation.¹¹⁵ These reports suggest that increased myocardial voltage may reflect adverse electrical remodeling, leading to a risk higher than just anatomic LV hypertrophy.

Abnormalities of Repolarization

Prolongation of the QT interval has long been associated with an increased risk of ventricular arrhythmias (like LQTS). However, multiple findings suggest that this may also be an important risk factor for SCD.

Oregon-Sudden Unexpected Death study suggested that though diabetes and QT-affecting drugs contributed to SCD

risk, idiopathic QT prolongation unrelated to either of these factors was the strongest predictor of SCD in CAD, conferring up to a 5-fold increased risk.¹¹⁶ Kinoshita et al.¹¹⁷ found a QTc of more than or equal to 450 ms in men and more than or equal to 470 ms in women to be an independent predictor of SCD in subjects undergoing cardiac surgery. A recent meta-analysis incorporating 23 studies confirmed an increased risk of SCD in subjects in the highest versus lowest categories of QTc; thus, relative variations even within the traditionally defined normal limits for the QTc may be relevant in terms of risk.¹¹⁸ The measurement of JT interval may be a more useful measure in patients of prolonged QT.¹¹⁹

Another new novel ECG marker recently is the T-peak to T-end interval (Tpe). This has been thought to be a measurement of the transmural dispersion of repolarization.¹²⁰ A prolonged Tpe may reflect a period where the epicardium has fully repolarized, but the subendocardium is still recovering. This could create an electrical disturbance for after depolarization driven re-entrant ventricular arrhythmias.^{121,122} A recent study showed the Tpe to be significantly prolonged in cases of SCD. Also, Tpe was significantly associated with SCD in patients with prolonged QRSD, where measurement of QTc is challenging.¹²³ Thus, Tpe may be a useful addition to the QTc in assessing abnormal repolarization.

Studies have also shown the Tpe or the Tpe/QT ratio to be a predictor of arrhythmic events in inherited conditions such as BS¹²⁴ and HCM.¹²⁵ The ER pattern or J point elevation, previously was considered to be a benign finding, but recently has been reported to have a link with idiopathic VF.¹²⁶⁻¹²⁷

A new parameter that involves both depolarization and repolarization is the QRS-T angle, which can be assumed as the difference between the net directions of depolarization and repolarization in the heart. Recently in studies, this increased QRS-T angle has been associated with an increased SCD risk.^{128,129}

MULTIPLE RISK MARKERS: CUMULATIVE RISK

While several of the markers indicated in the article from a pathological aspect have the potential to lead to SCD, it is unlikely that a single marker would have adequate discriminative power to be noted as a singular potential risk predictor.¹³⁰ As SCD represents the combination of multiple risk processes, the use of multiple risk markers, which reflect the different facets of the heart's electrical activity, would help to convey more information than a single marker. The validation of these multiple markers in large population-based studies would be needed to finally be able to develop an "electrical" risk score based on ECG which could be by a primary physician to target potential at-risk individuals. This early concept for a cumulative risk approach using a combination of variables has been noted in various analyses from all the defibrillator trials.¹³¹

Though ECG represents only one arm of the approach to SCD risk prediction, ECG with cumulative risk markers can be

useful combined with clinical markers, genetics, biomarkers, and imaging.¹³²

IMPORTANCE OF DYNAMIC MONITORING

One study suggested that the total magnitude of ST elevation in all leads can predict VF in patients with ST elevation MI.¹³³ Moreover, continuous monitoring may help identify dynamic changes immediately before the onset of VF which may give insights into pathophysiology and etiology of the arrhythmia. Implantable loop recorders may help yield dynamic information as well. Dynamic monitoring approaches may aid SCD risk assessment. It can be assumed that parameters from an ECG at one point in time can help attain information about long-term risk of susceptibility to arrhythmia which may be the static risk of the patient, wherever the dynamic monitoring in the acute setting, including ECG in the field at the time of an ACS and various forms of ambulatory ECG monitoring can help understand changes preceding arrhythmia^{134,135} which could help identify the markers for triggers of arrhythmia.

CONCLUSION AND FUTURE DIRECTIONS

The 12-lead ECG continues to be a simple and useful tool for identification of individuals at increased risk of SCD. At present, the utility of this modality is unquestionable for making a diagnosis and assessing at risk patients with primary and inherited arrhythmia syndromes; and even the acquired forms of drug-induced LQTS. As clinicians we should be able to put this widely available and inexpensive tool to use in decision making for who may be in need to receive a primary prevention defibrillator. It is likely that these ECG variables will not be the individual predictors of increased SCD risk but will rather be utilized to predict risk as cumulative markers.

Premature Ventricular Complex: When and How to Ablate?

Joseph Theodore, Raja Selvaraj

INTRODUCTION

Premature ventricular complexes (PVCs) are fairly common in the general population. They are more frequently seen in the elderly and in patients with hypertension, obesity, sleep apnea, and structural heart disease. PVCs can arise from anywhere in the heart but have a predilection for specific sites. The most common sites of origin are in the ventricular outflow tracts (right > left).¹ Other sites for PVCs include the His-Purkinje system, especially the left posterior fascicle, endocavitary structures including the papillary muscles, moderator band, and false tendons.

The mechanisms of PVCs are varied. Outflow tract PVCs are caused by delayed afterdepolarizations or triggered automaticity, and are provoked by catecholamines, exercise, and menstrual cycles. Extensions around fibrous valvular annuli have also been hypothesized to allow conduction slowing and unidirectional block, which can lead to reentrant PVCs. Delayed afterdepolarizations also cause pathologic PVCs, frequently in a bigeminal pattern, in channelopathies such as Andersen-Tawil syndrome or catecholaminergic polymorphic ventricular tachycardia (VT), and in digoxin toxicity. On the other hand, early afterdepolarizations may cause PVCs that are precursors for torsades de pointes in long QT syndromes and drug-related QT prolongation. Reentry is the likely mechanism for PVCs originating from regions of fibrosis or infiltration in cardiomyopathies such as ischemic heart disease, arrhythmogenic right ventricular (RV) cardiomyopathy, sarcoidosis, hypertrophic cardiomyopathies, dilated cardiomyopathies, valvular cardiomyopathy, and postsurgical cardiac patients.

WHEN DO PREMATURE VENTRICULAR COMPLEXES NEED TO BE TREATED?

In most patients, PVCs in the structurally normal heart are considered benign and do not need treatment especially when asymptomatic. A few patients may complain of palpitations,

while some may complain of fatigue due to decreased cardiac output caused by high frequency of PVCs. Presence of any significant symptoms provides a justification to treat PVCs to provide symptom relief to the patient.

In patients with ventricular dysfunction and frequent PVCs, the possibility that ventricular dysfunction is caused by the PVCs and may be reversible with abolition of the PVCs has to be considered. In the presence of such a possibility, consideration should be given to treat the PVCs. Even in patients with coronary artery disease (CAD) or other causes of ventricular dysfunction, the presence of a large number of PVCs may contribute to further worsening of left ventricular (LV) function. In these patients, partial improvement of LV function may be seen with treatment of the PVCs.

In patients with a normal LV function, frequent PVCs may be associated with a small risk of developing PVC-induced cardiomyopathy in the future. The number or proportion of PVCs associated with this risk varies in different reports and probably reflects the fact that the risk is linear without a single threshold. Commonly, more than 15–20% PVC burden per day¹ is considered to be associated with a risk of developing cardiomyopathy, but the burden may be as low as 10% and the risk may depend on the duration, coupling interval, and other characteristics of the PVC apart from only the burden. Presence of even 1,000 PVCs per day (<1%) for 4–8 years may sometimes be significant.²

Other rare indications for treating PVCs include PVCs triggering sustained tachycardia and PVCs that interfere with optimal delivery of resynchronization therapy.

TO TREAT OR NOT TO TREAT A PREMATURE VENTRICULAR COMPLEX

In summary, the situations in which treatment of PVCs may be considered include:

- Symptoms
- Likely presence of PVC-induced cardiomyopathy

- Risk of developing PVC-induced cardiomyopathy [asymptomatic burden >15%, left bundle branch block (BBB) morphology, wide QRS, large variability in the coupling interval, interpolated PVCs]¹
- Premature ventricular complex observed to induce VT/VF (ventricular fibrillation)
- Premature ventricular complex interference with cardiac resynchronization therapy (CRT) function.

Use of electrocardiogram (ECG), echocardiography, and long-term ECG monitoring [Holter, pocket ECG, implantable loop recorder (ILR)] is required to evaluate the patients and helps to make a decision regarding treating PVC. The management of several forms of structural heart disease associated with PVCs may be guided by magnetic resonance imaging (MRI), including dilated cardiomyopathy, hypertrophic cardiomyopathy (HCM), sarcoidosis, amyloidosis, and arrhythmogenic right ventricular cardiomyopathy (ARVC).

HOW TO TREAT?

Reversible factors causing PVCs are uncommon, but should be looked for and treated. Electrolyte abnormalities (potassium, magnesium) should be corrected. Treat contributing diseases like hypertension, sleep apnea, and obesity. Although some continue to recommend reducing or stopping caffeine intake, there is no evidence that this is required.³

Beta-blockers and calcium channel blockers [nondihydropyridine (non-DHP)] are the first-line pharmacologic agent to suppress PVCs. Antiarrhythmic drugs like flecainide [caution in reduced ejection fraction (EF), CAD], sotalol (QTc, structural heart disease) can be used as second line drugs. Even though amiodarone can be effective in selected patients, long-term use is avoided because of toxicity, especially in patients with a structurally normal heart. Medical therapy is, however, limited by lack of efficacy for many patients. Additionally, beta-blockers, calcium channel blockers, and sodium channel blockers might cause unacceptable adverse effects such as fatigue or reduced inotropy and are difficult to take regularly on a long-term basis.

Catheter ablation of PVC is considered when treatment of PVCs is considered necessary, but drug therapy is ineffective, not tolerated or not preferred.

TECHNIQUE OF PREMATURE VENTRICULAR COMPLEX ABLATION

Prior to ablation, a careful assessment of justification, risks, and success of ablation is essential. Infrequent PVCs might make mapping impossible and all drugs-suppressing PVC are to be stopped prior to the procedure depending on their half-lives. Triggered PVCs (outflow) are catecholamine sensitive and can be completely inhibited with anesthesia. Therefore, general anesthesia and even sedation should be avoided if possible. Sympathomimetic agents (isoproterenol) or awakening the patient on the table may provoke PVCs. Rapid atrial or ventricular pacing causes an increase in triggered

PVCs. Atrial or ventricular extrastimulation can provoke reentrant PVCs.

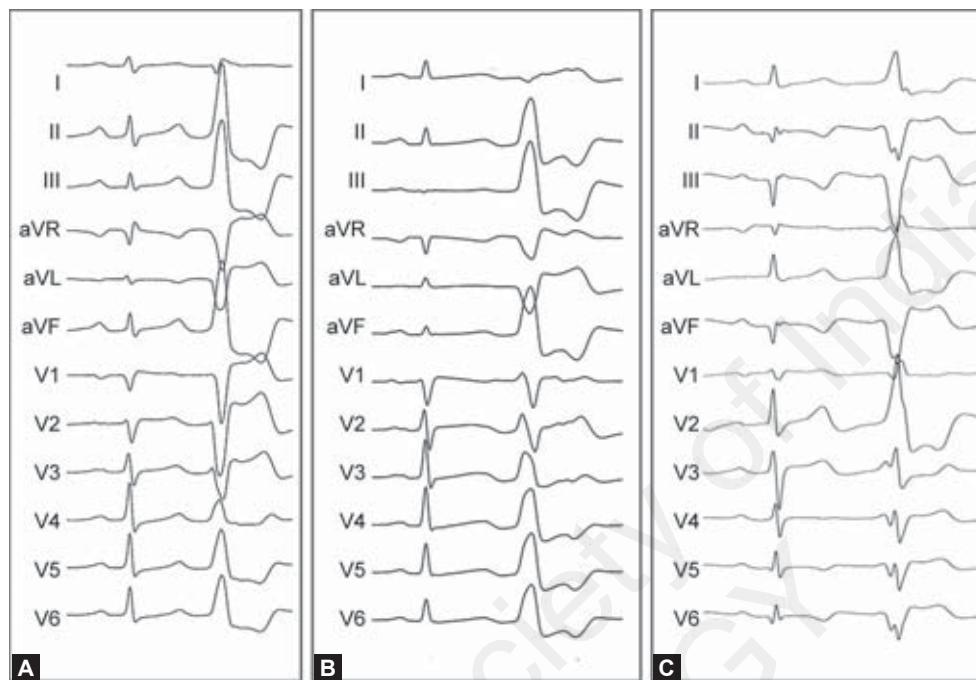

Localization from 12-lead Electrocardiogram

First step in ablating PVC is to get an idea of approximate origin of PVC from surface ECG and decide about the chamber to be mapped (Table 1). Clues to mapping, regarding the chamber of interest, endocardial or epicardial mapping (coronary

TABLE 1: Electrocardiographic features that suggest particular region as site of origin or exit of PVC

ECG finding	PVC localization
Inferior axis with tall positive leads II, III, aVF, and QS complex in aVR, aVL	Outflow tract
LBBB morphology in lead V1 with late precordial transition (after lead V3)	Right ventricular outflow tract (RVOT)
Early precordial transition	Left ventricular outflow tract
Lead V1	
QS	RVOT free wall
rS	Posterior RVOT, pulmonary valve, right (or left) coronary cusp (RCC/LCC)
qR	Aortomitral continuity
R	Mitral annulus
<i>Left-sided leads (I and aVL)</i>	
Positive lead I	RCC, rightward parts of RVOT
Negative lead I	Leftward portions of outflow tracts including pulmonary valve, LCC and mitral valve annulus
Positive aVL and I	Para-Hisian region
Pseudo delta wave (34 ms) or maximum deflection index >0.55	Epicardial or coronary sinus
RBBB morphology with R (slurred) in V1 and transition to rS in V4-6 Axis	
Left/superior	Posteromedial papillary muscle/left posterior fascicle
Right/inferior	Anterolateral papillary muscle/left anterior fascicle
Tall positive precordial leads	
LBBB morphology in V1	Tricuspid annulus
Negative aVR, positive aVL	Anterior tricuspid annulus
RBBB morphology in V1	Mitral annulus
Positive aVR, negative aVL	Anterolateral mitral annulus
Superiorly directed frontal plane axis	Posterior annulus

ECG, electrocardiograms; LBBB, left bundle branch block; PVC, premature ventricular complex; RBBB, right bundle branch block; aVR, augmented vector right; aVL, augmented vector left; aVF, augmented vector foot.

FIG. 1: Identifying site of origin from PVC morphology. A sinus beat and a PVC are shown from three different patients. In panels A and B, tall upright QRS complexes in the inferior leads with a QS morphology in aVR and aVL are suggestive of PVC arising from the outflow tract. The precordial transition is at V4 in panel A, consistent with origin from the right ventricular outflow tract. Whereas, a transition earlier than V3 in panel B suggests origin in the left ventricular outflow tract. Panel C shows a PVC with a totally different frontal plane axis. There is left axis deviation and right bundle branch block like morphology in lead V1 with negative QRS complexes in the inferior leads suggests origin from the inferior wall of the left ventricle. In the sinus beat, deep Q-waves are seen in the inferior leads, suggesting an old inferior wall myocardial infarction with PVCs arising from the scar.

sinus may be used in appropriate PVC) would be suggested by 12-lead ECG.

Figure 1 shows representative PVCs to illustrate identification of site of origin from the PVC morphology.

Activation Mapping

Activation mapping is the principal modality for mapping PVCs as it helps in precise localization of PVC origin. As opposed to sustained VT, entrainment of single PVCs is not possible, and mapping of both focal and reentrant PVCs is largely dependent on activation mapping. Local ventricular activation is assessed in different regions in the chamber of interest and the earliest local ventricular signal with respect to the QRS onset of the clinical PVC is mapped. For assessment of local activation time, the first sharp deflection in the bipolar signal is used. Recording of unipolar signals can be very useful and a completely negative unipolar signal is typically seen at the origin of the PVC. Figure 2 shows illustrative bipolar and unipolar signals at the site of successful ablation of a PVC. Activation mapping can be done using a three-dimensional (3D) electroanatomical system where a 3D map of the ventricle is created and colored according to the local activation time at each site. To maximize success, care is needed to ensure only the relevant PVC morphology is being mapped and to exclude fused beats different morphologies, or catheter ectopy.

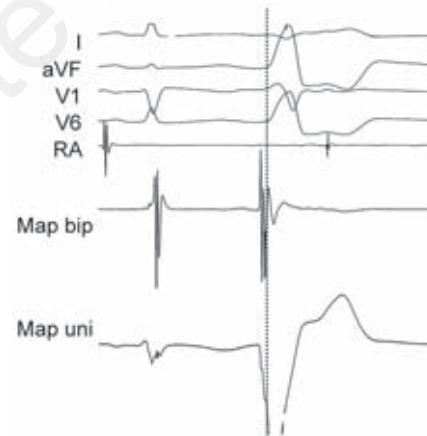

FIG. 2: Signals at the site of successful ablation in the right ventricular outflow tract in a patient with frequent premature ventricular complexes (PVCs). Shown are a sinus beat and a PVC. A dotted line is drawn at the onset of the QRS. The bipolar signal (map bip) shows local activation 30 ms ahead of the QRS onset. The unipolar signal shows a QS morphology with the local activation (steep negative deflection) occurring before the QRS onset.

Pace Mapping

In certain situations, e.g., in the case of infrequent PVCs, pace mapping is an alternative method that may be useful. The mapping catheter is positioned at a possible site of interest

and pacing is performed from this catheter. Comparing the morphology of the paced QRS to the clinical PVC will help in assessing the proximity to the origin of the PVC. At the origin of a focal PVC, a 12/12 match (good match of morphology in all 12 surface ECG leads) will be observed. The disadvantage is that pace mapping is not very accurate and pacing from a reasonably large surrounding area may also result in an exact pace map. Therefore, activation mapping is always to be preferred when possible.

ABLATION OF PREMATURE VENTRICULAR COMPLEXES

During mapping and while preparing for ablation, careful attention is needed to prevent a mechanical bump to the PVC focus with the catheter that will suppress PVCs temporarily. Confirming catheter contact and integrating information from the bipolar and the unipolar recordings can facilitate correct annotation of the breakout site at the tip of ablation catheter. Radiofrequency (RF) energy is delivered at the origin of the PVC using a nonirrigated or irrigated catheter depending on the situation. Common outflow tract PVCs will require 20–30 watts energy.⁴ Anterior or free wall locations will require lesser energy than septal location or a transmural lesion targeting an epicardial focus. Cryoablation (not available in India) can be used safely in areas closer to conduction tissue or coronary artery where RF ablation might pose danger.

OUTCOMES

The success rate of ablation of outflow tract or fascicular PVCs is 80–100%.⁵

In 60% of patients undergoing PVC ablation due to PVC-mediated cardiomyopathy, LV function improves to normal within 4 months, although it may take more than a year in a few patients.⁵ Recurrence after successful ablation is possible due to remodeling of the arrhythmogenic substrate. The risk of collateral injury with ablation of PVCs close to critical structures needs to be considered. Coronary artery injury

can occur when ablating in the coronary veins, epicardial space, above the coronary cusps close to coronary ostia, and in posterior right ventricular outflow tract (RVOT) near the pulmonary valve. Ablation at noncoronary aortic cusp (NCC), midseptum, and parahisian region can cause AV blocks. Thromboembolic complications can be minimized with therapeutic heparin anticoagulation during and following procedure. Cardiac tamponade or valve perforation is rare but catastrophic complications for which the operator has to be watchful.

CONCLUSION

Premature ventricular complexes are generally benign and are only occasionally symptomatic. In patients showing a clear association between PVCs and symptoms, PVC-induced ventricular tachyarrhythmia, PVC-mediated cardiomyopathy, or with a high PVC burden with future risk of developing cardiomyopathy, catheter ablation is safe and feasible alternative to long-term medical therapy. Localizing with 12-lead ECG, approximation with pace mapping and precise localization with activation mapping, using an electroanatomical mapping system when required, will improve procedural success.

Epicardial Ventricular Tachycardia: Recognition and Approach

Maki Ono, Walid I Saliba, Oussama Wazni, Mandeep Bhargava

INTRODUCTION

Failure of endocardial radiofrequency catheter ablation for ventricular tachycardia (VT) has often been thought to be due to subepicardial or midmyocardial circuits, where the ability of delivering energy epicardially can greatly enhance the efficacy of the ablation procedure. In 1996, Sosa et al. demonstrated the efficacy of an epicardial ablation by subxiphoid approach in Chagas disease and since then the utility of gaining access into the normal pericardial sac has been described with increasing enthusiasm.¹⁻³ We are now in an era where epicardial ablation has been shown to be useful not only for structural heart disease such as nonischemic cardiomyopathy (NICM), arrhythmogenic right ventricular cardiomyopathy (ARVC), and hypertrophic cardiomyopathy (HCM) but also for channelopathies like Brugada syndrome.

PREOPERATIVE ASSESSMENT AND RECOGNITION

Epicardial ablation has potential risks of both cardiac and noncardiac complications while obtaining access, during ablation and that of postprocedural adhesions and inflammation, which make it difficult to perform a second epicardial ablation in the future. Hence, the decision to obtain epicardial access should be made carefully and limited to the patients who have higher likelihood of having an epicardial origin of the arrhythmia. Electrocardiographic criteria, imaging features, and other clinical characteristics like activation and voltage mapping information from previous ablation attempts should be considered while determining the indication for the same. Many algorithms for making such decisions have been suggested by various authors.⁴⁻⁸ It can often be the access of choice for patients where retrograde and trans-septal routes are not an option at all, as in patients with a left ventricular thrombus or in patients with a metallic valve in both the aortic and mitral position.

If a 12-lead electrocardiography (ECG) of the VT is available and the QRS onset is easy to identify, evaluating certain “interval criteria” and “morphology criteria” can be helpful to differentiate an epicardial origin.^{5,6,9} Sometimes, the onset of QRS or deflection points can be difficult to determine or the 12-lead ECG may not be available until the VT is induced at the electrophysiological study as the only diagnosis of the VT may have been from the intracardiac electrograms on an implantable cardioverter-defibrillator (ICD). Berreuezo et al.⁵ initially evaluated and described important QRS intervals which could be used to predict an epicardial origin of the VT. They described four important intervals as follows:

1. *Pseudo-delta wave (PDW)*: Interval from the earliest ventricular activation to the onset of rapid deflection in any precordial lead
2. *Intrinsicoid deflection time (IDT)*: Interval from the earliest ventricular activation to the peak of the R wave in V2
3. *Shortest RS complex (SRS)*: Interval from the earliest ventricular activation to the nadir of the first S wave in any precordial lead
4. QRS duration.

Using these criteria, they showed that a PDW of more than or equal to 34 ms had a sensitivity of 83% and a specificity of 95%, an IDT of more than or equal to 85 ms had a sensitivity of 87% and specificity of 90%, and an SRS of more than or equal to 121 ms had a sensitivity of 76% and specificity of 85%, respectively for identifying an epicardial origin for the VT. Most patients had coronary artery disease and the study was based on pace mapping which were realized as limitations over a period of time but the study clearly showed that epicardial breakout is associated with wider QRS and slower initial forces as it engages the His-Purkinje system later when compared to endocardial breakouts from similar areas.

Patients with ischemic cardiomyopathy often have endocardial circuits as these scars are “inside out”. A fair number of these patients may have epicardial circuits, but many such circuits may have a critical endocardial isthmus or may be approachable by deep endocardial lesions. Later

studies have shown that ECG criteria are less useful to predict epicardial origin in patients with ischemic cardiomyopathy and patients on antiarrhythmic drugs.¹⁰ Additionally, prior open heart surgery, bypass grafts and adhesions may make epicardial access difficult in these patients. Hence, in these patients, we usually reserve access for patients with failed endocardial ablation, patients with left ventricular thrombus or rarely in the primary procedure when the conviction for an epicardial circuit is very high.

Nonischemic cardiomyopathy patients have a higher chance of having an epicardial circuit as their scars can often be epicardial. Figure 1 shows a patient with nonischemic cardiomyopathy who has a relatively small scar on the endocardial map which can be deceptive as the epicardial access and mapping showed that the patient had a large epicardial scar as shown and was harboring the circuit for the

culprit VT. Different types of ECG criteria have been proposed to especially look at the VT from the basal anterolateral walls but Valles et al. proposed a four-step algorithm.⁶ The criteria include first looking for "Q" waves in the inferior leads and their presence for VTs in that region high up would suggest initial forces going away from the inferior leads and would suggest an endocardial origin. One would then look for a PDW of more than or equal to 75 ms or a maximal deflection index (ratio of onset to peak to that of the total QRS duration in the mid-precordial leads) and the presence of either of these would favor an epicardial origin. If neither of these helps, they recommend looking for "Q" waves in leads I and the presence of that would also favor an epicardial origin. The four-step algorithm claims to have a sensitivity of 96% and specificity of 93% for predicting an epicardial origin in patients with nonischemic cardiomyopathy. Figure 2 shows

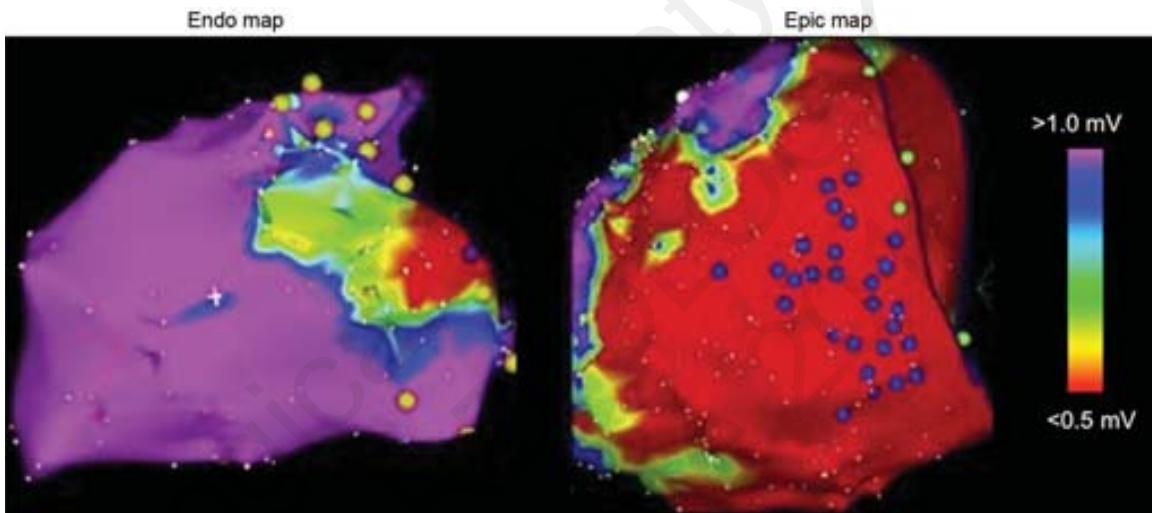

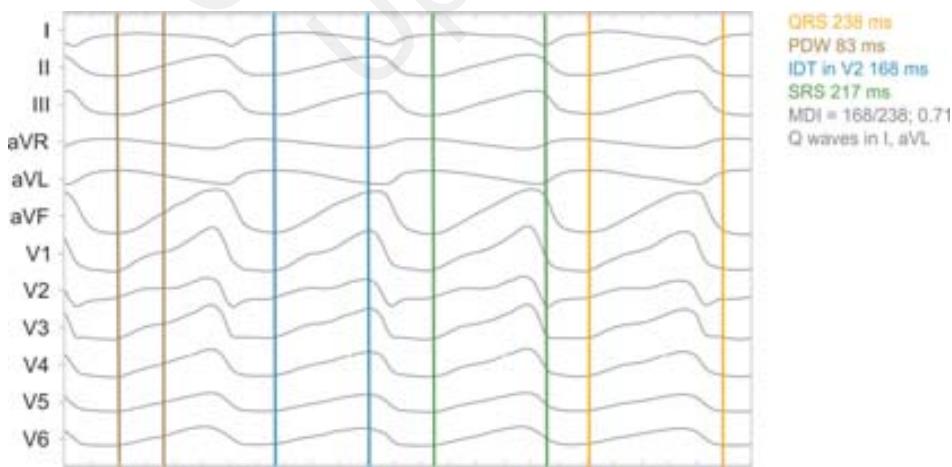

FIG. 1: A left lateral view of a voltage map of the endocardium and the epicardium in a patient with nonischemic cardiomyopathy. The endocardial map on the left panel shows a small scar along the basal lateral wall close to the mitral annulus. The voltage map on the right shows that the scar is much larger and predominantly epicardial and spans the basal and mid-anterolateral, lateral and inferolateral walls of the left ventricle.

IDT, intrinsicoid deflection time; MDI, maximum deflection index; PDW, pseudo-delta wave; SRS: shortest RS complex; aVF, augmented vector foot; aVL, augmented vector right; aVR, augmented vector right.

FIG. 2: The various "interval criteria" on an electrocardiography measured in a patient with ventricular tachycardia originating from an epicardial focus from the basal lateral wall in a patient with nonischemic cardiomyopathy. The "morphology criteria" also show a Q-wave in leads I and augmented vector left.

one of our patients with a VT with right bundle branch block like pattern with a right inferior axis. The VT was originating from an epicardial focus along the basal lateral wall and the surface ECG shows a pattern consistent with an epicardial focus as per the various “interval criteria” and “morphology criteria” noted.

There are also ECG criteria for predicting epicardial origin for patients with VT from an ARVC but we feel that this decision is less stressful because patients with ARVC do not usually need anticoagulation during mapping and ablation for VT and epicardial access can be obtained anytime without concerns for reversing anticoagulation if not obtained at the beginning of the procedure. Similar to patients with NICM, patients with ARVC also can have a fair percentage of patients with epicardial circuits as both these disease states can be associated with scars which are epicardial or “outside in”.

Imaging has been shown to be useful to identify the arrhythmogenic substrate of VT and to plan an appropriate mapping and ablation strategy. Bogun et al. showed the utility of delayed-enhancement magnetic resonance imaging (DE-MRI) in 29 nonischemic cardiomyopathy patients.⁷ Scar was identified in 14 of 29 patients. Five patients with predominant endocardial scar were successfully ablated from the endocardium, two patients with predominant epicardial scar were successfully ablated from the epicardium, and no effect on VT could be achieved in five patients with predominant intramural scar. Intracardiac echo has also been described to look for epicardial scars but we do not use it often as a predictive tool. Recent studies have also shown that preserved endocardial bipolar voltages on electroanatomical maps with reduced unipolar voltages are also predictive of epicardial scars and may be a “far-field reflection” of low voltages in the epicardium.

Hence, the patient’s clinical background is important to assess the probability of an epicardial focus given the cardiac substrate.⁸ Assessing ECG, imaging, and probability before procedure is important to plan a safe and effective ablation. Other important assessment and preparation before procedure includes discontinuation of anticoagulants and antiplatelet agents and the availability of surgical backup in the event of a complication.

APPROACH TO ACCESS THE PERICARDIAL SPACE

It is critical to understand relevant anatomy to prevent complications while obtaining subxiphoid access. The normal pericardium¹¹ is a double-layered flask-shaped sac with an outer fibrous envelope and an inner serous sac, i.e., invaginated by the heart. The serous pericardium is divided into the visceral pericardium which surrounds the myocardium and the great vessels also called the epicardium and the outer parietal layer which is the inner serous layer of the fibrous pericardium. The pericardial space is the virtual space in between these two serous linings and by separating it from the heart and its surrounding structures, in normal conditions, it provides a smooth lubricated space for free motion around the heart. The pericardial space contains

about 20–25 mL of fluid in the physiological state and in the supine position this is largely seen in the posterior network of sinuses and recesses of the pericardium.

A blunt tipped epidural Tuohy needle (17G, 90 mm, BD, Medical Franklin Lakes, NJ, or 17G, 152 mm, Hakko Co, Ltd., Tokyo, Japan) is used with a spring guidewire. Hydrophilic wires cannot be used with metal Tuohy needle. Recently a “needle-in-needle” method using two needles (21G micro-puncture needle in 18G needle) was reported^{12,13} and the new methods using pressure sensor lines¹⁴ have also been described.

For most averagely built patients, it is best to start about an inch below the line between the xiphoid process and the costal margin but adjustments may need to be made in accordance with the patient’s size and depth that need to be negotiated. Given the relatively blunt and angulated nature of the Tuohy needle, it may often be helpful, especially in patients with thicker skin, to give a skin incision. This could also allow the operator to have a better tactile sensation of the structures encountered and their pulsatility. This also makes it easier to feel the give-away sensation on entering the pericardial space or to appreciate the contractile nature of the myocardium. The Tuohy needle is gently aimed at an angle toward the left scapula with the patient in the supine position. Under fluoroscopic guidance, the needle is gently moved toward the cardiac border. There are two approaches—an anterior versus posterior approach—and the angle of the needle is guided by the intent to achieve access for one or the other approach. Table 1 shows comparable differences between the two approaches.

The anterior approach requires a shallower angle of the needle. The guidance by a catheter placed at the right ventricular (RV) apex or pre-existing lead of an implantable cardiac rhythm device can be of additional help. Fluoroscopically, a shallow left anterior oblique (LAO) view may help to show the anterior and posterior relationship and a slight right anterior oblique (RAO) view to stay midway between the apex and the annulus can be extremely helpful. A left lateral projection¹⁵ has also been described to address the needle angle posterior to the sternum and to help to avoid the diaphragm. In the posterior approach, a steeper

TABLE 1: Comparison of anterior versus posterior approach for epicardial access

	Anterior approach	Posterior approach
Angle of the needle	Shallow, <30°	Steep, >30–45°
Direction of the needle edge and wire	Anterior	Posterior
Marker of the direction	RV apex catheter or lead	RV apex catheter or lead, and coronary sinus catheter or lead
Useful fluoroscopic angle	RAO, LAO, and left lateral	LAO and RAO
Intra-abdominal bleeding	Rare	Possible

LAO, left anterior oblique; RAO, right anterior oblique; RV, right ventricle.

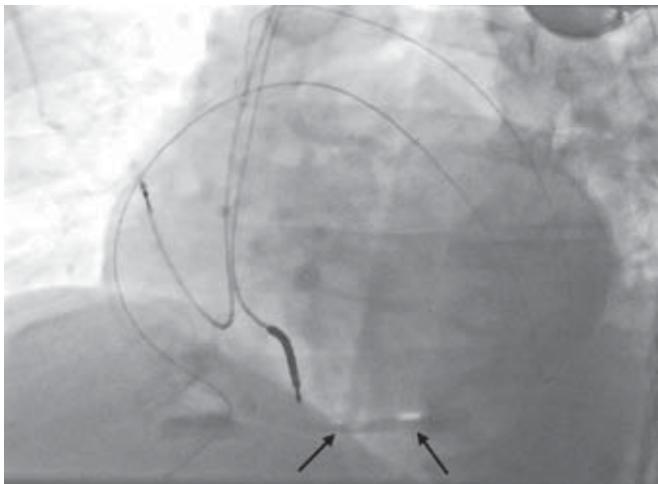

FIG. 3: A fluoroscopic left anterior oblique view of a patient with a relatively anterior approach to access the pericardial space. The tip of the implantable cardioverter defibrillator lead is close to the right ventricular apex. The wire is seen to span the complete heart border from the anterior portion on the left of the screen to the posterior portions on the right of the screen confirming that it is in the pericardial space and not in one of the chambers. The arrows show the layering of contrast at the bottom.

angle of the needle is required and both catheters or leads at RV apex and in coronary sinus are helpful. Intra-abdominal hemorrhage by diaphragmatic and hepatic puncture is higher with posterior approach. We like to make sure that the site of entry is preferably close to the midpoint between the annulus (as seen by the coronary sinus catheter or lead) and the RV apex (as assessed by an RV apical catheter/lead) in a RAO projection.

As the needle comes in close proximity to the cardiac border, small puffs of contrast are injected to visualize tenting of the parietal pericardium or entry into the pericardial space. The latter is most often identified by layering of contrast into the pericardial space (Fig. 3). With experience, this is usually preceded by a sensation of the pericardium “giving away” but this may not be appreciated all the time. A common mistake by inexperienced operators is a combination of minimal advancement of the needle with injection of too much contrast. This tends to cloud the fluoroscopic view and should be avoided.

As soon as the sensation of the parietal pericardium “giving away” is achieved or contrast layering is seen in the pericardium, it is crucial to stabilize the needle with one hand and gently pass a guidewire into the pericardial space with the other. Some operators prefer using a Y connector with the Tuohy needle, so that they can inject contrast from the side port and insert a wire from the main port at the same time. Under usual circumstances, this wire should pass and move freely into the pericardial space. Our preference is to visualize the wire in LAO position (Fig. 3). It is important to see that the wire crosses over on both, the right and left sides of the cardiac border and hence seen anterior and posterior in this view as this would further confirm that the wire is in the pericardium. It is also best if the wire can be seen along

the posterior and anterior border of the heart. Any contact with the myocardium with the needle or the wire is likely to produce ventricular ectopy and should be watched for. It is of absolute importance to confirm that the wire is in the pericardial space and not in a cardiac chamber prior to insertion of a dilator or a sheath over the wire. If there is doubt that the needle or wire is in the cardiac chamber, it should be gently withdrawn and attempts to slowly retract and stay in the pericardial space are often successful. However, if a dilator or sheath is passed over the wire and then a realization is made that it is in one of the cardiac chambers, surgical help should be sought before pulling this back any further. Most often, gentle invasion of the ventricle with the needle or wire *per se* is usually forgiving but injuries to the epicardial vessels, diaphragmatic vessels or the liver can be much more serious.

Once access has been achieved with a guidewire, it is reasonable to exchange that with a stiffer sheath and in procedures needing more stability, we may often use a steerable or a metallic sheath to have better navigation within the pericardial space. Through this, one may pass catheters or wires at will but it is important to try and minimize the time where the sheath is left without a catheter as the sharp and stiff edges of a sheath can often cause damage to the fragile blood vessels on the epicardial surface of the heart which can lead to incessant bleeding.

Epicardial access for the patient with prior cardiac surgery has been reported to be feasible;^{16,17} but, in our experience, it may be limited to about 15–40% patients at best. It is suggested that a more inferior approach is helpful in these patients. Such patients are likely to have more adhesions and scarring even after successful access. Care should also be taken to protect the bypass grafts coursing through this space. Gentle disruption of adhesions with catheters and guidewires has been reported when presents, but this should be cautiously ventured into. Soejima et al. first reported the feasibility of surgical subxiphoid epicardial approach in the electrophysiology laboratory in six patients with prior cardiac surgery or failed percutaneous epicardial access.¹⁸ Michowitz et al. did detailed analysis of the relationship of surgical window and accessibility.¹⁹ While limited anterior thoracotomy enabled access to the apex, anterior, and mid to apical anterolateral walls, subxiphoid surgical window provided access to the inferior and diaphragmatic surface of the heart extending posteriorly to the basal lateral wall.

MAPPING AND ABLATION

Mapping by epicardial approach creates less premature ventricular complexes (PVCs) and is relatively smooth in handling ablation catheter if there are no adhesions. We find the short steerable sheath very useful to obtain better stability and navigation for the catheter. Three-dimensional mapping systems such as CARTO (Biosense Webster, Diamond Bar, CA), Ensite (St Jude Medical/Abbott, St Paul, MN), and Rhythmia (Boston Scientific, Marlborough, MA) can be used with multielectrode catheter such as Pentarray (Biosense Webster, Diamond Bar, CA) and Intellamap Orion (Boston Scientific, Marlborough, MA). Orion should be used

without full expansion, and small amount of normal saline (10–20 mL) can be added into the epicardial space if the noise is significant. If an irrigated-tip ablation catheter is chosen for the mapping, irrigation during mapping can be stopped but care should be taken to regularly aspirate the epicardial space if irrigation is used during mapping and ablation.

Mapping approaches to epicardial VT could include substrate mapping during sinus rhythm, activation mapping during VT, or pace mapping. Low voltage has been reported as 0.5–1.5 mV²⁰ or less than 0.94 mV²¹ but these criteria obtained by mapping with conventional ablation catheters need to be reassessed in the era of high-density mapping.

It is important to understand the distribution of fat in relation to the pericardium during mapping. The presence of epicardial fat is seen in relation to the sulcus, the interventricular grooves, and the coronary vasculature and can vary from 0–14 mm in thickness. The thickness is often related to age and may not necessarily have a relationship to the body habitus of an individual but has two important implications. The fat could act as a layer of electrical disturbance and could falsely give low amplitude signals in an area of viable tissue by causing a layer of inertness electrically or increase pacing thresholds and could also act as a layer of insulation which prevents the delivery of radiofrequency energy in the most optimal manner. In animal studies, scar from healed myocardial infarction exhibits more fractionation and longer EGM duration when compared to fat and late potentials are highly specific for locating infarct scars.²²

An irrigated-tip ablation catheter that can show the contact force and vector orientation is most useful for ablation. It is most important to make the catheter tip vector toward heart muscle, not toward lung or pleura to obtain effective ablation and to avoid collateral damage.²³ Caution should also be exercised along the lateral and posterolateral walls of the left ventricle as these areas could be in close proximity to the left phrenic nerve. Appropriate energy is unknown but we usually use 20–40 Watts of power with irrigated tip catheters and occasionally up to 50 Watts while keeping a very close watch on the impedance and temperature.

Coronary angiography can sometimes be necessary before ablation to define the proximity of coronary arteries (Fig. 4). High-output pacing may be required on the left anterior and lateral border to determine the location of the left phrenic nerve. While ablating with irrigated catheters, intermittent or continuous pericardial aspiration from the sheath is necessary to avoid fluid accumulation and cardiac tamponade.

After the ablation, evaluate and aspirate pericardial effusion before removing the sheath. It may be safe to use transthoracic echocardiography or intracardiac echocardiography to see the remaining pericardial effusion before withdrawing the sheath to avoid the situation that epicardial sheath is obstructed with blood clot and fluid cannot be aspirated or that epicardial access has been lost in the face of a significant effusion or tamponade. Prophylaxis of inflammation and adhesions is important and intrapericardial steroid injection using pig-tail before

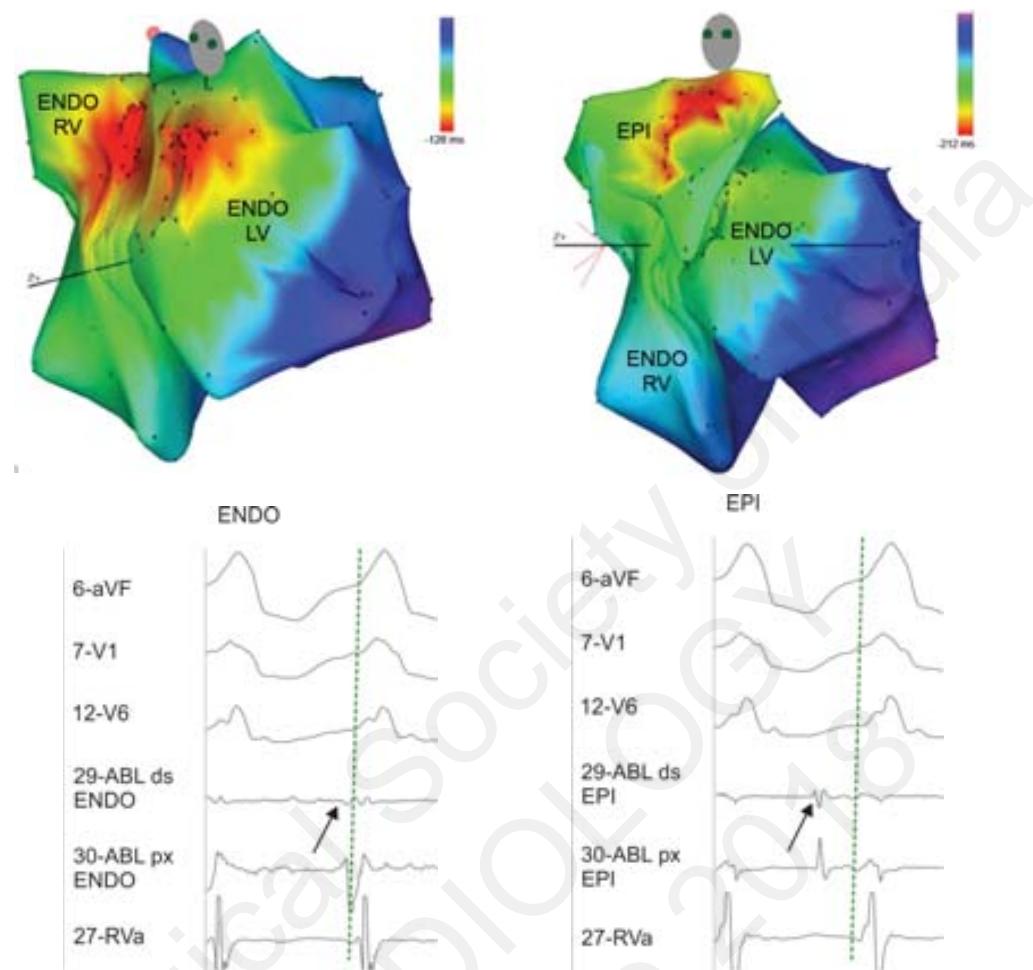

FIG. 4: A left anterior oblique caudal view of a coronary angiogram done in a patient just prior to ablation. The mapping or ablation catheter can be seen close to the left circumflex artery and its branches but at a fair distance where ablation can be deemed safe in this area.

removing sheath reduces postprocedure pain and we tend to use 1–2 mg/kg of triamcinolone on a routine basis.

Although epicardial access is most commonly required for patients with nonischemic cardiomyopathy and arrhythmogenic RV dysplasia, it can often be a useful bailout strategy in patients with normal hearts or ischemic cardiomyopathy. Figure 5 shows a patient with a focal tachycardia in a patient with a normal heart where the VT shows a right bundle branch like pattern with an inferior axis. The morphology of the QRS in lead V1 would change with lead position and mapping of the right and left ventricular endocardium did not show any great sites of early activation or pace matching. The activation pattern was focal with a centrifugal spread suggesting a non-reentrant mechanism. Epicardial mapping showed sites which were more than 80 ms earlier than the endocardial sites and ablation in those areas resulted in prompt termination and noninducibility of the tachycardia. In contrast, Figure 6 shows a re-entrant tachycardia along the apical anterior wall on an aneurysm in a patient with ischemic cardiomyopathy, old anterior wall myocardial infarction, and a left ventricular thrombus. The arrhythmia had a critical isthmus within the scar (noted on the left panel in the voltage map) and ablation in this area resulted in a successful outcome.

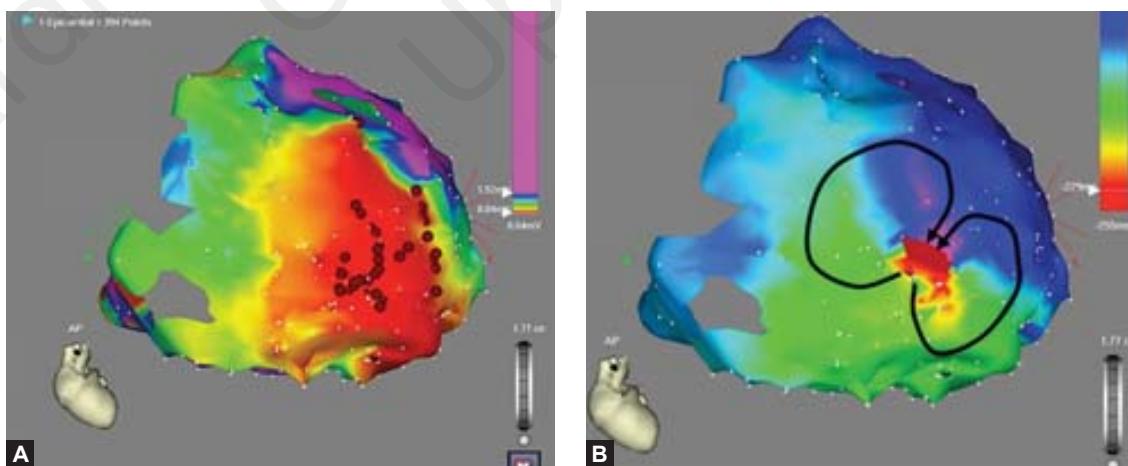

COMPLICATIONS

It is important to be aware of the possible complications during percutaneous epicardial access and ablation and only then can we focus on the prevention and management of these complications.²⁴ An RV puncture can happen in 4–5% of the cases but usually safe if observed with just the needle but without advancement of the sheath. RV puncture can be detected at the time of puncture with contrast. The needle should gently be withdrawn and the pericardial space should be cannulated with the wire. We must carefully monitor for

aVF, augmented vector foot; RV, right ventricular.

FIG. 5: An activation map of a focal ventricular tachycardia in a patient with a normal heart. The left panel shows activation map of the right and left ventricular outflow tract respectively in this patient with a ventricular tachycardia showing a right bundle branch block pattern with an inferior axis. Both show large areas of early activation and even the earliest point of activation shows that it is just at best at the onset of the rapid deflection of the QRS but not earlier than the pseudo-delta wave. Epicardial access was obtained and it showed a much earlier site of activation at the basal anterior portion of the left ventricle with a near-field electrogram and ablation was successful at this site.

AP, anteroposterior.

FIG. 6: The voltage and activation map of a patient with ventricular tachycardia involving the apical aneurysm in the patient with an old anterior wall myocardial infarction. A, Right anterior oblique view of a bipolar voltage map shows a large apical scar; B, An activation map with a circular activation pattern with a figure of 8 appearance. The narrow critical isthmus is the area highlighted as the one where "early meets late" as highlighted by the bold red band. Ablation along this critical isthmus resulted in prolongation, termination and non-inducibility of the tachycardia. Epicardial ablation was performed as the patient had a left ventricular thrombus.

pericardial effusion not only at the time of puncture but also after the procedure. To prevent RV puncture, it is important to advance needle slowly with using contrast and with appropriate needle direction, and to carefully observe for PVCs. Intrapericardial bleeding can happen at 4–5% of the cases anytime from puncture to the time after the procedure. Discontinuation of anticoagulant agents before the procedure and careful handling of both sheath and mapping and ablation catheters are warranted. The sheath should not be left in the epicardial space without a catheter because of the possible damage by its sharp edges. Intra-abdominal bleeding and diaphragmatic injury are rare but can occur in 0.5% of patients and may require careful assessment for diagnosis. Anatomical evaluation with imaging before the procedure may be critical to assess the appropriate approach. Anterior approach reduces the risk of intra-abdominal bleeding. Any bleeding can be observed if it stops spontaneously but may require surgery if it shows no signs of settling on its own.

Damage to the coronary artery and coronary veins can happen in about 0.6% patients but can happen anytime from puncture to ablation. Access very septally increases the risk of damage to the posterior descending artery or middle cardiac vein injury. Expert consensus recommends at least 5 mm distance from coronary artery by assessing coronary angiography even during ablation.²⁵ Before ablating in the lateral left ventricular area, evaluation of left phrenic nerve should be assessed by high output pacing to avoid the rare complication of phrenic nerve injury. Fan et al. reported the utility of high output pacing more than 10 mA to determine the pathway of phrenic nerve.²⁶ A fertile substrate for ventricular arrhythmias is often observed around the basal to mid-lateral and basal to mid-anterolateral left ventricle in patients with nonischemic cardiomyopathy which increases the risk of phrenic nerve injury. If the nerve is in close proximity to ablation targets, injection of normal saline or insertion of balloon into epicardial space has been reported^{27,28} to protect the same.

Mild pericarditis occurs in almost all patients after the procedure, and clinically important pericarditis happens in 30%, but severe pericarditis is rare at 0.6%. Dyrda et al. reported on the incidence of pericarditis in 85 consecutive patients after epicardial VT ablation.²⁹ Intrapericardial steroids (triamcinolone 2 mg/kg) significantly reduced the incidence of pericardial pain (58% vs. 21%; $p = 0.006$) compared to no steroid, but the difference was not significant with systemic steroids alone (58% vs. 43%; $p = 0.31$).

CONCLUSION

Epicardial VT ablation is a relatively novel approach which can significantly enhance the efficacy of catheter ablation for arrhythmias, especially in patients with VT. This requires invasive electrophysiologists to understand anatomy for areas other than the heart itself. The rate of any complications goes higher by adding this approach to an endocardial ablation and we should take all precautions to avoid the same.

Cardiopulmonary Resuscitation: What's New?

Nitin Modi, Sunil Sharma

INTRODUCTION

The practice of cardiopulmonary resuscitation (CPR) has a long history dating back to 1740 when the Paris Academy of Sciences recommended mouth-to-mouth resuscitation for rescue of drowning victims. The first documented chest compression for resuscitation was performed by Dr Friedrich Maass in 1891. However, mouth-to-mouth resuscitation remained the mainstay of resuscitative efforts with Dr Peter Safar and Dr James Elam promoting respiratory support for resuscitation. It was only in 1960s that a program on CPR was initiated in the US. In 1947 Dr Claude Beck reported first successful ventricular defibrillation of a 14-year-old boy using open chest massage and internal defibrillation with alternating current.

The CPR guidelines have been periodically published every 5 years and were last revised in 2015 when they were published as the 2015 American Heart Association Guideline Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care jointly by the American Heart Association (AHA), the European Resuscitation Council (ERC) and the International Liaison Committee on Resuscitation (ILCOR). These bodies reviewed the evidence published since 2010 and published these guidelines as an update to the 2010 Guidelines. Though an update, it is interesting to note that only 1% of all recommendations put forward in 2015 guidelines have the highest level of scientific evidence (Level of Evidence A) and only 25% have a class I recommendation. Majority of these guideline updates have a low level of scientific evidence (either evidence is based on expert opinion guided by clinical experience or based on studies that have limitations in study design or execution (including meta-analysis) or are based on physiologic or mechanistic studies involving human subjects. As a result most of the recommendations in these guidelines carry only a Class IIb recommendation. Yet, there are major implications for clinical practice and are hence reviewed in this chapter.

2015 AMERICAN HEART ASSOCIATION GUIDELINE UPDATE FOR CARDIOPULMONARY RESUSCITATION AND EMERGENCY CARDIOVASCULAR CARE

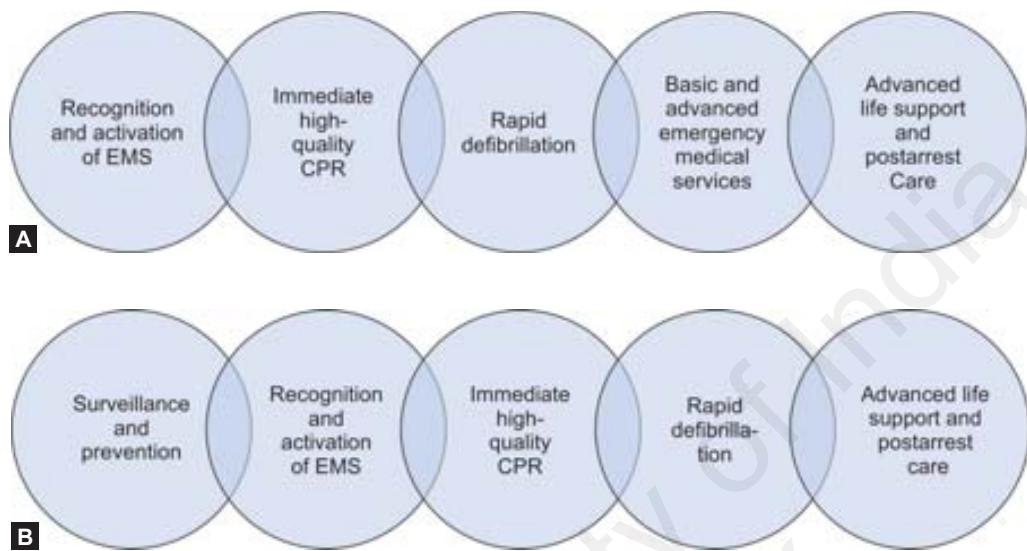

The updated guidelines have revisited the entire process of CPR and have come up with major changes in the entire steps of CPR. Hence, important changes in these new guidelines will be discussed in connection with the revised changes.

Chain of Survival

The revised 2015 AHA guidelines have suggested separate chain of survival for out-of-hospital versus in-hospital cardiac arrest, emphasizing the importance of surveillance and prevention of cardiac arrest in in-hospital patients by paying adequate importance to clinical symptoms and signs that may predict occurrence of cardiac arrest (Fig. 1). The guidelines have paid emphasis to the formation of rapid response teams (RRT) to improve survival of cardiac arrest victims especially in general care wards in both adult and pediatric patients. In addition hospitals are encouraged to initiate quality improvement programs to assess and improve upon existing systems of care in their hospitals. Recognizing the importance of primary percutaneous coronary intervention (PCI) in patients with cardiac arrest, communities are encouraged to develop regional centers that have expertise in cardiac resuscitation. The use of mobile phones and social media to initiate the call for help has been recognized and added to the 2015 guidelines.

Chest Compression, Depth, and Rate

The 2015 guidelines have emphasized the lay rescuers may perform chest compression only CPR for adult victims. If the lay rescuer is trained and willing to perform rescue breaths then he should deliver rescue breaths in a ratio of 30 compressions to 2 rescue breaths (for both single and 2 rescuer CPR). In infants and children, the rescuer should

CPR, cardiopulmonary resuscitation; EMS, emergency medical services.

FIG. 1: Chain of survival for cardiac arrest victims in A, out-of-hospital; B, in-hospital conditions.

maintain the 30:2 ratio for a single rescuer situation while in a two-rescuer situation this should be augmented to 15:2. The rate of chest compression has been changed from at least 100 per minute in 2010 to a rate of 100–120 per minute in the current guidelines. This range has been defined as chest compression i.e., either too fast or too slow can limit cardiac output during CPR and variations beyond this range have been associated with a lower rate of return of spontaneous circulation (ROSC). In addition, the extent of chest compression has also been defined—chest compression in an adult should be at least 5 cm (2 inches) and not more than 6 cm (2.4 inches). In children, the appropriate depth is about one-third of the anteroposterior diameter of the chest (usually about 2 inches); in infants chest compression should be about one-third of the anteroposterior diameter of the chest (usually about one and a half inches). To achieve these criteria rescuers are encouraged to use CPR feedback devices. Many new defibrillators now incorporate these guidelines with voice prompts to ensure high-quality CPR. To ensure high-quality CPR the 2015 guidelines have reemphasized that there should be no interruptions in chest compression of more than 10 seconds. Guidelines have therefore been accordingly simplified—e.g., if a patient has an advanced airway in position then ventilation should be provided in a ratio of 1 breath every 6 seconds (10 breaths/min).

An important update is in victims who have had a witnessed out of hospital cardiac arrest. In these victims ventilation may be delayed by using a strategy of 3 cycles on 200 chest compressions with passive oxygen insufflation using airway adjuncts. In addition, patients who have had a witnessed cardiac arrest and an automated external defibrillator (AED) is immediately available then it is reasonable to use the AED as soon as possible. Previous guidelines had suggested that a brief period of chest compression (1.5–3 min) before defibrillation maybe useful.

Though scientific evidence has not shown any difference in clinical outcomes, current guidelines recommend that chest compression should be continued even as the AED is being applied and the AED should be used as early as possible.

Use of Mechanical Devices for Chest Compression

The 2015 guidelines have suggested that when available mechanical compression devices may be used to provide high-quality CPR when performing manual CPR is difficult or impossible (e.g., in a moving ambulance, during PCI, limited rescuers, hypothermic cardiac arrest, prolonged CPR, etc.). However, it should be noted that piston-type devices have not been found to be superior to manual CPR in clinical studies.

Extracorporeal Techniques

Extracorporeal membrane oxygenator (ECMO) may be used as an alternative to conventional CPR in selected patients in whom the cause of cardiac arrest is deemed reversible and when this can be rapidly implemented. Available data is on a very select patient population from limited centers with this expertise. As there are no clinical trials of ECMO in patients with cardiac arrest and this decision needs to be individualized depending upon availability, center expertise, and clinical condition. ECMO allows time to reverse potentially treatable causes during cardiac arrest.

Advanced Cardiac Life Support Monitoring and Pharmacotherapy

Vasopressin

The use of vasopressin (40 units IV or intraosseous) in conjunction with epinephrine in cardiac resuscitation has been dispensed with in the 2015 guidelines as there is no

evidence of benefit in cardiac arrest victims. As the two drugs have equal efficacy, vasopressin has been removed to simplify cardiac arrest care.

Epinephrine

The new guidelines have suggested that epinephrine may be administered as soon as possible after cardiac arrest due to an initial nonshockable rhythm. This is because the results of a clinical study reported improved outcomes in patients who were administered epinephrine at 1 minute and 3 minutes in cardiac arrest due to a nonshockable rhythm.

Lidocaine

Routine use of lidocaine during cardiac arrest due to pulseless ventricular tachycardia or ventricular fibrillation has been removed. However, use of lidocaine in postcardiac arrest care after ROSC remains.

Beta-blockers

An observational study had reported improved outcomes in patients with cardiac arrest due to pulseless VT/VF (ventricular tachycardia/ventricular fibrillation) who were administered beta-blockers. However, at present current guidelines do not recommend routine use of beta-blockers in such cardiac arrest victims. They may however be considered after ROSC in appropriate clinical conditions.

End-Tidal Carbon Dioxide Level

Monitoring of end-tidal carbon dioxide level (ETCO_2) to assess ROSC in intubated patients; conversely failure to achieve ETCO_2 of more than 10 mm Hg in intubated patients even 20 minutes after CPR is considered a poor prognostic marker and may be useful in association with other clinical markers to assess termination of ventilation. It however should not be used in isolation to determine when to terminate resuscitative efforts.

Postcardiac Arrest Care

Coronary Angiography and Acute Coronary Syndrome Assessment

An important change in the 2015 guidelines is the early use of coronary angiography in select patients with cardiac arrest. Patients with electrocardiogram (ECG) evidence of ST elevation on the ECG after cardiac arrest as well as those patients who are electrically unstable but without ST elevation on the ECG in whom cardiovascular disease is suspected should be considered for emergency coronary angiography to rule out acute coronary syndrome as a cause of cardiac arrest.

Targeted Temperature Management

Current guidelines recommend that all comatose adult patients after ROSC following cardiac arrest should be considered for targeted temperature management with a goal to achieve temperatures between 32 and 36°C for at least 24 hours. However, a recent high-quality study did

not report superior outcomes in patients who received temperature management during postcardiac arrest care. Current guidelines are still based on previous studies that found superior outcomes in patients who received targeted temperature management during the postcardiac arrest care.

However, there is no evidence that prehospital cooling of patients after ROSC with IV fluids does not improve outcomes and is not recommended.

Prognostication

Neurologic prognostication of patients who have had poor neurologic outcomes after ROSC is best done 72 hours after cardiac arrest. This is because various drugs used during cardiac arrest including sedatives and neuromuscular blockers may take a prolonged time to clear from the body. Multiple modalities should be used to arrive at a clinical decision as no single method is accurate in predicting clinical outcomes. Poor prognostic markers include absence of pupillary reflex 72 hours after cardiac arrest, status myoclonus in the first 72 hours, marked reduction in gray-white ratio on CT brain within 2 hours of cardiac arrest, absence of electroencephalogram (EEG) reactivity to external stimuli at 72 hours after cardiac arrest, and extensive restriction of diffusion on brain MRI 72 hours after cardiac arrest.

Cardiopulmonary Resuscitation in Special Situations

Pregnancy

The 2015 guidelines have made a significant change in the recommendations on how to perform CPR in pregnancy. These guidelines have recommended just manual left uterine displacement in pregnant women with cardiac arrest if the fundal height is above the umbilicus. This prevents aortocaval compression which may impede venous return during chest compression. The previous guidelines had suggested that a wedge maybe used to tilt the patient to an angle of up to 30° to prevent uterine effect on venous return.

Opioid Overdose

Current guidelines suggest empiric intramuscular or intratracheal administration of naloxone in suspected opioid overdose in patients who are unresponsive and have a definite pulse, but are not breathing or are gasping. These measures should not in any way delay standard resuscitative measures. In patients who have no definite pulse focus should be on standard resuscitation. It may be that some of these patients are in respiratory arrest and not in cardiac arrest with a weak and slow pulse—it may be reasonable to administer naloxone based on clinical suspicion.

Prone Cardiopulmonary Resuscitation

Though not specifically addressed in the 2015 guidelines, when patient have cardiac arrest in prone position, e.g., as in neurosurgical procedures, in road traffic accident victims when it is impossible to switch to a supine position, the only viable option is to perform CPR in prone position. In the

prone position, heart area is maximum behind 1-2 vertebral segments below the inferior angle of scapula. Delivering compression at this location gives adequate hemodynamic results. Defibrillation maybe performed in prone position by placing one of the pads in the left fifth intercostal space in the midaxillary line and the other between the tip of right scapula and the spine.

Ineffectual Therapies

Many therapies during CPR have noted to be ineffective yet continued to be practiced at times. These include the following described here.

Sodium Bicarbonate

Use of sodium bicarbonate during CPR is widely prevalent despite ample evidence to suggest that it does not but may rather impair outcomes in patients with cardiac arrest. Though, it is clinically logical to counteract metabolic acidosis during cardiac arrest with sodium bicarbonate, use of this drug may lead to intracellular acidosis, hypernatremia, and even metabolic alkalosis on recovery from cardiac arrest. The only indication for use of sodium bicarbonate is in patients with cardiac arrest due to hyperkalemia or that occurring due to drug toxicity like tricyclic antidepressants or antiarrhythmic drugs such as flecainide. Many clinicians still support the use of sodium bicarbonate in cardiac arrest especially in those with pre-existing metabolic acidosis ($\text{pH} < 7.10$), clinical outcomes do not support its use.

Magnesium Sulfate

Magnesium sulfate should not be used routinely in patients with VT/VF unless these rhythms result from QT prolongation (acquired or congenital).

Cardiac Pacing

Temporary pacemakers are often inserted during cardiac arrest presenting as asystole. However, pacing is not a recommended technique for CPR as it does not improve outcomes. The only indication for temporary cardiac pacemaker is in cardiac arrest resulting from complete heart block.

Fibrinolysis

Although both myocardial infarction and pulmonary embolism account for a large number of cardiac arrest episodes, fibrinolysis in cardiac arrest has not been shown to improve outcomes. A number of studies including randomized controlled trials have failed to demonstrate any benefit of fibrinolysis. However, it may be useful in some selected patients with suspected pulmonary embolism.

“Cough” Cardiopulmonary Resuscitation

Coughing increases intrathoracic pressure which increases peripheral perfusion pressure. In a monitored condition such as in the cardiac catheterization laboratory a patient with a nonperfusing cardiac rhythm offers a few seconds before he or she losses consciousness. In this period, vigorous coughing

can maintain consciousness for a few seconds and can give time for reversal of cardiac arrhythmia. However, it is not recommended as a method for CPR.

Precordial Thump

A precordial thump is ineffective in majority of cases of malignant ventricular arrhythmias though there are occasional occasions when these arrhythmias may convert to sinus rhythm with thump version. However, it may result in sternal fracture and strokes have been reported as well.

Active Compression–Decompression Cardiopulmonary Resuscitation

This is method of chest compression in which a suction device is used over the chest to convert passive chest recoil into an active mode in order to improve venous return. Preliminary studies in both animals and humans evoked some interest with improvement in some cardiac parameters. However, clinical trials have not found any major advantage of this method in improving patient outcomes. As a result current guidelines have neither supported nor rejected this method of CPR.

Cardiac Implantable Electronic Devices

Improving Outcomes in Patients with Cardiac Resynchronization Therapy

Rohit Malhotra

INTRODUCTION

As patient survival has improved postmyocardial infarction, congestive heart failure (CHF) has become increasingly prevalent. Cardiac resynchronization therapy (CRT) reduces morbidity and mortality in these patients but optimizing therapies in these patients can be challenging. There are well-established guidelines for patients who qualify for CRT and derive the most benefit (Table 1). It is estimated that up to 30% of patients do not respond to therapy.¹ There are a number of approaches to improving outcomes in these patients.

PATIENT SELECTION

Requirements for medical therapy prior to implantation suggest benefits to patients who have taken optimal guideline directed therapy for at least 3 months as medical therapy is the cornerstone for heart failure management in these patients. The first trials examining CRT (COMPANION and CARE-HF)^{2,3} included 1,502 and 813 patients, respectively. In each of these trials, angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) were utilized in roughly 90% of patients. Beta-blockade therapy was utilized in approximately 70% of patients, and spironolactone in about 50%. More recent data, from the DANISH⁴ trial, indicated that 90% of patients received both beta-blockers and ACEI or ARB therapy with 60% receiving mineralocorticoid receptor antagonists. While this trial did not demonstrate a benefit to implantable cardioverter-defibrillator (ICD) therapy, and the impact of CRT was not clear and was not studied, it does demonstrate the increased utilization of medical therapy in patients eligible for these medications. In addition, with the impact of valsartan or sacubitril on patient outcomes, the definition of optimal medical therapy becomes more nebulous. In summary, optimal medical therapy is defined by the implanting physician and not specifically by medications being utilized.

The QRS duration is a large determinant of patient responsiveness to CRT. Recent American^{5,6} and European⁷

guidelines differ from prior guidelines, changing the class I indication for CRT implantation from more than or equal to 120 ms⁸ to more than or equal to 150 ms (Table 2). While QRS duration is the cornerstone of guidelines for CRT therapy, there is a lot of controversy regarding response to therapy in left bundle branch block (LBBB) and non-LBBB patients.

The predominance of these data arises from differences in outcomes in patients with LBBB and non-LBBB. Mechanistically, earliest electrical activation of the left ventricle in non-LBBB patients is at the septum⁹ with the free wall of the right ventricle (RV) contracting last. However, if there are issues with conduction in the left ventricle, such as fascicular blocks, patients may have some benefit from left ventricular (LV) lead implantation, though these data are less clear. For example, Chandra et al.¹⁰ demonstrated that patients with RBBB and fascicular block had better outcomes as assessed by New York Heart Association (NYHA) class or an improvement of more than or equal to 5% in ejection fraction. Varma¹¹ demonstrated that the initiation of QRS deflection and time to basal lateral LV depolarization correlated with QRS duration, suggesting that those patients with significantly prolonged QRS duration may have more benefit from CRT. While these studies suggest that patients with non-LBBB may benefit from CRT, other data are contradictory. However, analysis of MADIT-CRT indicates that while patients with left anterior hemiblock on ECG may have improvement in echocardiographic parameters such as LV end systolic volume, end diastolic volume, and left atrial volume, survival did not differ.¹²

Furthermore, this change is based upon the data from multiple studies, including analysis of echocardiographic dyssynchrony in patients with prolonged QRS durations.¹³ This study indicates that QRS duration does not correlate with the area of mechanical dyssynchrony. Analysis of large population post-CRT implantation with non-LBBB indicates that outcomes did not improve post-CRT implantation and were actually worse.¹⁴ Thus, while echocardiographic

TABLE 2: European guidelines for the year 2016

European guidelines	2016
Class I with evidence level A	CRT indicated for: <ul style="list-style-type: none"> Symptomatic patients with EF $\leq 35\%$ and CHF in normal sinus rhythm with QRS duration ≥ 150 ms and LBBB morphology despite optimal medical therapy (OMT) CRT rather than RV pacing recommended for patients with heart failure with reduced EF and indication for ventricular pacing
Class I with evidence level B	CRT considered for patients: <ul style="list-style-type: none"> Symptomatic patients with EF $\leq 35\%$ and CHF in normal sinus rhythm with QRS duration between 130 and 149 ms and LBBB morphology despite OMT
Class IIa evidence level B	CRT should be considered: <ul style="list-style-type: none"> Symptomatic patients with CHF in sinus rhythm with QRS ≥ 150 ms and non-LBBB pattern with EF $\leq 35\%$ Symptomatic patients with CHF in sinus rhythm with QRS between 130 and 149 ms and non-LBBB pattern with EF $\leq 35\%$ EF $\leq 35\%$ with NYHA class III or IV CHF despite OMT if they have atrial fibrillation and QRS duration ≥ 130 ms with a strategy to induce pacing or restoration of sinus rhythm is anticipated
Class IIb evidence level B	CRT may be considered for: <ul style="list-style-type: none"> Patients symptomatic with CHF with QRS between 130 and 149 ms and non-LBBB pattern with EF $\leq 35\%$ despite OMT Patients with existing pacemaker or ICD with worsening CHF despite OMT and have a high-proportion of RV pacing may be considered for upgrade to CRT
Class III	CRT contraindicated in patients with QRS duration < 130 ms

CRT, cardiac resynchronization therapy; CHF, congestive heart failure; EF, ejection fraction; ICD, implantable cardioverter-defibrillator; LBBB, left bundle branch block; NYHA, New York heart association; RV, right ventricular.

or electrocardiographic parameters may improve post-CRT implantation, survival may not improve. As a result, indications for CRT implantation have changed (Fig. 1). While non-LBBB patients are not excluded, these patients are most likely to benefit if the QRS duration is long.

Studies of CRT implantation¹⁵ in patients with echocardiographic dyssynchrony but with QRS duration less than 130 ms do not demonstrate benefit. In this study, which terminated early due to futility of therapy, 809 patients with class III or IV CHF and ejection fraction of 35% or less with LV

aVR, augmented vector right; aVL, augmented vector left; aVF, augmented vector foot.

FIG. 1: A, Preimplantation ECG; B, Post-cardiac resynchronization therapy (CRT) implantation ECG; C, Post CRT implantation ECG with altered left ventricular and right ventricular timing.

dyssynchrony demonstrated by echocardiography underwent CRT implantation with a 1:1 randomization to either CRT therapy or no CRT therapy, if the LV lead was successfully implanted. Dyssynchrony was defined by tissue Doppler with opposing wall delay of 80 ms or more in apical four-chamber view or apical long-axis views or by speckle tracking analysis of radial strain of the anteroseptal to posteroseptal walls of 130 ms or more in the short-axis view. Patients were followed every 3 months. The primary outcome was death or first CHF hospitalization. Unfortunately, the study was stopped early due to a potential for harm. In total, 1,680 patients were consented, but due to lack of echocardiographic dyssynchrony, 602 were excluded. There was no difference in death from any cause or first CHF hospitalization between groups.

Some studies do indicate that QRS duration may not alone predict a favorable response. A number of studies have analyzed QRS duration relative to body surface area, body mass index, or LV mass and have demonstrated CRT benefit even in patients with QRS durations less than 150 ms.¹⁶⁻¹⁸ These studies suggest that smaller patients, particularly women, may benefit from CRT at shorter QRS durations. However, these studies have not been sufficient to alter current guidelines for CRT.

PREPROCEDURE PLANNING

In clinical practice, QRS duration is the predominant predictor of benefit from CRT implantation, though calculators do exist that may predict outcomes postimplantation.¹⁹ However, in trying to determine factors that may contribute to response to therapy, a number of approaches have been undertaken, including echocardiographic and magnetic resonance imaging (MRI)-based evaluation.

Echocardiography is a widely available and inexpensive method to assess baseline ejection fraction. For example, analysis of echocardiography pre- and postimplantation demonstrated that patients who responded to therapy had improvement in lateral and anteroseptal activation while nonresponders did not (Auger). Unfortunately, this analysis does not help with prediction of response to CRT implantation. However, it may provide insight into where to implant leads.

More advanced echocardiographic techniques, such as speckle tracking, have been utilized to assess response to therapy. Prior trials have attempted to predict response to therapy, and they have not demonstrated power to predict response based upon one echocardiographic parameter.²⁰ This trial evaluated regional strain and was unable to identify a predictor of response, which was in part attributed to variability in interpretation. In order to predict responses to therapy, Park et al.²¹ developed a score using a combination of LV global longitudinal strain (LVGLS), end diastolic dimension, left atrial area, RV end diastolic area, right ventricular fractional area change (defined as the percentage change in right ventricular end diastolic and end-systolic areas), and right atrial area that predicted response to therapy. The higher the score, the better the outcome, independent of

clinical factors such as age, gender, baseline functional class, and heart failure etiology. However, performing this difficult analysis is not often undertaken in clinical practice given the complexity.

Another study²² examining speckle tracking suggests that strain offers prediction of clinical outcome as defined by time to death, LV assist device implantation, or transplant. However, this single center study does note that performing a portion of the analysis (global circumferential strain) is more dependent upon the skills of the sonography and the interpretation, complicating the generalizability of this approach.

Additionally, speckle tracking has been utilized to aid in LV lead implantation at the time of the procedure.²³ In this study, a double-blinded approach to echocardiographic LV lead implantation was performed over the course of 6 years, from 2005-2011 in 187 total patients, with 110 undergoing echocardiographic guidance. Speckle tracking echocardiography was performed prior to the procedure, and the areas of latest activation designated. LV leads were implanted in areas closest to the area of latest activation based upon the left anterior oblique fluoroscopic view in echocardiographically-guided patients and placed routinely in a lateral or posterior position in control patients, regardless of activation site. Patients with leads implanted at the site of latest activation had significantly better outcomes with fewer hospitalizations in the echocardiogram-guided implant group and an overall 26% reduction in events in the intervention group. However, while outcomes were better in this group, the intervention is cumbersome and expensive, particularly, since 66% of patients in the control group had LV lead placement in the site of latest mechanical activation, suggesting that performing speckle echocardiography prior to implantation would likely be costly to perform in all patients. Cost analysis was not performed in this study, but this practice has not become a part of routine clinical care.

Finally, MRI has been utilized to assess scar, mechanical, and electrical properties at the site of LV lead placement.²⁴ Using displacement encoding with stimulated echoes (DENSE), a technique that allows for strain assessment without the potentially subjective and operator dependent aspects of echocardiographic speckle tracking coupled with an algorithm to evaluate the time to regional peak strain, analysis of patients who underwent CRT implantation was performed to determine CRT response. Of the parameters compared, including lead not in scar, stretch at the LV lead position, and time from QRS onset to the electrogram at the lead position, the time to regional peak strain was most predictive of response to therapy. However, much like speckle tracking, this technique involves a costly test prior to device implantation.

A final approach to optimal placement of LV leads is to seek out longest time from onset of QRS to the electrogram at the site of the LV lead, also called QLV. A substudy of the SMART-AV trial, which examined atrioventricular (AV) optimization techniques in patients with CHF undergoing CRT implantation, evaluated the effect of QLV on outcomes. In this study, Gold et al. compared the QRS and the RV and

LV lead electrograms, allowing measurement of the QLV. A total of 426 patients were analyzed. Those patients with a QLV longer than the median had better outcomes overall as assessed by LV end systolic volume, end diastolic volume, ejection fraction, and quality of life. However, QRS duration did not correlate with QLV.

While preprocedural imaging with MRI or echocardiography can identify areas of dyssynchrony, incorporating this testing into routine clinical practice can be costly and potentially not helpful. Examination of QLV can be helpful in predicting a favorable response and can potential direct implanting physicians to the ideal location for lead placement and pacing. This technique can be used at the time of the procedure, unlike the preprocedural imaging.

Lead Implantation

Coronary sinus leads are placed via a guiding sheath that allows for implantation of the lead. Commonly, the left anterior oblique cinefluoroscopy is utilized to identify coronary sinus branches and their locations (anterior or posterior/inferior).²⁵ Unfortunately, endovascular lead implantation is limited to the available anatomy, which may lead to implantation of LV leads in areas of scar, and thus, poor response and high thresholds. In addition, pacing energy can lead to stimulation of the phrenic nerve, resulting in significant patient discomfort. Furthermore, LV leads do not have any support and sit in a large pool of blood in the coronary sinus vein. As a result, some areas of the lead may be close to ventricular myocardium and others far away, potentially impacting the amount of energy required to pace the left ventricle. The quadripolar LV lead was designed to combat these issues.

Prior generation LV leads were capable of unipolar or bipolar pacing, exposing patients to the noted risks. Quadripolar leads have four pacing electrodes with variable spacing, depending upon manufacturer. In addition to allowing for variable pacing vectors which may reduce pacing threshold and help reduce the risk of phrenic nerve capture, these leads allow for changes in pacing vector over the duration of device implant. If there is a small movement in the lead, lead repositioning can be avoided in many cases. In addition, if the heart configuration changes, such as due to response to LV pacing and reduction in LV volume, pacing poles can be altered to help maintain battery longevity and to avoid phrenic nerve stimulation if this should become an issue. Furthermore, given the data on QLV, current devices can give automated read-outs on the timing differential between RV and LV electrogram timing, potentially allowing for pacing at the longest QLV.

Additionally, quadripolar leads allow for multipoint pacing (MPP). When utilized in this configuration, pacing can occur at two different LV sites. There may be benefits to this type of pacing configuration, if there are areas of scar that lead to delay in signal conduction through the left ventricle.²⁶ To maximize the possibility of simultaneous LV depolarization despite areas of slowed conduction that may limit response to CRT, these devices can be programmed to pace at different points. Niazi

et al.²⁷ demonstrated safety and efficacy of this technology in 2017. In this Investigation Device Exemption (IDE) trial, indicated patients underwent implantation of CRT devices. At 3 months postimplant, patients underwent echocardiographic analysis, with particular emphasis on velocity-time integral of the transmural flow (EA VTI) as this parameter most closely replicates dP/dt_{max} , which has been documented to best assess hemodynamic response to CRT, and those patients who had the best response to MPP in various configurations were randomized to biventricular pacing or MPP. MPP was programmed per investigator discretion. Subsequently, analysis was performed on which programming performed best in terms of clinical response, and those patients who were programmed to pace at points of maximal anatomic separation with short pacing delay between electrodes had significantly better clinical outcomes than those programmed to other configurations. Furthermore, patients who were nonresponders to CRT had a significant improvement with MPP activated. This technology holds promise for improving outcomes in nonresponders. Integration of imaging techniques such as MRI and speckle tracking may further improve response to therapy.

Noncoronary Sinus Left Ventricular Pacing

Unfortunately, while successful implantation rates of LV leads has increased overtime, there is up to a 20% rate of LV lead implantation failure.²⁸ There are a number of reasons that coronary sinus leads cannot be implanted, such as poor venous targets, lack of coronary sinus access, and scar in areas near the coronary sinus. As a result, alternative approaches to LV pacing have been developed.

First, for patients with poor vascular targets in the coronary sinus, venoplasty, and snares have been used to improve lead delivery. For example, Worley et al.²⁹ described a technique where the coronary sinus is cannulated. A long wire is delivered to the vein, and the end of the wire snared. This loop of wire, with both ends controlled outside the body, allows the lead to be advanced to targeted vessels, even when they are small. In addition, techniques to venoplasty small veins to facilitate lead implantation have been utilized. Hesselson et al. describe a single center experience of this technique in 47 patients over 12 years. Using the guiding sheath size as a gauge for measurement of angioplasty balloon, veins were dilated to allow lead passage beyond valves, to small vessels, and past focal stenoses. In this series, there was a 77% success rate though others have described 88–99% success rates. Unfortunately, Worley et al. have also describe coronary sinus vein rupture related to venoplasty, so this technique must be used with appropriate caution. The patient described was able to have the LV lead implanted. These techniques have been used in combination to assist in LV lead delivery.

For patients in whom the coronary sinus is not identified, surgical LV lead implantation has also been utilized to surmount issues with coronary sinus lead implantation. There are a number of different approaches to surgical LV lead implantation,³⁰ including left thoracotomy and thoracoscopic approaches, both with video assistance or

without. There are data that suggest that patients did not do as well with surgically placed leads, predominantly due to anterior LV implantation. However, more recent data indicate that patients post epicardial lead implantation have similar outcomes to endovascularly placed leads, though the initial recovery period has higher morbidity.³¹ Recovery in these patients can be prolonged, and due to poor LV function, the surgical risk is high.

Recent advances in His bundle pacing tools have led to an increased usage of His bundle pacing, and this approach may become an option for management of patients with unsuitable anatomy for LV lead implantation. Pacing from the His bundle position can lead to QRS narrowing, even in patients with underlying bundle branch block. Placing leads in this position is technically challenging, with higher outputs required to maintain His bundle capture, and is thus not performed standardly. Lustgarten et al.³² implanted standard CRT devices with both a LV lead and a lead in the His bundle position. Patients who had narrowing of QRS due to His bundle pacing were then randomized to undergo either biventricular pacing or His bundle pacing for 6 months. After 6 months, patients were crossed-over to the alternate therapy. Ultimately, 12 patients completed the protocol. In both groups, there was an improvement in quality of life, ejection fraction, and NYHA class. Echocardiographic parameters were not significantly different from baseline in either group. This approach allows for alternative pacing sites in patients where coronary sinus leads cannot be implanted due to anatomy, high pacing thresholds due to LV scar, or phrenic nerve stimulation.

Finally, there are data to suggest that endocardial pacing of the left ventricle may have more benefit than epicardial pacing.^{33,34} As a result, and in the setting of poor coronary sinus options, an endocardial approach has been attempted in some patients. These leads have been placed in the left ventricle via either transatrial septal, transventricular septal, or trans-ventricular apical techniques. Response rates to these approaches are not as high as with conventionally placed LV leads. However, due to surgical risk and the difficulty of placing surgical LV leads on the posterior aspect of the heart, these patients underwent these types of procedures. There is also an increased rate of stroke and transient ischemic attacks in these patients due to the need for anticoagulation related to endovascular leads in the arterial circulation. There is limited experience with these types of leads, and refinements of both implant techniques and ventricular locations will develop, with likely improvements in outcomes. In fact, new technologies using an endovascular pacing approach are in development and have been recently tested in a trial intended to assess feasibility and safety.³⁵ In this nonrandomized trial, 34 of 35 patients had a novel endocardial LV pacing system implanted. In this system, an ultrasound receiving electrode is placed endocardially in the LV via a retrograde aortic approach and a transmitter that emits focused ultrasound to the receiver to induce pacing is placed subcutaneously in the 4th to 6th intercostal space lateral to the parasternal border. The transmitter requires a direct line of site view to the receiver, without lung or bone intervening. This transmitter

is attached to a battery supply that may be placed up to 30 cm away. The transmitter senses pacing signals from an existing RV pacing device (either a pacemaker or ICD) that prompts LV pacing that will occur 3–5 ms post RV pacing. Endpoints in the study included demonstrated biventricular pacing at 1 and 6 months. This endpoint was achieved in 33 out of 34 patients at 1 month and 31 out of 33 at 6 months with the absence of biventricular pacing in 2 patients due to transmitter failure that improved with transmitter replacement. Approximately, 66% of patients had improvement in clinical parameters (improvement in NYHA class ≥ 1 and improved quality of life scores. Unfortunately, 3 patients had complications related to implantation, with one dying 4 days postimplantation after suffering ventricular fibrillation during endocardial receiver implant and the other two having arterial issues. With the potential freedom to place the endovascular pacing element in very targeted locations, the data gleaned from the speckle-tracking or MRI-based methods discussed may provide insight on exactly where to pace the left ventricle for maximal patient benefit.

Postimplant Programming

Postimplantation, device programming can impact response to therapy. In 2010, Ellenbogen et al. examined 3 approaches to AV timing intervals. The 980 patients enrolled were randomized to either a fixed AV delay of 120 ms, echocardiographically optimized AV delays, or an algorithm designed to optimize AV delays based upon the initial AV interval and QRS duration. The primary end point of this trial was LV end systolic volume with secondary end points of NYHA class, Quality of life based upon survey analysis, 6 minute walk distance, LV end-diastolic volume, and ejection fraction. Patients enrolled in the trial had class III to IV CHF based upon NYHA classification, ejection fraction less than or equal to 35%, and QRS duration of more than or equal to 120 ms. Patients in the algorithmic arm had programming performed at randomization (1–14 days postimplantation) and then again at 3 months post reprogramming. Unfortunately, this trial demonstrated that there was no difference in setting a fixed AV timing delay of 120 ms, echocardiographic timing of AV-delays, or the algorithmic approach.

While this trial demonstrated no difference in the algorithm based approach with reprogramming performed again 3 months postimplantation of the device, the FREEDOM trial was intended to analyze more frequent reprogramming of AV delays. This trial, presented only in abstract form, did not demonstrate significant improvements in LV ejection fraction, quality of life, or other echocardiographic parameters. In addition, a number of trials have examined RV and LV timing, and no significant clinical differences have been noted in outcomes. Thus, interest in avoiding RV pacing has evolved.

More recently, attention has been directed to pacing the left ventricle rather than pacing both the right and left ventricle, thus relying on intrinsic depolarization of the RV. Small scale studies have demonstrated that RV function is improved in patients if intrinsic RV conduction is relied upon³⁶ rather than RV pacing. Furthermore, LV pacing has been

demonstrated to have a positive effect on ejection fraction.³⁷ These data were integrated and applied to a larger population as described by Martin et al.³⁸ In this study, 522 patients were randomized to conventional echocardiographic optimization of biventricular pacing versus pacing using an algorithm designed to pace the left ventricle when the AV interval is normal, and to pace both ventricles if the AV interval is prolonged. This algorithm periodically assesses conduction and alters pacing based upon the sensed results. Patients enrolled had NYHA Class III or IV symptoms, ejection fraction more than or equal to 35%, and QRS duration more than or equal to 120 ms. There were three primary endpoints. The first was a commonly utilized clinical composite score where patients can be defined as worse, unchanged, or better depending upon death, hospitalization, NYHA class, and other clinical parameters. The second was that the aortic velocity time integral (AoVTI) was greater than 0.82 in both the echo-optimization group and the algorithm group. The third endpoint was to evaluate the safety of dynamic programming adjustment. Patients who had changes in either the AV delay or the ventricle to ventricle delay of greater than 60 ms in a 28 day period were reviewed in an unblinded fashion. The adaptive algorithm was deemed noninferior to echocardiographic programming in terms of clinical composite score. AoVTI in each group was not significantly different in each group, and the programming changes did not exceed 60 ms in the adaptive group in any patient in any month, suggesting safety of this algorithm.

CONCLUSION

Cardiac resynchronization therapy has evolved significantly in the time since this approach to management of patients with heart failure was devised. Approaches to LV pacing, from interventional approaches to coronary sinus lead implantation, endocardial pacing, and His bundle pacing provide physicians and patients with a number of different options to help with resynchronization. Furthermore, for leads that are successfully implanted in the coronary sinus, quadripolar LV leads offer options to lower pacing thresholds and prolong battery life. In nonresponders, MPP provides options for pacing that may help improve symptoms. Imaging techniques that are being pioneered now may help with future approaches to providing synchronization by helping to direct placement of endocardial pacing electrodes.

CRT-D versus CRT-P—What should be the Standard of Care in Nonischemic Cardiomyopathy?

TS Kler, Avinash Verma

INTRODUCTION

There are two ways to interpret the new data that has emerged from the recent trials of patients of cardiac resynchronization in heart failure (HF) due to nonischemic dilated cardiomyopathy (NICM). One and more direct way to look, it will be as further evidence in the series of evidence that addition of implantable cardioverter defibrillator (ICD) therapy in HF patients due to NICM is of little value. However, as with most things in medical research, the result should be interpreted for and hence applied to the specific subset of patient population. That is the second, and the correct way of looking the results of DANISH trial.¹ DANISH trial asked a specific question, i.e., Does adding ICD therapy over and above of Guideline Directed Medical Therapy (GDMT), including cardiac resynchronization therapy (CRT) provide any incremental benefit? The answer was "No". This result cannot, and should not, be generalized to include NICM patients not receiving CRT therapy.

As we can see there are two separate questions about usefulness of ICD in NICM patients.

1. Does ICD therapy provide survival benefit in patients of NICM in current medical era?
2. Does addition of ICD therapy to CRT provide additional survival advantage?

The DANISH investigators wanted answers for the first question. However, by trial design 323 out of 560 (57.7%) patients in control group and 322 out of 556 (57.9%) patients in the ICD group had CRT device implanted. Therefore, by trial design the DANISH study answers the second question.

Hence, one thing should be clear, DANISH study did not provide any evidence to withhold ICD therapy in patients of NICM with narrow QRS. They still qualify for ICD therapy for prevention of sudden cardiac death (SCD). As per current guidelines, ICD should be prescribed to the NICM patients [class 1 recommendation Level of Evidence A as per American College of Cardiology (ACC) and Level of Evidence B as per European Society of Cardiology (ESC)].

Now the question which remains is whether in patients with NICM who are eligible for CRT, does addition of ICD provide any incremental benefit? Let's examine the available body of data.

BURDEN OF SUDDEN CARDIAC DEATH IN NICM

To date, no single randomized trial has demonstrated that ICD implantation for primary prevention has a significant effect on overall mortality in patients with NICM (Table 1), and only the Sudden Cardiac Death in Heart Failure (SCD-HeFT) trial demonstrated a mortality benefit in a group that included both ICM and NICM patients.² However, many meta-analysis (Table 2), many of which included the recent DANISH study, have shown that all the studies combined to give an evidence base that ICD is beneficial for primary prevention of SCD in NICM and HF.²

Burden of Sudden Cardiac Death in Presence of CRT

Drug therapy, ICD, and CRT are all available modalities to treat HF in present era and to reduce HF symptoms and risk of SCD. Each treatment given according to GDMT reduces all-cause mortality by approximately 15–35%. However, the mortality reduction, by guideline-directed medical therapy (GDMT) and HF devices, varies for different modes of death. ICD is a very specific therapy which provides protection only against SCD in HF patients. Unlike CRT, it does nothing to the disease progression, symptoms, and deaths related to pump failure.

Cardiac resynchronization therapy on the other hand has more profound effect on HF disease progression. It works by remodeling the heart and in effect it can potentially lift the patient out of high-risk with low ejection fraction (EF) bracket to the low risk with higher EF category. It has been postulated that by this disease modifying and remodeling effects, CRT

TABLE 1: Randomized control trials on primary prevention implantable cardioverter defibrillator in nonischemic dilated cardiomyopathy patients

Study year published	Total no. of patients, N (ICD/MT)	Follow-up period (years)	Inclusion criteria	Design of the study	Death from any cause with event rate
CAT 2002 ³	104 (50/54)	1.9	NICM EF ≤30% NYHA II–III	ICD vs. medical therapy	Early termination of the study
AMIOVIRT 2003 ⁴	103 (51/52)	2	NICM EF ≤35% NYHA I–III NSVT	ICD vs. medical therapy	Early termination of the study
DEFINITE 2004 ⁵	458 (229/229)	2.4	NICM EF <36% NYHA I–III PVCs or NSVT	ICD vs. medical therapy	<ul style="list-style-type: none"> • ICD: 12.2% • Medical therapy: 17.4% • HR, 0.65 • 95% CI, 0.40–1.06 • p = 0.08
SCD-HeFT 2005 ⁶	1211 (398/394/419) (NICM subgroup)	3.8 (median)	ICM or NICM EF ≤35% NYHA II–III	ICD vs. amiodarone vs. medical therapy	<ul style="list-style-type: none"> • ICD: 21.4% • Medical therapy: 27.9% • HR, 0.73 • 95% CI, 0.50–1.07 • p = 0.06
COMPANION 2004 ⁷	397 (270/127) (NICM subgroup)	1.3 (median)	ICM or NICM	CRT-ICD vs. CRT vs. medical therapy	<ul style="list-style-type: none"> • HR, 0.50 in favor if CRT-ICD group in NICM patients • 95% CI: 0.29–0.88 • p = 0.015 • CRT-ICD vs. CRT only: • p = 0.12
DANISH 2016 ¹	1116 (556/560)	5.6 (median)	NICM EF ≤35% NYHA II–III NYHA IV if CRT NT-pro-BNP >200	ICD vs. medical therapy including CRT	<ul style="list-style-type: none"> • ICD: 21.6% • Medical therapy: 23.4% • HR, 0.87 • 95% CI, 0.68–1.12 • p = 0.28

CI, confidence interval; CRT, cardiac resynchronization therapy; EF, ejection fraction; HR, hazard ratio; ICD, implantable cardioverter defibrillator; MT, medical therapy; NICM, nonischemic dilated cardiomyopathy; ICM, ischemic cardiomyopathy; NT-proBNP, N-terminal prohormone of brain natriuretic peptide; NSVT, nonsustained ventricular tachycardia; NYHA, New York Heart Association; PVCs, premature ventricular contractions.

may also reduce risk of malignant ventricular arrhythmias. At 12-month follow-up in MADIT-CRT, 85% of the patients with CRT had left ventricular ejection fraction (LVEF) greater than 35% with significantly lower risk of ventricular arrhythmias compared to those with EF less than 35%.¹⁷

The CARE-HF (Cardiac Resynchronization-Heart Failure) extension phase study also suggested that CRT pacing, without an ICD function, could reduce the rate of sudden death [54 vs. 32 or 4.3% vs. 2.5% per annum; hazard ratio (HR) 0.54, 95% confidence interval (CI): 0.35–0.84, p = 0.005].¹⁸ Similarly in the COMPANION study, the mortality with CRT alone vs a CRT defibrillator was similar after 2 years of follow-up.⁷

It can thus be inferred that the ability of CRT to reduce sudden death is probably delayed and possibly dependent on improvements in cardiac function and positive ventricular remodeling. Therefore, the inclusion of CRT patients in a study evaluating the impact of ICDs on mortality and SCD may impact the potential benefit of ICD therapy.

CRT-D IN NICM—LACK OF BENEFIT IS CONSISTENT

In an observational study by Martens et al, during a mean follow-up of 38 ± 22 months, five patients with cardiac resynchronization therapy pacemaker (CRT-P) (1.4%) experienced an episode of ventricular tachycardia with syncope whereas in patients with primary prevention cardiac resynchronization therapy defibrillator (CRT-D) with a nonischemic etiology the rate of appropriate therapy was 3.5% per patient year.¹⁹ In comparison in the same study, the patient's primary prevention CRT-D with an ischemic etiology the rate of appropriate therapy was 6.7% per patient year.¹⁹

This observation of less arrhythmia burden in NICM as compared to ICM in equally diseased heart is very important and is a consistent observation. In an interesting study, Shadman et al. found a higher risk for SCD in patients with ICM in their proportional hazards model.²⁰

TABLE 2: Recent systematic reviews and meta-analysis of implantable cardioverter defibrillator for primary prevention in nonischemic dilated cardiomyopathy

Study year	No. of trials	Total no. of patients (ICD/MT)	Primary end-point all-cause mortality (in favor of ICD arm)	Sudden death	Summary
Al-Khatib et al. 2017 ⁸	4 (CAT, DEFINITE, SCD-HeFT, DANISH)	1874(937/937)	HR, 0.75 95% CI 0.61–0.93 p = 0.008	N/A	Primary prevention ICDs are efficacious in reducing all-cause mortality in NICM
Narayanan et al. 2017 ⁹	6 (CAT, AMIOVIRT, DEFINITE, SCD-HeFT, COMPANION, DANISH)	2347(962/1385)	RR, 0.76 95% CI 0.63–0.91; p = 0.003	RR, 0.27 95% CI 0.15–0.50 p <0.001	ICDs associated with 24% reduction in all-cause mortality and 73% reduction in SCD in non-CRT patients
Golwala et al. 2017 ¹⁰	6 (CAT, AMIOVIRT, DEFINITE, SCD-HeFT, COMPANION, DANISH)	2970	HR, 0.77 95% CI 0.64–91	N/A	Meta-analysis of all published RCTs to date shows significant clinical benefit on primary prevention ICDs on all-cause mortality in patients with NICM
Kołodziejczak et al. 2017 ¹¹	5 (CAT, AMIOVIRT, DEFINITE, SCD-HeFT, DANISH)	2992(1284/1708)	HR, 0.81 95% CI 0.72–0.91 p = 0.006	HR, 0.44 95% CI, 0.17–1.12 p = 0.064	ICD therapy associated with statistically significant reduction in all-cause mortality along with numerical trend in the same direction in case of sudden death
Barakat et al. 2017 ¹²	5 (CAT, AMIOVIRT, DEFINITE, SCD-HeFT, DANISH)	2573(1284/1289)	HR, 0.79 95% CI 0.64–0.93 p <0.001	RR, 0.47% 95% CI, 0.30–0.73 p = 0.001	Primary prevention ICD is associated with significant reduction in all-cause mortality in NICM patients
Stavrakis et al. 2017 ¹³	6 (CAT, AMIOVIRT, DEFINITE, SCD-HeFT, COMPANION, DANISH)	2967 (1553/1414)	HR, 0.78 95% CI, 0.66–0.92 p = 0.003	N/A	Primary prevention ICD is associated with 22% significant reduction in all-cause mortality in NICM patients

Source: Adapted from Ganga HV, Maan A, Kevin Heist E. Should Primary Prevention ICDs Still Be Placed in Patients with Non-ischemic Cardiomyopathy? A Review of the Evidence. *Curr Cardiol Rep.* 2018;20(5):31.

In a 2017 large observational study in Europe Barra et al.²¹ after a mean follow-up period of 41.4 ± 29.0 months, in patients with NICM no difference in survival was observed when receiving CRT with a defibrillator compared with those who received CRT without a defibrillator (HR for mortality adjusted on propensity score and all mortality predictors: 0.92; 95% CI: 0.73–1.16; p = 0.49). Compared with recipients of defibrillators, the excess mortality in patients who did not receive defibrillators was related to SCD in 8.0% among those

with ICM but in only 0.4% of those with NICM.²¹ Similarly, in a study of 1,122 patients Kutyifa et al. reported there was no mortality benefit of CRT-D over CRT-P in NICM patients (HR 0.98; 95% CI: 0.73–1.32; p = 0.894, interaction p value = 0.15).²²

Other putative reason for lack of benefit of CRT-D over CRT-P in NICM as compared to ICM may be that NICM are better responders to CRT than ICM. MADIT-CRT and CARE-HF both showed that NICM were more favorable responders to CRT.²³ In their review article Yokoshiki et al. have shown

CONCLUSION

Based on all the above evidence we can come to a reasonable conclusion about whom to give CRT-D in NICM. Routine use of CRT-D for primary prevention of SCD in elderly NICM patient with low expected survivability has not been proven effective and should not be done. Younger patients of NICM, particularly those having LV midwall fibrosis should be given benefit of SCD prevention by ICD or CRT-D.

ICD in HFrEF—When are They not Needed?

Rajnish Sardana, Praloy Chakraborty

INTRODUCTION

In the initial era, automatic implantable cardioverter defibrillator (AICD) implantation was primarily considered for secondary prevention of sudden cardiac arrest or hemodynamically unstable ventricular arrhythmias. With time, the concept of primary prevention evolved. Patients with heart failure and reduced ejection fraction (HFrEF, both ischemic and nonischemic) carries substantial risk of sudden cardiac death. Eight large randomized trials have evaluated the use of implantable cardioverter defibrillators (ICDs) in patients at risk of sudden cardiac death due to heart failure (HF) or left ventricular (LV) dysfunction (Table 1). Based on results of these trials, current guidelines (both American¹ and European²) consider AICD implantation, in large subset of HFrEF patients, as Class I indication for primary prevention. However, that does not justify AICD implantation in all patients in this group. In certain subsets in this group of patients, AICD implantation is not justified on the basis of evidence-based practice.

EARLY AFTER MYOCARDIAL INFARCTION

The risk of sudden cardiac death (SCD) is highest immediately after acute myocardial infarction (AMI). In the Valsartan in Acute Myocardial Infarction Trial (VALIANT), risk of sudden death was highest in the first 30 days after a myocardial infarction (MI).³ Multicenter Automatic Defibrillator Implantation Trial II (MADIT-II) trial clearly demonstrated mortality benefit with AICD in patients after acute MI⁴ [The study population included patients with an MI >1-month from study entry and an left ventricular ejection fraction (LVEF) ≤0.30]. Looking at the highest risk of SCD in early post MI and benefits of ICD therapy in post-AMI LV dysfunction, it seems that ICD implantation will be beneficial to prevent SCD in immediate post-MI period. However, Defibrillator in Acute Myocardial Infarction Trial (DINAMIT) and IRIS trial failed

to demonstrate benefit of ICD implantation within 30–40 days after MI. DINAMIT trial included patients within 6–40 days of AMI. AICD implantation in this group reduced the incidence of arrhythmic death [95% confidence interval (CI) 0.22–0.83; p = 0.009] but the benefit was offset by an increased incidence of nonarrhythmic death; thus, overall survival was not improved.⁵ IRIS trial enrolled patients within 1-month of MI and once again there was a 45% lower risk of sudden arrhythmic death in the ICD group. However, this lower risk was offset by a significantly increased risk of nonarrhythmic death (p=0.001).⁶ Evaluation of autopsy records demonstrated that in the 1st month after AMI, 80% of sudden deaths were due to mechanical complications like myocardial rupture and only 20% were attributed due to arrhythmic death.⁷ By 1 year, the proportions of sudden deaths due to nonarrhythmia versus arrhythmia causes were equal and over time there appeared to be a very gradual increase in the proportion of sudden deaths due to arrhythmia (approximately 60% at 30 months). Recurrent ICD shocks can result in injury to the myocardium, and that ventricular function can be further impaired as a consequence of backup ventricular pacing, thus increases the nonarrhythmic mortality due to pump failure and cardiogenic shock.^{5,6} Analysis of 16,793 patients⁸ who were referred to the cardiac catheterization laboratory for acute management of MI, found that a 90-day cardiovascular mortality rate of 9%, out of which 75% of the deaths were due to coronary artery disease (CAD) related nonsudden death, 9% CAD-related sudden death, and 4% due to sudden death not related to CAD.

Aggressive therapy to reduce the risk of sudden cardiac death in the early period after MI directed toward revascularization and improvement in LV function and clinical HF can be a more prudent and effective strategy as compared with early ICD implantation. As per current guidelines implantation of an ICD is not recommended within the first 40 days after the MI. However, ICD implantation in patients within 40 days of AMI is justified in any of following conditions.¹¹

TABLE 1: Major randomized controlled trials of AICD in primary prevention in heart failure with reduced ejection fraction

Name of trial	Etiology of heart failure	Early after AMI	Early after revascularization	Early after diagnosis of NICM	Specific inclusion criteria	Result
Multicenter Automatic Defibrillator Implantation Trial (MADIT) ¹⁰	Ischemic	No	No	N/A	LVEF <35%, NSVT, inducible nonsuppressible sustained VT/VF at EPS	Mortality benefit with ICD
Coronary Artery Bypass Graft (CABG) Patch Trial ¹¹	Ischemic	No	Yes	N/A	LVEF ≤0.35, abnormal SAECG, undergoing CABG	No mortality benefit with ICD
Multicenter Unsustained Tachycardia Trial ¹²	Ischemic	Yes	Yes	N/A	EF ≤0.40 • NSVT within the last 6 months • ≥4 days post-MI or revascularization	Risk of sudden death reduced in patients with ICDs
Multicenter Automatic Defibrillator Implantation Trial-II (MADIT-II) ⁴	ischemic	No	No	N/A	EF ≤0.30 • >1-month after MI • >3 months after revascularization	Mortality benefit with ICD
Defibrillators in Nonischemic Cardiomyopathy Treatment Evaluation (DEFINITE) ¹³	Nonischemic	N/A	NA	Yes	EF <36% due to NICM • NYHA Class I–III • NSVT or PVCs	Trend to mortality reduction with ICD (both in recently diagnosed and remote diagnosed patients)
Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) ¹⁴	Both ischemic and nonischemic	Yes (33 patients)	No	No	EF <35% • NYHA Class II or III	Mortality benefit with ICD
Defibrillator in Acute Myocardial Infarction Trial (DINAMIT) ⁵	Acute CAD	Yes	No	N/A	MI past 6–40 days • EF <0.35 • Abnormal HRV	No mortality benefit with ICD (decrease in arrhythmic death but increase in nonarrhythmic death)
Immediate Risk-stratification Improves Survival (IRIS) Study ⁶	Acute CAD	Yes	No	N/A	MI in the past 5–31 days and either: • EF ≤40% and initial HR >90 beats/min • NSVT >150 beats/min	No mortality benefit with ICD (decrease in arrhythmic death but increase in nonarrhythmic death)

AICD, automatic implantable cardioverter defibrillator; AMI, acute myocardial infarction; CAD, coronary artery disease; EF, ejection fraction; HRV, heart rate variability; ICD, implantable cardioverter defibrillator; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NICM, nonischemic cardiomyopathy; NSVT, nonsustained ventricular tachycardia; NYHA, New York Heart Association; SAECG, signal-averaged electrocardiography; N/A, not applicable.

1. Presence of sustained (or hemodynamically significant) ventricular tachyarrhythmia more than 48 hours after an MI and in the absence of ongoing ischemia
2. In patients who require nonelective permanent pacing, who also would meet primary prevention criteria for implantation of an ICD, and recovery of LV function is uncertain or not expected
3. Patients presenting with syncope that is thought to be due to ventricular tachyarrhythmia [by clinical history, documented nonsustained ventricular tachycardia (NSVT) or electrophysiological study]
4. In patients who have an ICD that requires elective replacement due to battery depletion (after careful assessment of comorbidities and the current clinical situation).

EARLY AFTER MYOCARDIAL REVASCULARIZATION

Pathophysiological consequences of coronary ischemia is formation of nonviable (dead or scar) as well as ischemic but viable myocardium. The second category is of immense electrophysiological and mechanical importance. This partially damaged myocardium has electrophysiological properties (conduction velocities and refractory periods) different from healthy myocardium and the electrical heterogeneity creates the milieu for generation of reentrant ventricular tachycardia (VT), the commonest cause of SCD in this subset. This ischemic but viable myocardium is dysfunctional at rest contributing to ventricular dysfunction. Contrary to

dead myocardium, the physiological derangement of the second group is reversible. Revascularization can lead to complete normalization of electrophysiological as well as mechanical properties of ischemic but viable myocardium although the normalization process is not instant after revascularization and the exact time period is not known. The rationale for waiting after revascularization to implant an ICD is based upon the hypothesis that LV function can improve. As a result of improvement in perfusion in ischemic but viable myocardium, it leads to reduction in life threatening ventricular arrhythmia events. It remains a major challenge to predict those patients who will or will not significantly improve their LV function. Although imaging studies like magnetic resonance imaging (MRI) and positron emission tomography (PET) are supposed to identify the viable myocardium, in a large study, preoperative imaging failed to identify the group of patients who will show benefits after revascularization.¹⁵ None of the primary prevention trial analyzed the benefit of AICD in early period after revascularization. Both multicenter automatic defibrillator implantation trial (MADIT) and MADIT-II trial excluded patients after revascularization. Sudden cardiac death in heart failure trial (SCD-HeFT) made no specific exclusion with respect to the timing of revascularization. However, in SCD-HeFT, the median time from coronary artery bypass graft (CABG) to enrollment was 3.1 years and from percutaneous coronary intervention (PCI) to enrollment was 2.3 years.¹⁴ Early revascularization was permitted in multicenter unsustained tachycardia trial (MUSTT) and CABG Patch trial. CABG Patch trial which randomized patients to ICD therapy or no ICD at the time of CABG, failed to demonstrate any survival benefit with ICD.¹¹ Although, it is clear that patients with LVEF less than 35% are at high-risk for revascularization procedure (both PCI and CABG)^{16,17} and early mortality after revascularization is high in this group, the proportion of arrhythmic death is not clear. In a substudy of MUSTT, patients enrolled within 30 days of CABG had significantly lower rates of arrhythmic events despite other high risk characteristics, than patients not enrolled within 30 days after CABG. Few nonrandomized, retrospective studies, however, have suggested a benefit of ICD implant early after coronary revascularization.^{18,19} Based on evidences from primary prevention studies, current guidelines recommend waiting for 90 days after revascularization for implantation of AICD for primary prevention. However, a limitation of these studies was that they analyzed patients several months to years from revascularization and not within 90 days from revascularization. However AICD implantation is justified within 90 days of revascularization in following conditions.⁹

- If secondary prevention criteria is fulfilled (in patient with cardiac arrest or hemodynamically unstable or sustained VT before or after revascularization where the arrhythmia is not related to ischemia)
- Patient of nonelective permanent pacing, who would also meet primary prevention criteria for implantation of an ICD, and in whom recovery of LV function is uncertain or not expected

- Patient with syncope that is thought to be due to VT [by clinical history or documented NSVT, or electro-physiologic (EP) study]
- Patient who have been listed for heart transplant or implanted with a ventricular assist device, and who are not within 40 days of an AMI
- In patients who have an ICD that requires elective replacement due to battery depletion (after careful assessment of comorbidities and the current clinical situation).

RECENT ONSET NONISCHEMIC CARDIOMYOPATHY

Natural history of nonischemic cardiomyopathy (NICM) is unpredictable. Before the widespread usage of optimal medical therapy (OMT), 5 years mortality was estimated to be 50%, of which 30% were due to sudden death. However, in the last few decades, remarkable progress took place in the field of pharmacotherapy in HF. Introduction of disease modifying drugs like angiotensin-converting enzyme inhibitor (ACEI), angiotensin receptor blockers (ARBs), β -blocker, mineralocorticoid receptor antagonists (MRA) and angiotensin receptor-neprilysin inhibitors (ARNI) has made a change in the natural history of NICM. The primary challenge is to decide whether to advise ICD implantation in newly diagnosed patient or to try OMT for a specific period. Long term follow-up with OMT was found to reduce mortality and significant improvement in LVEF was documented in more than 50% patients. In 4 year follow-up, 25% of the cohort achieved near normalization of LVEF (>50%) with OMT.²⁰ In patients with NICM, LVEF has been found to be significant independent risk factor for major arrhythmic events, with each 10% decrease in ejection fraction associated with a 2.3-fold increase in risk.²¹ Subgroup analysis in Defibrillators in Nonischemic Cardiomyopathy Treatment Evaluation (DEFINITE) study found similar benefit in AICD implantation regardless of the duration of NICM.¹³ It is important to note that patients with potentially reversible causes of cardiomyopathy such as peripartum cardiomyopathy, myocarditis or acute drug-induced cardiomyopathy were excluded from the study. Although studies have included different electrocardiography (ECG), biopsy,²⁰ and MRI criteria,²² it is difficult to separate patients who will have improvement in LVEF on initial OMT, from those patients with irreversible or progressive LV dysfunction. Genetic testing can also play a role in risk stratification of patients with NICM. Preliminary studies suggest that NICM due to LMNA, TNNT2, SGCD, RBM20, and CHRM2 mutations can be at higher risk of sudden cardiac death.²³⁻²⁵ Patients with cardiac sarcoidosis and LVEF less than 0.30 are unlikely to improve with medical therapy.²⁶ Giant cell myocarditis is a rare cause of myocarditis characterized by large multinucleated cells, has an extremely virulent course that does not respond to therapy.²⁷

Taken together, the published literature suggests that significant number of newly diagnosed NICM patients will have improvement in LVEF with OMT. The current guideline supports that for all patients with NICM, it is imperative

that patients be on OMT for HF for at least 3 months before a primary prevention ICD is offered. The clinician must carefully evaluate those patients with relatively recent onset NICM and early AICD implantation can be useful in selected patients with NICM who are unlikely to have recovery of LV function. An early AICD (between 3 and 9 months of diagnosis of NICM) will also be useful for primary prevention in patients with sarcoidosis, giant cell myocarditis or familial cardiomyopathy with a family history of sudden death.⁹

Incessant Ventricular Tachycardia

Automatic implantable cardioverter defibrillator is considered as double-edge sword in patients of HFrEF. An infrequent, appropriate ICD shock aborts sudden cardiac death and is life saving and at the same time repeated shocks (appropriate or inappropriate) is detrimental for the patients. The repeated shocks are painful and increase the psychogenic stress of the patient. At the same time each shock causes myocardial injury and increase in serum troponin level.²⁸ This transient postshock myocardial dysfunction,²⁹ complicated by dyssynchrony due to backup pacing is detrimental in patients with already compromised LV function. Shocks, both inappropriate and appropriate, have been associated with increased HF and mortality in this group of patients.^{30,31} Keeping in mind the detrimental effect of repeated shocks, AICD should not be implanted in patients with incessant VT. If a patient with AICD has incessant VT, the ICD should be switched-off and appropriate pharmacological or interventional strategy (like catheter ablation) should be taken for the refractory VT.

New York Heart Association Class IV Patients

Mode of death in HF depends on stage of HF. Contrary to early stage, where sudden death is common, in advanced stage the pump failure death is common. On the other hand, shock can increase the HF and mortality in advanced HF. Most of randomized controlled trials (RCTs) in AICD did not include New York Heart Association (NYHA) class IV patients. Ambulatory class IV patients with HF were included in the COMPANION (Comparison of Medical Therapy, Pacing, and Defibrillation in Heart Failure) trial, which showed an overall improved functional status and survival with a cardiac resynchronization therapy (CRT) defibrillator.³² Unless such a patient is a candidate for CRT or advanced HF therapies such as heart transplantation or a left ventricular assist device (LVAD), an ICD is not expected to meaningfully prolong survival.

Patient with Life Expectancy More Than 1 Year

Economic outcomes of ICD implantation for primary prevention of SCD were assessed in MADIT-I,¹⁰ MADIT-II,⁴ and SCD-HeFT.¹⁴ All studies reported increased survival and life expectancy and higher lifetime costs of medical care

with an ICD than without an ICD. The incremental cost-effectiveness ratios were generally less than \$50,000 per year of life added by an ICD, which provides high value according to the benchmarks adopted for the current guideline.³⁰ The value provided by an ICD was consistently high when life expectancy was projected to increase by more than 1.4 years.³¹

On the other hand the survival benefit with ICD is not instant. In MADIT II⁴ trial, the benefit did not become evident until approximately 9 months after device implantation. Similarly, separation of the survival curves in SCD-HeFT was also observed 12–15 months after device implantation.¹⁴ Considering the economic outcomes and survival benefit curve, patients with serious comorbidities associated with a survival of less than 1-year are generally not considered ICD candidates. Since, its introduction before more than 30 years ago, the ICD has evolved to a widely accepted and important treatment for patients with cardiovascular disease who are at risk of life threatening ventricular arrhythmias. However, the device is not free of complications and is expensive. Cardiologists must continue to refine their understanding of who benefits from ICD implantation and how to optimally implement ICD therapy in these patients.

CONCLUSION

Since its introduction before more than 40 years ago, the ICD has evolved to a widely accepted and important treatment for patients with cardiovascular disease who are at risk of life threatening ventricular arrhythmias. However, the device is not free of complications and is expensive. Cardiologists must continue to refine their understanding of who benefits from ICD implantation and how to optimally implement ICD therapy in these patients.

Leadless Pacemakers: Current Review and Future Directions

Vanita Arora

INTRODUCTION

Bradyarrhythmia with symptoms is a clinical condition which affects millions of people worldwide. Patients with symptomatic bradycardia are eligible to get a pacemaker implanted but an estimated 1.5 million pacemakers are implanted annually worldwide.¹ The increasing usage of these novel devices has led to proper diagnosis and improvement in the quality of lives of bradycardia patients.² In addition, the latest technological achievements in the field of pacing, which are related to battery longevity and miniaturization, device software and programming, lead performance, remote monitoring systems, and implantation techniques, have transformed pacing into an extremely reliable and safe therapy.

POTENTIAL COMPLICATIONS WITH CONVENTIONAL PACING SYSTEM

Although conventional pacemakers with leads improve the clinical status of patients, the pacing leads have long been considered their Achilles' heel.³ Some of the early postprocedural complications include micro- or complete dislodgement of lead, perforation of right ventricular (RV) or right atrial (RA) wall, pneumothorax and tamponade. However, chronic lead problems affect in around 10% of cases. These are but not limited to conditions such as thrombosis in the venous access, superior vena cava (SVC) block, severe tricuspid regurgitation (TR), and infections which occur at a rate of 1-2% and often require a lead extraction procedure which is technically demanding.⁵ Overall, the rate of periprocedural and early postprocedural complications in cardiac pacing therapy is estimated, approximately, to be 10%. Adoption of strict sterile techniques in electrophysiology (EP) laboratories are not sufficient to contain pacemaker related infections especially pocket infections. The occurrence of the same is a dreaded situation for the patient and the doctor alike. This leads to removal of pulse generator or sometimes the entire assembly which

increases the morbidity. The incidence of pacemaker lead fracture is about 1-4%,⁵ phenomenon happening due to subclavian crush.

Insulation breach can also be a cause for potential lead failure which leads to pace or sense error and battery longevity (Fig. 1). Leadless cardiac pacemakers (LCPs) can overcome these issues due to absence of leads and no requirement for a surgical pocket. Spickler et al. in 1970 were the first to introduce the concept of LCP.⁶ The LCP is an innovative concept which involves the placement of a completely self-contained intracardiac device. Like other innovations usage of LCP also were thought to be possible in humans only when they were successfully studied in animals.⁶ In this article, we would review the progress made in the leadless space and analyze the potential use of the same in various arrhythmic disorders.

ANIMAL STUDIES AND TECHNOLOGICAL ADVANCEMENTS

Various animal studies have been conducted to understand the technological advancements.⁷⁻¹¹ Spickler et al. tried implanting the nuclear-powered device in the dog way back in the early 90's but the concept was not commercialized due to battery longevity and safety. Vardas et al. in 1991 tried to pace dog heart (8 dogs) asynchronously with an LCP powered by three 1.5 V battery in 1991; the commercial introduction of this was also not possible.

Spickler et al. and Vardas et al.'s research was ahead of its time, and it was not until 1999 that Goto et al., explored the concept of using an automatic power-generating system (AGS) to power the LCP. The AGS worked on the principle of conversion of kinetic energy into electrical energy like quartz watches. The investigators successfully paced a mongrel dog's heart at 140 beats/min for 60 minutes with a fully charged AGS system.¹² Ultrasound as a power source was later used by Echt et al. in 2006.¹³ This later became a viable power source and was accepted in multiple studies.

CURRENT LEADLESS CARDIAC PACEMAKERS

The new era of miniaturization started with leadless devices and currently there are three companies which are into leadless pacing devices (Table 1). The first is the device

called Micra Transcatheter Pacing System (TPS), made by Medtronic Inc., which is the “world’s smallest pacemaker” (93% smaller than a conventional pacemaker) with dimensions of just 7 mm in width, 26 mm long and 2 g in weight (Fig. 2). In a postapproval registry, the device was successfully implanted in 792 of 795 patients (99.6%) by

149 implanters at 96 centers in 20 countries. Through 30 days post implant, a total of 13 major complications occurred in 12 patients, for a major complication rate of 1.51% (confidence interval, 0.78–2.62%). Major complications included cardiac effusion or perforation (1, 0.13%), device dislodgement (1, 0.13%), and sepsis (1, 0.13%). The rate of major complications in the registry was lower than that of the Investigational Device Exemption (IDE) but after the baseline differences were adjusted (odds ratio, 0.58, 95% confidence interval, 0.27–1.25). The TPS is delivered through a 27-French (Fr) outer diameter catheter the inner diameter of which is 25 Fr through the femoral route. the pacemaker could be repositioned as many number of times as possible. The pacing capture thresholds were low during the study period. The estimated battery life was around 10–12 years. The TPS uses self-expanding nitinol tines to fixate in the trabeculae. At the end of battery life of Micra and other Micra can be implanted in the ventricle, in fact three Micra devices can be accommodated in the ventricle.¹⁴

Nanostim device is manufactured by Abbott Inc. The device is smaller than a AAA battery and can be directly placed inside the heart through the femoral route approach.

Implantation technique: Nanostim LPS has a screw-in helix. A steroid-eluting disk is located at the center of the helix acts as the cathode, whereas the anode is the uncoated ring of the titanium case (Fig. 3). The Nanostim LPs uses conductive communication via a dedicated programmer, which uses skin leads to apply subliminal 250 kHz pulses for signal transmission and programming. The Nanostim LPs uses a temperature-based sensor for rate control. This LCP which is 4 cm long, 6 mm wide and just 2 g in weight is delivered by an 18 Fr catheter attached to a docking button on the end of the device, which introduces it into the body via the femoral vein and subsequently into the right ventricle. In order to tug on the device after implantation, a tether mode is used. If positioning has to be changed or if it has not been completely fixed the LCP can be unscrewed during the operation. The device has a long battery life of 9–10 years as it uses electrical impulses to communicate rather than the standard antenna and coil system leading to a need for fewer replacements.¹⁵

After the LEADLESS trial, this LCP was given the CE mark. A Wireless Cardiac Stimulation system for the left ventricle (WiCS-LV) is also being developed by electronic

batch record (EBR systems) (Sunnyvale, CA, USA). The system utilizes ultrasound emitted from a transmitter implanted subcutaneously in the left chest and a receiver implanted in the ventricle which converts ultrasound energy to electrical energy that can be used to pace the heart (Fig. 4). In contrast to the aforementioned devices, the WiCS-LV system has been used in cardiac resynchronization therapy (CRT) when used with conventional RV pacers. This results in both ventricles contracting almost simultaneously thus allowing resynchronization. Another added advantage of the EBR system (WiCS-LV) is its capability of endocardial pacing which runs contrary to epicardial pacing seen with conventional CRT devices.

Endocardial pacing may be more physiological and theoretically could improve patients' clinical response to CRT therapy. This hypothesis clearly requires study.

Figure 5 shows evolution of leadless pacemakers from animal studies to past and currently ongoing human studies.¹⁶

FIG 4: Wireless Cardiac Stimulation system for the left ventricle.

It should be noted that Nanostim from St Jude Medical (now Abbott) is not available commercially while WiCS-LV is not commercially launched in many countries worldwide.

Clinical indications where ventricular single-chamber rate-modulated (V-VIR) leadless pacemaker is recommended:

- Symptomatic intermittent or permanent high-grade atrioventricular (AV) block in the presence of atrial fibrillation (AF)
- Symptomatic intermittent or permanent high-grade AV block (AVB) in the absence of AF as an alternative to dual chamber pacing when atrial lead placement is considered difficult, high risk, or not deemed necessary for effective therapy
- Symptomatic tachy-brady syndrome or sinus node dysfunction (SND) (sinus bradycardia or sinus pauses), as an alternative to atrial or dual chamber pacing when atrial lead placement is considered difficult, high risk, or not deemed necessary for effective therapy.

Unique indications for leadless pacemaker:

- Prior device and lead infection
- Vascular access issue (dialysis, subclavian thrombosis)
- Potential Twiddler's syndrome
- Renal failure
- Tricuspid regurgitation probably because of conventional lead implantation.

Comparative Review of Micra IDE Study and Micra Postapproval Registry

In comparison to IDE study patients, significantly fewer patients in the postapproval registry had congestive heart failure, coronary artery disease, hypertension, chronic obstructive pulmonary disease, or AF. A couple of more characteristics at enrolment in patients of the registry were: the mean left ventricular ejection fraction (LVEF) was significantly lower, patients had a cardiac device previously implanted and or did not have any venous access as the

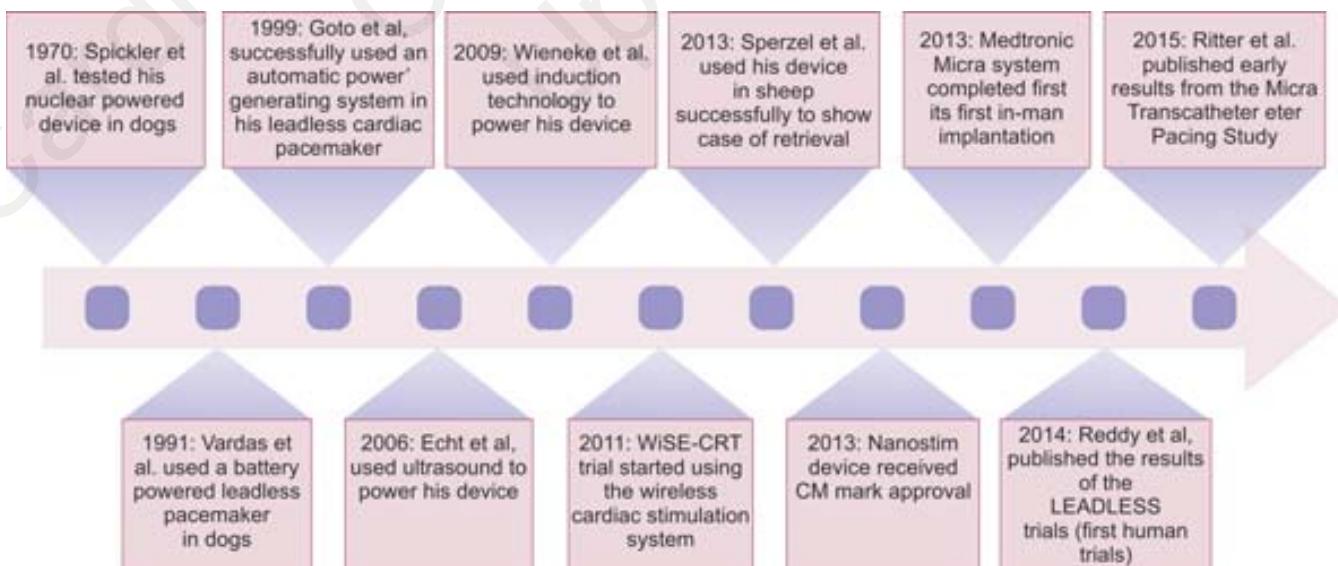

TABLE 2: Comparative analysis of Micra postapproval and investigational studies

	Micra Transcatheter Pacing System Postapproval	Micra Investigational Device Exemption Study	
Success rate (%)(n/N)	99.6 (792/795)	99.2 (719/725)	–
Procedure duration (min)	–	35 ± 24	–
30-day event rate			
Major complication criterion	Postapproval (n = 795) no. (patients, %)	Investigational (n = 726) no. (patients, %)	Odds ratio (postapproval vs. investigational) (95% CI)
Total Major Complications	13 (12, 1.51%)	24 (21, 2.89%)	0.58 (0.27, 1.25)*
Death	1 (1, 0.13%)	1 (1, 0.14%)	0.91 (0.06–14.66)
Hospitalization	4 (4, 0.50%)	9 (8, 1.10%)	0.45 (0.14–1.51)

later was an exclusion criterion in the IDE study. The major complication rate trended lower in the registry compared with that of the IDE study (1.51% vs. 2.89%; odds ratio, 0.515, 95% CI, 0.251–1.053; $p = 0.0691$), although this did not reach statistical difference. (Table 2). Among the 795 patients in the registry, there were fewer cardiac effusion or perforation major complications, compared with the 726 patients from the IDE study (1 patient, 0.13% vs. 10 patients, 1.38%). The number of major complications related to the groin puncture site was similar in both studies (6 events, 0.75% for the registry vs. 5 events, 0.69% for the IDE study). Though the patient demographics were slightly different between the groups, the implant success rate was similar (99.6%) with a low level of major complications (1.51%). The registry population had less congestive heart failure, coronary artery disease, hypertension, chronic obstructive pulmonary disease, and AF, but a higher percentage of patients had no venous access for a transvenous pacemaker. The outstanding electrical performance of Micra TPS has also been maintained within the registry population, with a 97% implant threshold of 2 V, and 87.2% had a pacing capture threshold 1 V, like what was reported for the IDE study.¹⁷ The average impedance was 721Ω at implant, and the mean R-wave amplitude was 11.4 mV. Longer term follow-up in the IDE study has shown a trend to improvement of these parameters with time.

Current Challenges

Leadless pacemakers eventually would become the first-choice for treatment of symptomatic bradycardia, but this novel technique offers its own challenges like:

- Learning curve associated to implantation techniques, interpretation of data diagnostics is different for different manufacturers.

The current devices are capable of single chamber pacing and not dual-chamber (DDD) pacing or¹ CRT pacing. The WiCS-LV system is capable of CRT pacing but unfortunately doesn't have a defibrillator.

Although, the promising technology of leadless pacemakers might minimize the lead associated complications, the possibility of new complications such as device dislodgement, late perforation or tamponade, early battery depletion and mechanically induced arrhythmia has yet to be clinically explored.

Optimal management of patients who develop gram-positive bacteremia late after LCP implantation (which represents a class I indication for transvenous lead extraction) remains unknown.²

Transfemoral explantation of the device when dense adhesions form at the interface with the endocardium may also prove difficult.

Future Perspectives

The use of single-chamber pacemakers is limited to 14% of pacemaker implantations only.¹⁹ This is largely due to the potential benefits of atrial pacing in patients with SND as well as the recognized benefits of AV synchrony (AVS) in decreasing the incidence of pacemaker syndrome, improving stroke volume, and positively influencing functional status and quality of life in patients with AVB.^{20–22} Three clinical trials were conducted to develop and evaluate the performance of a novel downloadable algorithm for the Micra single-chamber ventricular leadless pacemaker, based on intracardiac accelerometer data. The development and performance of this algorithm in successfully achieving AVS in a large proportion of patients with high grade AVB and an implanted Micra device is reported.

HOW THE ALGORITHM FUNCTIONS³

Accelerometer signals collected from MASS/MASS 2 (Micra Accelerometer Sensor Sub-Study) patients demonstrated that four distinct segments of cardiac activity were seen in the accelerometer signal. These segments corresponded to isovolumic Q2 contraction and mitral or tricuspid valve closure (A1), aortic or pulmonic valve closure (A2),

passive ventricular filling (A3), and atrial contraction (A4). Accelerometer segments corresponding to passive filling and atrial contraction was associated with mitral valve flow E- and A-wave measurements.³

Based on these signals, an AV synchronous algorithm was developed to provide a VDD pacing mode. Blanking periods must be manually set to reject signals in the accelerometer originating from the ventricular region as the accelerometer can also sense mitral and aortic valves closure movements. Atrial contraction was detected when the filtered and rectified accelerometer signal exceeded one of two programmable thresholds. There is a high probability that at high sinus rates of >80 bpm, the two ventricular signals can fuse creating a large accelerometer signal hence two programming thresholds should be looked into—a larger passive ventricular filling threshold to detect fused passive ventricular filling or atrial contraction threshold and a lower atrial contraction threshold for detecting the same signal later in diastole. If atrial contraction was detected, an atrial marker (AS) was³ output via telemetry, and a programmable AV interval was initiated. Because of the electromechanical delay between the electrical p wave and the atrial signal, the accelerometer, the A4 VP was typically programmed to 10 msec. The algorithm incorporated a rate smoothing feature designed to maintain AVS during intermittent atrial under sensing. If an atrial contraction was not detected, a ventricular pace was delivered a programmable rate smoothed interval (typically 100 m) longer than the median Q3 R-R interval.³

Clinical Evidence

The purpose of the (MASS/MASS 2) was to characterize the intracardiac accelerometer signals during various patients' activities and to assess the feasibility of sensing atrial contraction through the sensor and these studies were conducted in prospective patients in multiple centers and was nonrandomized. The Micra implanted patients were followed up in an office setting at the end of 12 months from implant. The software was incorporated in these devices and accelerometer signal was collected from all three vectors. The primary endpoint of interest was to measure the atrial contraction amplitude by the accelerometer signal during each cardiac cycle. The mean atrial contraction amplitude which varied across postures and vectors were analyzed for 75 patients. The findings from the MASS/MASS 2 studies were used to develop an AV synchronous pacing algorithm.³

The Micra Atrial TRacking Using A Ventricular AccELerometer (MARVEL) study was an acute, prospective, nonrandomized, multicenter clinical feasibility study. The primary aim of MARVEL was to test the feasibility of providing AVS pacing in patients with AVB using the algorithm developed from MASS and MASS 2 studies. Usable Holter recordings from 64 patients enrolled in the MARVEL study were evaluated. Majority of these patients had a second or third degree AVB while 48% had an intrinsic conduction. The AVS percentage was 87%. The AVS percentage age was noticed mostly at rest when the AV algorithm mode was put on (Table 3).

TABLE 3: Baseline and medical history of patients in Micra Atrial TRacking Using a Ventricular AccELerometer

Characteristics	Enrolled (n = 70)	Usable Holter (n = 64)
Age (years):		
Mean ± SD	71.3 ± 15.1	72.0 ± 14.4
Range	24–92	30–92

AVB, atrioventricular block; AV, atrioventricular.

Importance of these Studies

The MARVEL study demonstrated the feasibility of tracking atrial contractions and providing AVS using a mechanical accelerometer-based sensor in the Micra³ ventricular pacemaker. Specifically, the average AVS percentage at rest was 87%.³ In patients with high-grade AVB, AVS improved from 37.5 to 80% when comparing VVI versus AV algorithm mode.³ The presence of the algorithm had no detrimental impact on AVS in patients with intrinsic AV conduction. The achievement of AVS had a significant effect on stroke volume as measured by velocity time integral (VTI)³ on echocardiography. It was very natural that, SND, premature ventricular complexes and low-amplitude signals contributed to a lack of synchrony,³ although this was evident in a relatively small number of patients. The study demonstrated that AVS with this algorithm was impacted by activity. With increase in heart rate, the atrial and ventricular signals superimposed on the accelerometer resulting in loss of AVS. The AVS was not impacted by changes in posture while at rest. In this circumstance, it is important to consider that the loss of atrial synchrony is compensated for by an increase in heart rate and ejection fraction during exercise, particularly in patients with preserved left ventricular systolic function.²³ When sensing atrial contraction was difficult a rate smoothing feature takes over so that AVS is

maintained; this increased the AVS by 9%.³ There were no instances of pacemaker-mediated tachycardia or significant interruption in ventricular pacing resulting in symptomatic pauses.³ The literature and published guidelines support use of single-chamber pacemakers in patients with AVB under certain circumstances.²⁴ These include infrequent need for pacing, vascular access issues, sedentary patients, and comorbidities likely to impact clinical outcomes.⁶ However, this does not preclude the benefit of AVS, if it can be achieved safely in this population of patients.⁶ This provides the opportunity for this patient population to benefit from AVS and increased stroke volume, reduction in pacemaker syndrome incidence, and improvement in functional status and quality of life; however, this would require long-term evaluation.²⁵⁻²⁷ A limitation of the algorithm could be the loss of AVS with increased levels of activity. However, this may be mitigated by the fact that cardiac output at higher rates has been shown to be more dependent on heart rate than AVS.²⁷ Thus, rate responsive pacing (i.e., VVIR) may be an adequate option for patients when active. Patients with lower AVS tended to have SND (manifesting primarily as sinus arrhythmia, sinus bradycardia, and sinus tachycardia) or had low-amplitude A4 signals.³ It is clear that implantation of these devices would not benefit those patients with persisting or permanent atrial arrhythmias; furthermore, the A4 signal during AF will likely be low and not detected, resulting in pacing near the lower rate.³ Loss of AVS also occurred because of low-amplitude signals measured by the accelerometer.³ The accelerometer signals can be complex and setting up the algorithm will require knowledge of the cardiac components of the accelerometer signal.

CONCLUSION

There is a paradigm shift in pacing. It is a little early to know if leadless pacing is the future of pacing but it looks very promising from the results.

Curious thoughts:

- Will all pacemakers be leadless soon? Is that what we want?
- VDD will be a programmable option soon and what about DDD version?
- Dual chamber and triple chamber devices, how will they communicate with each other?
- What will be the ideal battery longevity?
- What will be the role of LCP with S/C ICD for postshock pacing and ATP?

The early results from clinical evaluations suggest that leadless pacing could gain wider adoption. Whether leadless systems expand beyond a small niche to replace traditional transvenous pacing systems remains to be determined and will likely depend in large part on the evolution of feasibility and ease of multichamber headless stimulation. Long-term follow-up will need to verify device performance, including the projected battery longevity, stable stimulation thresholds, adequate sensing, and the safety of extraction, if needed.

Cardiac Surgery

Time to Embrace Total Arterial Revascularization

Ramakanta Panda, Sunil Vanzara

INTRODUCTION

The left internal mammary artery (LIMA) to the left anterior descending artery (LAD) graft, unanimously considered the gold standard of coronary revascularization and conduits, has not only shown to improve survival but also decrease the rate of reoperation compared to the use of only vein grafts.¹ However, the conventional surgery of one internal mammary artery (IMA) and vein grafts do not reduce the incidence of recurrence of angina and late myocardial infarction (MI) because of the high occlusion rates of vein grafts of 12%, 25%, 50%, and 75% within 1, 5, 12, and 15 years, respectively, after coronary artery bypass grafting (CABG).²⁻⁴ Conceptually arterial grafts with higher patency rate should reduce above adverse events if grafted to circumflex (Cx) and right coronary artery (RCA). This has been corroborated by numerous retrospective analyses documenting an incremental survival benefit by increasing the number of arterial grafts.⁵⁻⁹ Two independent meta-analyses have corroborated the long-term benefit.^{5,10} A large retrospective study (8,622 patients),¹¹ which involved a large cohort of multivessel coronary artery disease (MVCAD) patients, has shown that in isolated CABG performed more than 15 years ago with the use of LIMA to the LAD, bypassing the non-LAD targets with at least one additional arterial graft, was an independent predictor of survival during the succeeding 15 years. The improved survival was seen among both sexes, all ages, patients with preserved as well as impaired left ventricular function, those with pre-existing diabetes, chronic lung disease, or renal failure, and those without those risk factors. Patients with clinically significant left main coronary artery disease (CAD), double- and triple-vessel disease patients, operated electively or emergently also had improved survival. Despite this compelling evidence in the published literature, multiple arterial grafting is currently performed in <13% of CABG operations,¹² bilateral internal thoracic artery (ITA) in 4.1%, and radial artery (RA) in 10.8% patients.¹³

REASON FOR LOW ATHEROSCLEROSIS IN ARTERIAL CONDUITS

The superiority of IMAs over saphenous vein grafts (SVGs) can be attributed to its striking resistance to the development of atherosclerosis. Structurally its endothelial layer shows fewer fenestrations, lower intercellular junction permeability, greater antithrombotic molecules such as heparin sulfate and tissue plasminogen activator, and higher endothelial nitric oxide production, which are some of the unique ways that make the IMA impervious to the transfer of lipoproteins, which are responsible for the development of atherosclerosis. The IMA, an elastic artery, is dominated by a media with discrete lamellae of wavy collagen and smooth muscle, aligned nearly circumferentially. The SVG, in contrast, is more variable in its size and structure, characteristically with a narrow circumferential media comprised mostly of collagen, which is straightened and highly aligned at arterial pressures contributing to high mechanical stiffness of this vessel when exposed to arterial pressure. The high fraction of longitudinal muscle, in addition to the circumferential muscle cells in the SVG, makes it vulnerable to any pre-implant surgical preparation, and to the cyclical luminal pressures and longitudinal strains characteristic for epicardial arteries.¹⁴

Radial artery has a significantly greater prevalence of intimal hyperplasia, atherosclerosis, and medial calcification than the IMA. However, all severity indices are fairly low in both the RA and the IMA. Age, smoking, diabetes, and peripheral vascular disease (PWD) are correlated with intimal hyperplasia and atherosclerosis in the RA and the IMA. The left IMA is used almost exclusively as a graft to the LAD coronary artery; however, the choice of the second graft varies widely among surgeons. A caution should be exercised in selecting the RA in favor of the right IMA as a bypass conduit in patients who are elderly, diabetic, smoker, or have PWD, especially in patients with a combination of any of the above. Doppler ultrasonography may be useful in evaluating these

patients before surgery to select only disease-free RAs and to avoid an unnecessary incision.¹⁵

TYPES OF ARTERIAL CONDUITS

Left Internal Thoracic Artery

Since the landmark publication by Loop et al. in 1986¹ demonstrating the significant survival benefit of LIMA-to-LAD over SVG-to-LAD, LIMA is universally accepted as the best conduit for CABG, and LIMA-LAD graft is the gold standard as well as the single most important component of any coronary revascularization.

The Right Internal Mammary Artery

The right internal mammary artery (RIMA) is biologically identical to the LIMA.¹⁶⁻¹⁸ The RIMA is usually of greater diameter than the LIMA in right-handed people, easier to dissect and because of larger diameter easier to use.

Radial Artery (Unilateral and Bilateral)

Over the past 20 years RA has proven to be an important conduit, and for those not experienced with using bilateral IMA (BIMA), it is the second best conduit after LIMA. It is easy to harvest, has excellent length up to 22 cm to reach most distal coronary arteries, has appropriate size match for coronaries, and is very comfortable for surgeons to use.

Gastroepiploic Artery

The gastroepiploic artery (GEA) is the largest terminal branch of the gastroduodenal artery and is a muscular artery. The diameter of the right GEA (RGEA) is approximately 3 mm or more at its origin and is 1.5–2.0 mm in the middle of the greater curvature and length up to 24 cm can be harvested.¹⁹

Inferior Epigastric Artery

Like GEA, the inferior epigastric artery (IEA) is a muscular artery and originates from the external iliac artery. Though proximal diameter is between 3.0 and 4.0 mm, the short length (in between 6 and 10 cm) and smaller distal size of 1.0–2.0 mm limit its use.

INDICATIONS AND CONTRAINDICATIONS TO USE TOTAL ARTERIAL REVASCULARIZATION

While total arterial revascularization (TAR) is not necessarily indicated in all patients, it should be the primary objective in any coronary bypass surgery with BIMA grafting forming the foundation and RA as the third conduit when needed. Patients with a body mass index (BMI) of over 35, diabetes or severe airway disease, or who had or are undergoing radiotherapy or immunosuppression are only relatively contraindicated for BIMA use.²⁰ If more conduits are required, the RA can be harvested at the same time as the LIMA, and its harvesting is associated with favorable early and late outcomes.²¹ Prior

to harvesting RA, a modified Allen test, duplex examination, and pulse oximetry can also be used to preoperatively evaluate the RA and ulnar artery. Moreover, the RA should be avoided when cardiac catheterization has been recently performed through RA thereby injuring the vessel (RA) and when the RA might be used for future fistulae in patients with significant renal impairment.²² RAs <2 mm in diameter are also avoided due to the possibility of vasospasm. In 5–10% cases it cannot be used because of RA dominance, calcification, prior trauma, especially if a recent coronary angiogram is performed through the RA route, and collagen disease.²³ Another absolute contraindication is hypoplasia of ulnar artery or inadequate accentuation in ulnar artery (<20%) in response to compression of ipsilateral radial on Doppler study.

With greater acceptance of RA, GEA use has been restricted to limited centers or when there is a paucity of arterial conduits especially in coronary reoperations. It is usually used to graft RCA or its branches mostly as *in situ* graft and occasionally as free graft from aorta or composite from LIMA to proximal vessels such as diagonal (Dg), intermediate, or obtuse marginal (OM).

Inferior epigastric artery is extremely infrequently used but can be considered in situations of non-availability of other arterial conduits in redo CABG situations. Because of its limited length, it can be used to anastomose proximal coronary branches such as Dg or intermediate and OM1 from aorta or as composite conduit as Y from LIMA to Dg, intermediate or OM, or to RIMA as Y graft or extension to graft PDA or OM.

Finally, the extent of stenosis of the target coronary vessel with stenosis of <70% in the left coronary bed and <90% in a dominant RCA may also constitute a contraindication for arterial conduit use due to competitive flow causing graft attrition.²⁰

Commonly raised concerns regarding the use of BIMA that discourages many surgeons are:

- Surgeons not trained in RIMA harvest: Technique of harvesting RIMA is same as LIMA and there is no additional learning curve
- Not comfortable with the actual use of the RIMA to perform coronary grafting: The RIMA is usually larger than the LIMA in most right-handed individual and the wall is identical or sometimes slightly thicker than that of the LIMA. Technically, it is not more difficult to use RIMA for anastomosis
- Prolonging the operation: Though the operation time is prolonged approximately by 30–60 minutes, the benefits of using RIMA outweigh the additional operating time
- *Uncertainty as to how best to deploy the RIMA:* The common concerns are:
 - Whether to use *in situ*, free, or Y graft,
 - Whether to graft to single coronary artery or sequential to multiple coronary arteries, and
 - Whether to route the RIMA anterior or posterior to the aorta to reach the Cx, the RCA, or posterior descending artery (PDA).

Regardless of all of the above concerns, the patency of *in situ* RIMA is identical to free RIMA to the same vessel and should not be a concern.²⁴

- Concern regarding sternal infection, necrosis, and non-union: Though BIMA harvest is associated with increased incidence of sternal wound infection, it is so when the IMA is harvested in a pedicle manner. The sternal wound infection is minimized by skeletonized harvesting of the RIMA,^{25,26} appropriate prophylactic antibiotic regimens, and meticulous perioperative glucose management.^{16,27-29} A subgroup analysis of the ART trial showed that the risk of sternal wound infection is same with pedicled single IMA (SIMA) versus skeletonized BIMA. Though the risk of skeletonized SIMA was the lowest, the difference when compared with skeletonized BIMA was negligible.³⁰ However, there is no doubt that BIMA should be avoided in morbidly obese (BMI >40), insulin-dependent diabetes patients, female patients with diabetes, and those with severe chronic obstructive airways disease (COAD).¹⁶ At authors' institution, since the introduction of skeletonized IMA in 2006, we have been able to increase the use of BIMA from 17% in 2004 to more than 60% today, without any significant increase in wound infection.
- Concern regarding RIMA patency: Despite multiple angiographic studies showing higher patency of RIMA, as both *in situ* and free grafts, there are still concerns among surgeons about the superior patency of RIMA over SVG.¹⁶ Patency of conduits depends on multiple factors including the degree of proximal stenosis of the grafted vessel, surgical team experience, and harvesting technique. Many of the studies comparing patency of RIMA to vein grafts are intermediate-term follow-up studies and we know that while IMA attrition rate is highest in the first 5 years,³¹ the vein graft attrition is highest after 5 years. Short- and intermediate-term angiographic studies will not show the difference between RIMA and SVG. Only long-term angiographic studies (preferably >10 years) will show superior patency of RIMA or any other arterial grafts over SVG.
- Concern regarding lack of additional survival benefit: Adding even one arterial graft to LIMA-to-LAD has shown to reduce late cardiac events such as recurrence of angina or MI, but short-term follow-up studies including ART trial 5-year midterm outcome have failed to show additional survival benefit of BIMA over single internal mammary artery (SIMA).³² That is because firstly, the significant survival benefit of LIMA-to-LAD accrues from LAD mostly supplying the largest area of myocardium among the three coronary arteries and anatomic location of LIMA in relation to LAD providing the best patency rate among all conduits grafted to any other coronary arteries. To show additional survival benefit of multiple or total arterial grafting over only LIMA-to-LAD plus SVG, an equivalent or large area of myocardium needs to be revascularized using arterial conduits, presuming the patency rate of other arterial conduits will be as good as

LIMA-to-LAD. Secondly, as mentioned earlier, many of these studies are short- to medium-term follow-up³² and we know that while IMA attrition rate is highest in the first 5 years,³¹ the vein graft attrition is highest after 5 years. In fact, most follow-up observational studies of beyond 10 years have shown the additional survival benefit and protection from late cardiac events of multiple arterial grafting.^{7,33}

- Lack of randomized trials: Numerous single and multi-institutional observational, propensity-matched reports, and meta-analyses support survival benefit of BIMA over SIMA^{6,33-36} However, this issue is being addressed by randomized trials as well. Five-year results of arterial revascularization trial (ART), a multi-institutional randomized study, did not show any benefit between SIMA and BIMA, though close to statistical significance was observed in favor of BIMA in patients under 70 years.^{32,37,38} Recently, the 10-year ART results presented in the European Society of Cardiology meeting in August, 2018, though did not show difference in mortality or MI, surgeon's experience appeared to play a crucial factor for outcomes with BIMA graft. Again the follow-up duration of 5–10 years is short to show beneficial effect because while arterial graft attrition is maximum in first 5 years, the SVG attrition is more after 5 years and especially after 10 years. Also, the study suffered from high crossover: 14% of BIMA group received SIMA and a large number of single SIMA group received an additional RA graft. We know that RA grafts have nearly similar patency as that of RIMA.

While the above listed issues are real dilemmas, none of them justify not using BIMA.

TECHNIQUES OF HARVESTING

Basic Principles

- Proper exposure using appropriate specialized IMA retractor
- No touch technique of dissection without handling the arterial conduit
- Avoid injury to IMA - most dissections must be done with no touch and minimal handling
- Using harmonic scalpel or cautery at a very low setting
- If not using harmonic scalpel, using clips on either side of IMA branches and cutting with a sharp 45° angle Castroviejo scissors
- Irrigating the surface of IMA with dilute papaverine solution intermittently to avoid spasm
- Identifying occasional large pericardiophrenic and highest intercostal branch and clipping to prevent competitive flow
- Routing the IMA: If preserving pleura (to reduce pulmonary complications), create a space between mediastinal and parietal pleura and making an incision on extrapleural dissected area of pericardium and directing IMA behind lung to avoid stretching of IMA by lungs.

If pleura is opened, making an incision in the pericardium to direct the IMA behind lung as above.

Skeletonized Harvesting

- Internal mammary artery is dissected by ligating IMA branches close to it without removing the accompanying vein and surrounding tissues, so that collateral circulation to the sternum is maintained³⁹
- Avoid using electrocautery to divide branches to prevent thermal injury to IMA
- Minimal use of electrocautery at low thermal setting
- Divide branches using harmonic scalpel or cutting them with a fine scissor in between metal clips
- Cover the mammary bed, after IMA dissection, with the endothoracic fascia.

As discussed earlier, skeletonization of IMA not only reduces superficial and deep sternal wound infection^{25,26}, but also increases the length of IMA reaching out *in situ* to distal coronary branches such as PDA or OM and also increases diameter of IMA thus increasing flow.⁴⁰ Because of higher flow a skeletonized IMA, especially *in situ* IMA, can be used to graft a less critically stenosed coronary artery or stenosed vein graft,⁴¹ a relative contraindication for using pedicled IMA.

Prevention of Arterial Graft Spasm

The commonest cause of spasm of arterial conduits is due to injury to vessel wall or endothelium from rough handling during harvesting. The basic principles enumerated earlier, i.e., no touch harvest, with minimal conduit handling, low electrocautery setting, etc. must be adhered to. Spraying diluted papaverine during dissection is the most common method used. Other pharmacological agents used are:

- Intraluminal use of 2–3 mL solution of milrinone buffered in warm heparinized blood into lumen of harvested arterial conduit using a catheter with bulbous tip (milrinone mix = 10 mL milrinone + 18 mL heparinized blood + 2 mL – 2,000 IU – heparin)
- Storing harvested arterial conduits in buffered blood containing phenoxybenzamine or verapamil.²³

The above is supplemented in the postoperative period for 24–48 hours with intravenous nitroglycerine or/and IV diltiazem for 24 hours and amlodipine 5 mg daily for 6–36 months.²³

FACTORS INFLUENCING GRAFT PATENCY

Patency of arterial grafts depends on multitude of factors not intrinsic to arterial conduits, be it IMA or RA or RGEA or IEA. Extrinsic modifiable factors influencing graft patency include:

- Harvesting technique
- Graft ischemia
- Degree of stenosis in coronary artery (competitive flow)
- Coronary artery grafted
- Lie and length of the conduit
- Experience of surgical team.

Harvesting Technique

Importance of technique cannot be overemphasized. Many of the events that lead to an arterial graft failure occur early in the operation. Careful dissection, vasodilatation, storage, etc. as discussed earlier can avoid graft injury and ischemia leading to reduction in graft closure. While dissecting conduits, any direct, thermal, electrical injury, kinking, hematoma in arterial wall, branch avulsion, drying of blood vessel over distension should be avoided.

Graft Ischemia

Reducing graft ischemia, i.e., time between interruption of blood supply to the conduit (disconnection of arterial graft) and re-establishing circulation (i.e., by completing one anastomosis), is important in preventing damage to endothelium and vessel wall. Thatte et al.⁴² had reported that in veins, within 60 minutes of storing autologous heparinized blood, exhibited markedly diminished calcium mobilization and nitric oxide generation, as well as non-viability of 90% of endothelial cells. The ischemic period of a conduit should be kept minimum by careful planning of grafting order and disconnecting the arterial conduit at the last moment just before the particular anastomosis.

Degree of Stenosis in Coronary Artery

Unlike SVG, which are not affected by native coronary artery stenosis (NCAS) or competitive flow, all arterial grafts' (especially free grafts) patency are affected by NCAS.^{23,43,44} When the block in coronary artery is not critical (<70%), there is still significant flow in the native vessel which competes with the constructed graft. IMAs are less sensitive to this and their graft patency rate reduces if the NCAS is <60%. RA and RGEA are extremely vulnerable. The best patency rate of these conduits are achieved only when the NCAS is more than 80%, more so if NCAS is more than 90% especially for RCA. Unfortunately, assessment of NCAS is subjective and flow through a 80% stenosed 4 mm RCA will be far more than through 80% stenosis in a 2 mm Cx. Residual coronary artery diameter is probably a more objective indicator, with 1 mm or less residual diameter a threshold for significant influence on arterial graft patency.⁴⁵

Coronary Artery Grafted

Patency of arterial grafts depends on the coronary artery grafted, with highest patency of arterial grafts achieved when grafted to LAD, followed by Cx and grafts to RCA has the lowest patency rate.¹⁷

Lie and Length of the Conduit

The length, lie, and rotation of the conduit are important technical points affecting a graft's patency. A long graft may get kinked or a short graft may get stretched, especially if routed in front of the lung instead of behind it risking its patency. Skeletonized IMA are prone to 180–360° rotation of conduit in long axis, which can lead to graft closure.

Experience of Surgical Team

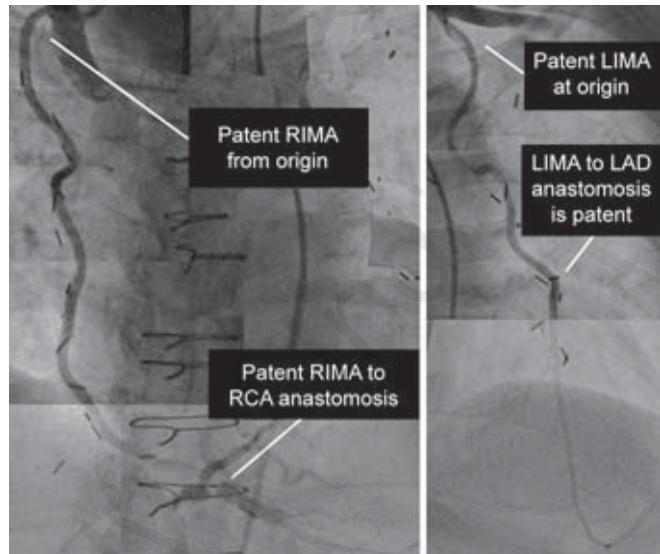

The relationship between center or operator (surgeon) experience and outcome has been extensively described in medicine and surgery.⁴⁶ Construction of coronary anastomosis using arterial conduits, especially BIMA or RGEA, is technically complex and surgical volume and experience plays a very important role. Grandjean et al.⁴⁷ have reported an RGEA patency of 77% in their first year of experience, which increased to 95% at the end of their learning curve by the fourth year. The results of 10-year ART data (unpublished) presented at the European Society of Cardiology meeting in August, 2018, suggest surgeon experience to be a crucial factor for outcomes with arterial grafts.

COMPARATIVE PATENCY DATA OF ARTERIAL GRAFTS

Graft Patency

Since the publication by Loop et al. in 1986¹ (and other publications around that time), it is universally accepted that LIMA is the best coronary graft, and LIMA-to-LAD is the single most important component of any coronary revascularization in reducing recurrent cardiac events and enhancing survival.⁴⁸ It is often described as “gold standard” or “benchmark”. LIMA-LAD improves perioperative mortality and can be used, and is strongly recommended, in all situations including emergency revascularization, older age, and in patients with comorbid states (diabetes, obesity, renal dysfunction, and COAD).⁴⁹ The only situations where it may not be usable are if it is damaged, is of insufficient size, and has inadequate flow to sustain the dependent vessel and myocardium. In our experience, it is extremely rare to find an IMA which is small for grafting to a coronary artery, and the low flow is usually due to improper harvesting techniques. As many as 80% of IMA conduits have been shown to be free from failure in the third decade after CABG.¹⁹ RIMA-to-LAD has the same patency as that of LIMA-to-LAD.⁵⁰ Tatoulis et al.¹⁷ reported similar patency between RIMA and LIMA when grafted to the same target vessel. When grafted to LAD, it was 98% versus 98% at 5 years and 95% versus 96% at 10 years. When grafted to Cx, it was 96% versus 96% at 5 years and 91% versus 89% at 10 years. Several angiographic studies from 6.7 to 12 years following surgery have reported similar RIMA patency rates (ranges from 86 to 97%) as compared to LIMA^{4,51} (Fig. 1).

The patency rates of the RA range from 83 to 91% at 5–7 years postoperatively, thus demonstrating a superior patency of the RA versus SVG.^{52–54} A meta-analysis of 35 studies showed a significantly lower RA graft failure compared to SV grafts (9.6% vs. 18.8%).⁴⁴ The graft patency of RAs of 88.6% was superior to that of the SVs of 75.8%. Similar findings have been reported by a recent single-institution study involving 1,851 patients showing a superiority of the RA compared to the SV in terms of graft patency and graft failure.⁵⁵ When grafted to largest non-LAD artery, the free RIMA patency is not significantly different from that of RA.^{18,55}

LIMA, left internal mammary artery; RIMA, right internal mammary artery; RCA, right coronary artery; LAD, left anterior descending artery.

FIG. 1: Patent bilateral internal mammary artery at 22 years postoperatively.

Patency of GEA grafts is dependent on tight stenosis and if grafted to RCA, must be done to one with a stenosis of >90%. Suma et al.⁵⁶ reported a graft patency of 85.5% at 5 years and 66.4% at 10 years in 172 angiographic studies among 1,352 patients receiving a GEA. However, most of these were grafted to an RCA with <90% stenosis. This poor long-term result has been improved to 94.7% at 5 years and 90.2% at 8 years by skeletonizing of GEA and grafting to >90% stenosed vessel⁵⁷ (Fig. 2).

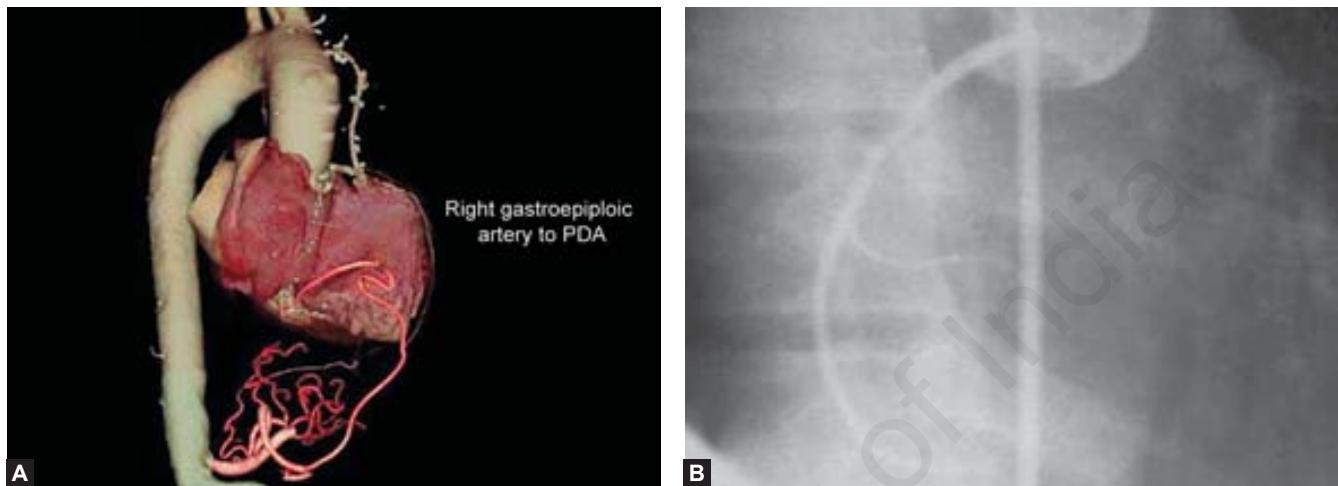

Very few studies published about the use and patency of IEA. Buche et al.⁵⁸ reported a patency rate of 92% at 8.5 months, 86% at 2 years, and all the five grafts studied at 5 years were patent. Of the grafts occluded, most were anastomosed to a non-critically blocked artery.

Multiarterial CABG, including bilateral ITA grafts, has been consistently associated with better arterial graft patencies (better than 90% at 10 years) and long-term survival in diabetic patients, those with renal dysfunction, women, and older patients.²¹

In summary, most of the arterial grafts have a good long-term patency, with RIMA equivalent or slightly superior to RA, which in turn is superior to GEA. The huge disparity in literature among the arterial conduit patency is because analysis of most studies has not included other factors affecting graft patency, mainly noncritical stenosis and the coronary artery grafted, i.e., Cx versus RCA. Table 1 summarizes some of the long-term patency rates of arterial grafts versus SVG published in literature.^{59,60}

SURVIVAL BENEFIT

Adding even one arterial graft to LIMA-to-LAD has shown to improve survival and reduce late cardiac events such as recurrence of angina or MI^{6,7} but some studies have failed

PDA, posterior descending artery.

to show additional survival benefit.³² This is because the significant survival benefit of LIMA-to-LAD derives from high patency rate of the graft supplying to the largest area of myocardium. An equivalent area of myocardium needs to be supplied by additional arterial conduits to show benefit. Grafting the second or third arterial conduit to a small Dg or OM or small PDA will not show survival benefit. Secondly, many of these studies are short- to medium-term follow-up and we know while arterial graft attrition is maximum in the first decade that the vein graft attrition increases after 5 years and more so after 10 years. In fact most follow-up studies of more than 10 years have shown the additional survival benefit and protection from late cardiac events of multiple arterial grafting.⁶⁷

There is no significant differences between BIMA and LIMA use with regard to perioperative complications and postoperative length of stay, deep sternal wound infection in non-diabetic or diabetic (if IMA is skeletonized), although more BIMA patients required blood transfusions and reoperation for bleeding.^{36,61} The in-hospital and 30-day mortality rates were not significantly different between BIMA and LIMA groups.

Multiple observational long-term follow-up studies have shown advantages of BIMA/TAR in terms of long-term survival, reoperation, and the need for angioplasty.^{6,7} A clear benefit is seen in the first postoperative decade and its advantage becomes even more apparent during the second postoperative decade as vein graft attrition increases. A retrospective study by Lytle et al.⁶² demonstrated survival in the BIMA group of 94%, 84%, and 67% versus 92%, 79%, and 64% in the LIMA group at 5, 10, and 15 years postoperatively, respectively ($p < 0.001$). Similar superiority of BIMA grafting over LIMA with regard to long-term survival throughout the follow-up period (96% vs. 91% at 5 years, 89% vs. 79% at 10 years, and 79% vs. 61% at 15 years) was reported by Grau et al.³⁶ The survival benefit of BIMA over SIMA has been reported to be from 8 years throughout the study period⁶³ to >10% for BIMA grafting at 20 postoperative years.^{6,7,62} Similar survival benefit of 10% at 10 years and 18% at 18 years was reported by Grau et al.³⁶ among patients receiving BIMA compared to LIMA use only.

Bilateral internal mammary artery grafting showed similar survival benefit over SIMA in diabetic patients too. In a large meta-analysis that compared 19,277 BIMA to 59,786 LIMA patients,⁶⁴ diabetic patients who underwent BIMA harvesting had an increased 10-year survival rate and a lower perioperative mortality rate compared to the LIMA group.⁶⁵

Although no freedom from adverse events such as angina recurrence, new MI is observed during the first 4 years, a clear benefit is gained from the use of BIMA after 10 years,⁶⁶ and a 9% decrease in angina recurrence at 15 years.⁶⁷ BIMA is also associated with an additional 7 years of freedom

CABG, coronary artery bypass grafting; GEA, gastroepiploic artery; IMA, internal mammary artery; RA, radial artery; SVG, saphenous vein graft.

FLOWCHART 1: Algorithm for total arterial revascularization, while considering that left internal mammary artery is always grafted to left anterior descending artery.

from reoperation as a result of better graft patency rates.⁶³ Incremental benefit of BIMA grafting has been shown in elderly though the data is not as convincing. Kurlansky et al.⁶⁸ have reported an enhanced long-term survival in patients older than 75 years receiving BIMA. There is evidence that RA and LIMA grafting has a strong protective effect against native CAD in previously grafted vessels, whereas SVG does not have such protective effect, again emphasizing the advantage of total arterial grafting.⁶⁹

Gastroepiploic Artery and Survival

Right gastroepiploic artery has poor long-term prognosis and patency when grafted to LAD⁷⁰ and should be avoided. Suzuki et al.⁷¹ in a comparative study of GEA versus SVG as a complement third conduit to left-sided BIMA graft reported superior freedom from death from all causes (96% GEA vs. 82.2% SVG) and freedom from cardiac events (cardiac death, MI, angina pectoris, repeat intervention, and heart failure) of 89.3% for GEA versus 77.5% for SVG.

DISCUSSION

In spite of overwhelming evidence of superiority of multiple arterial grafts over use of SIMA with vein grafts, hardly 5% patients receive BIMA whereas RA is used between 5 and 40% patients worldwide. Between 2004 and 2014, only one arterial graft was used in over 95.9% of all CABG in the United States (Society of Thoracic Surgeons (STS) database) and in 95.7% in the Australia and New Zealand (ANZ) patients.⁷² This trend is no different from usage of BIMA in earlier decade among STS participating institutions.¹³ Single arterial coronary bypass rate increased both in STS from 85.2 to 91.7% and in ANZ patients from 17.3 to 51.4%. BIMA use was very low

(STS: 4.1%, ANZ: 4.3%), unchanged in STS, and decreased in ANZ patients. RA graft use decreased among STS patients from 10.5 to 3.7% and ANZ patients from 65.8 to 39%. Total arterial/multiple arterial bypass grafting was an abysmal 0.5% among STS patients and a little better but still very low of 5.9% among ANZ patients. The reason for low use of arterial conduits is complex and multifactorial. The perceived concerns as mentioned earlier (technical difficulties, enhanced postoperative complications, lack of randomized trials, etc.) and focus on short-term “quality metrics” such as longer operating time and avoidance of deep sternal wound infection by hospital administrators contribute significantly to this low use. In many countries, insurance does not reimburse cost of treatment of deep sternal wound infection.

Though long-term conduit patency is the key factor for success of CABG, no precise guideline exists and the choice of revascularization strategy by most surgeons is more of an art than science. LIMA-to-LAD is the gold standard and forms the cornerstone of CABG. As discussed earlier, there is robust evidence to suggest that an additional arterial graft (RIMA or RA), rather than a vein, is associated with improved late survival and reduced cardiac event.^{6,7,36,63} The benefits of second arterial grafts also apply to those with unstable angina or reduced ventricular function.^{73,74} The location of second arterial conduit does not modify the extent of survival advantage.⁷⁵ In patients with risk of mediastinitis, the use of RA instead of RIMA can safely increase the use of second arterial conduit.⁷⁶ All the available evidence in literature points to the use of multiple arterial graft/total arterial graft except where contraindicated (Flowchart 1). Lack of proper protocol for BIMA grafting contributes to the variation of its use among the surgeons which can be mitigated by developing guidelines for BIMA usage taking

into variables such as age, diabetes, obesity, LV function, and a scoring system taking into consideration the SYNTAX and EuroSCORE can help standardize BIMA usage.⁷⁷

Right Internal Mammary Artery

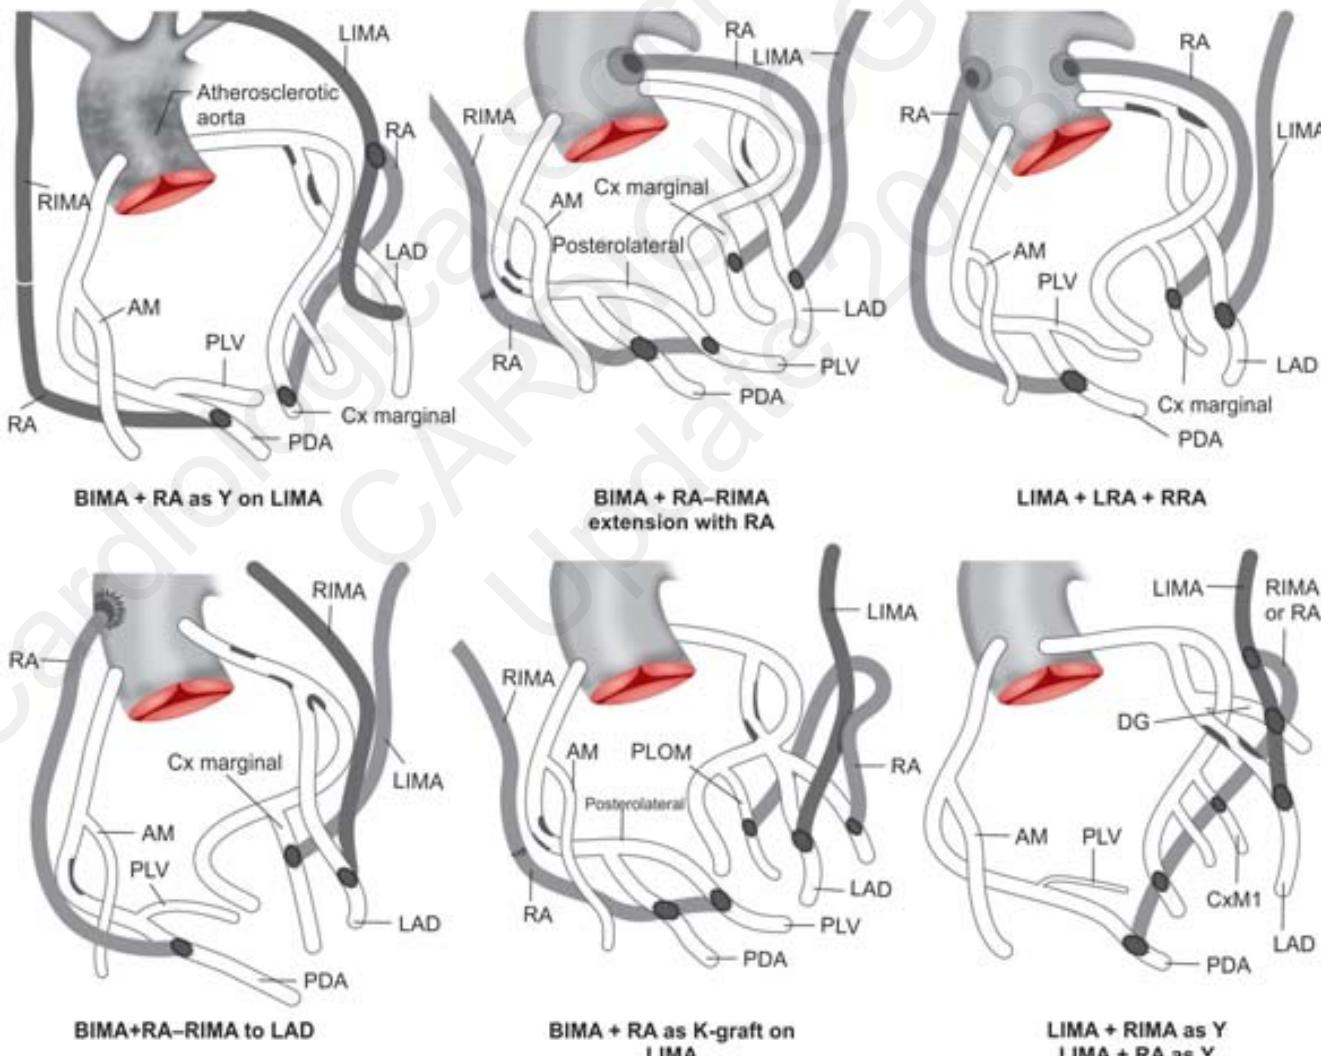

After LAD territory, Cx territory revascularization is more important than RCA except in patients with a large tightly stenosed RCA.⁹ RIMA can be used as *in situ* graft to intermediate or OM across midline behind thymus, either in front of aorta or behind through transverse sinus. Alternately, it can be used as free graft, with proximal anastomosis on aorta over hood of a vein graft, over vein patch, or directly to it. To reach the inferolateral and RCA branches, it can be attached as Y or T graft to the side of LIMA. RIMA preferably be grafted to a critically stenosed (>90%)^{4,17} large RCA, especially to its distal PDA and posterior left ventricular branches. It is better to avoid grafting to main RCA as either there is nonocclusive disease at crux at the time of grafting or crux develops occlusive disease over the next 5–10 years.^{4,17} If the length of

RIMA does not reach distal RCA branches, it is better to use as free graft. Skeletonization of RIMA helps getting additional length to reach distal RCA or Cx branches.

Radial Artery

The length and size of RA allows it to reach most distal coronary arteries and perform sequential anastomosis. The proximal anastomosis is preferably done to aorta over a vein graft hood, or vein patch or directly on aorta. Alternately, it can be attached to the side of LIMA or occasionally to RIMA as a T or Y graft to reach out both distal Cx and RCA branches. RA is more sensitive to competitive flow compared to IMA. While IMAs are resistant to competitive flow in coronary stenosis >70% and can be grafted to any coronary artery with >70% stenosis, RA preferably should only be grafted to an artery with stenosis of >90%.^{20,23}

In summary, BIMA (Flowchart 1), especially an *in situ* IMA, should be grafted to LAD and Cx with stenosis of >60% and RA-to-Cx with >70% stenosis, preferably >80% stenosis.

FIG. 3: A few suggested arterial graft configurations.

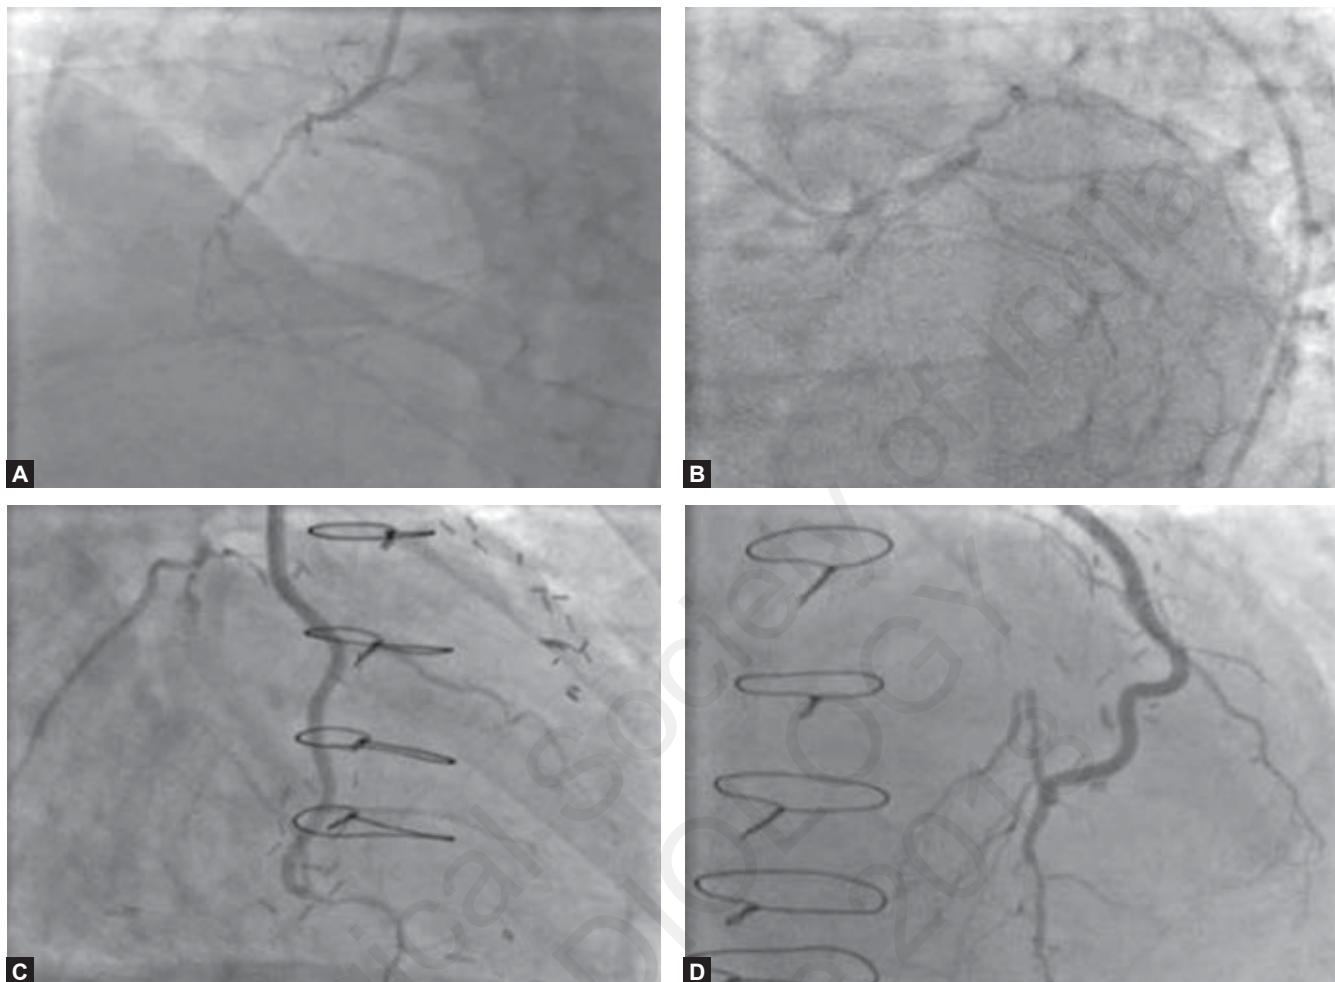

FIG. 4: Preoperative and 7 years postoperative angiogram of a patient with diffuse coronary artery disease. (A and B) Preoperative angiogram; (C and D) Postoperative angiogram.

Arterial conduits should only be grafted to RCA with >90% stenosis. SVG should be used in RCA stenosis of <90% and Cx stenosis of <60%. The choice of coronaries grafted by arterial conduits are BIMA to left system (preferably LIMA-to-LAD and RIMA-to-Cx) with RA to RCA if stenosis is >90% or SVG if <90%.

Graft Configurations

Left internal mammary artery, RIMA, and RA can be used in innumerable combinations depending on needs (Fig. 3).

Internal mammary artery can be *in situ*, LIMA-RIMA “Y,” RIMA can be brought across midline to LAD territory, and LIMA can go to Cx and PDA territory (both *in situ*). RITA can be used *in situ* for proximal Cx territory across transverse sinus. RA can be used as “Y” on any ITA or can be attached to aorta for proximal anastomosis. Any conduit length saved from one territory may be used to extend other conduit. Our preference is to use BIMA with RA when needed. In patients with high risk of deep sternal infection, we use LIMA with RA.

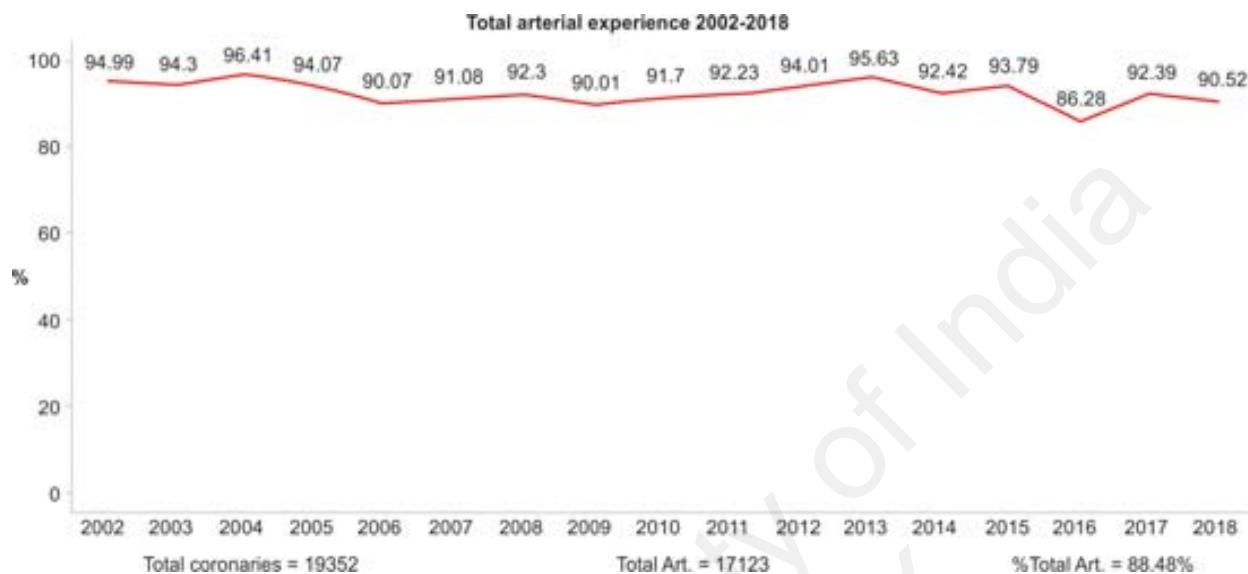

FIG. 6: Total arterial grafting—author's institution experience between 2002 and 2018.

Young Patients with Coronary Artery Disease

Though there is a paucity of information in literature, the few reports available in literature on short- and long-term results of young patients (a significant number of Indian patients fall into this category) with CAD undergoing conventional CABG of one IMA and SVG portray a very bleak outcome in this subcategory of patients. Lytle et al.⁷⁸ in a follow-up study of younger patients had reported an overall vein graft patency of 56% at mean interval of 47 months compared to 80% in older patients. Compared to this, IMA had a better overall graft patency of 93% in younger patients compared to 98% in older patients. A 20-year follow-up of young patients (below 40 years) undergoing predominant SVGs showed 27% mortality at 10 years and an estimated mortality of 69% in the second decade, while all these patients were still <60 years age.⁷⁹ Only 31% of patients who were operated when they were below 40 years were alive at 60 years. These horrendous results in young patient undergoing conventional CABG with one IMA and SVG grafts emphasizes the need for total arterial grafting in these subset of patients (Fig. 4).

Diffuse Coronary Atherosclerosis

Subgroup of patients with diffuse distal coronary atherosclerosis and small coronary arteries pose a difficult decision-making dilemma. This is more so in Indian scenario, where because of small body surface area resulting in smaller coronary arteries and high incidence of diabetes, more patients undergoing CABG have diffuse CAD with small coronary arteries. In our experience and that of Kasliwal et al.,⁸⁰ close to 50% patients undergoing CABG in India have diabetes compared to 40% among Western counterpart.¹³ As discussed earlier, most of these patients are younger and the short- and long-term vein grafts patency rate in these

patients are extremely poor⁷⁷ and long-term survival is abysmal.⁷⁹ We strongly believe that extending the principles of multiple arterial grafting, to revascularize all coronary branches above 1 mm, in symptomatic patients especially with a strongly positive exercise scintigraphy is the best option. We quite often perform more than five arterial grafts (Fig. 5), and our incidence of patients needing more than five grafts has increased from 23% patients in 2003 to 50% today (unpublished data).

CONCLUSION

Most patients with MVCAD, except those with non-critically blocked coronary artery, can and should receive total arterial grafting. Skeletonization of both IMAs reduces sternal infection, increases available length reaching out to distal coronary arteries, and improves flow thus increasing the number of patients who will benefit. BIMA grafting can be safely performed and increasing evidence points to fewer perioperative complications, higher graft patency rates, excellent long-term survival rate, reduced adverse cardiac events resulting in reoperation, and lower CAD progression in grafted arteries in patients undergoing TAR. Total arterial coronary revascularization (TACR) should be done in all patients except where contraindicated and is possible to achieve in over 80% patients (Fig. 6). Since 2003, we have been able to achieve TACR in close to 90% patients undergoing CABG at our institution.

Surgery in Acute Myocardial Infarction

Ganesh K Mani, Pramod K Sharma, Manju Mani

INTRODUCTION

The most serious consequence of coronary artery disease is acute coronary syndrome (ACS) which can lead to long-term disability and death. Mortality rates for men and women older than 40 years of age are 18% and 23%, respectively and account for nearly 1.5 million hospital admissions annually in the United States of America.¹

Prompt restoration of myocardial blood flow is essential to optimize myocardial salvage and decrease mortality in the first few hours after acute myocardial infarction (AMI). About 20–30% of patients with AMI come forward for coronary artery bypass grafting (CABG) as they are considered ineligible for percutaneous coronary intervention (PCI). The optimal timing of CABG in AMI setting has remained a matter of discussion and debate, making “myocardial salvage”, the combined responsibility of both the cardiologist and cardiac surgeons.²

Both the American College of Cardiology/American Heart Association (ACC/AHA) and European Society of Cardiology/European Association for Cardio-Thoracic Surgery (ESC/EACTS) guidelines provide guidance on the use of CABG as an emergency procedure.³

- *Class I:* Indication for CABG in the context of ST-segment elevation myocardial infarction (STEMI) if PCI has been impossible to perform or has failed and the patient has persistent pain and ischemia threatening a significant area of myocardium despite medical therapy
- *Class I:* Indication for emergency surgery:
 - Ventricular septal defect (VSD) (post MI)
 - Papillary muscle rupture resulting in acute and severe mitral regurgitation (MR)
 - Free wall rupture
 - Ventricular pseudoaneurysm
 - Life-threatening ventricular arrhythmias
 - Cardiogenic shock (CS).

However, emergency CABG is not recommended:

- Persistent angina, but only a small area of myocardium at jeopardy and patient is hemodynamically stable

- No reflow state (unsuccessful microvascular reperfusion)
- Ventricular tachycardia with scar and no evidence of ischemia.

CORONARY ARTERY BYPASS SURGERY AFTER FAILED PCI

Recommendations for emergency CABG after failed PCI include the following:

- Ongoing ischemia or threatened occlusion with myocardium at risk (class I)
- Hemodynamic compromise with impairment of coagulation and without previous sternotomy (class IIa)
- Hemodynamic compromise in a previous sternotomy (class IIb)
- Retrieval of foreign body (e.g., fractured guidewire or stent) in a critical location (class IIa).

Over the past decade, PCI has become primary treatment not only for STEMI but also non-STEMI (NSTEMI) (or unstable angina). CABG is reserved for multivessel disease or left main disease (LMD) and is most often performed as an elective or semiacute procedure after stabilization of acute ischemic symptoms.^{3,4}

Advancements in PCI have altered the need for emergency CABG.⁵ The unpredictable outcomes after emergency CABG triggered the strategy of allowing a “cooling off” period after AMI. However, mortality in patients undergoing emergency CABG could be reduced substantially⁶ by using a prospective treatment protocol.

A predictive formula was proposed on the basis of regression analysis (30-day mortality) (Table 1).⁷

When patients were taken up for CABG immediately (1–6 hours), mortality rate for NSTEMI was 2% and STEMI was 15%.⁸ Because of the relatively low mortality in NSTEMI, Caceres et al. concluded that in general, delaying CABG especially in hemodynamically stable patients cannot be considered “standard of care” any longer, especially in NSTEMI! The question however remains as to what is the

TABLE 1: Regression analysis (30-day mortality)⁷

Factor	p	p (logistic regression)
Cardiogenic shock	0.043	–
IABP preoperative	0.064	–
LVEF	0.002	–
STEMI	0.014	–
CK-MB >100 (U/L) 6-h	<0.001	–
CK-MB >100 (U/L) 24-h	0.054	–
EUROSCORE	0.04	p <0.001 HR 1.216 95% confidence interval 1.082–1.366

CKMB, creatine kinase-MB; HR, hazard ratio; IABP, intra-aortic balloon pump; LVEF, left ventricular ejection fraction; STEMI, ST-segment elevation myocardial infarction.

Source: Khaladj N, Bobylev D, Peters S, et al. Immediate surgical coronary revascularisation in patients presenting with acute myocardial infarction. *J Cardiothorac Surg*. 2013;8:167.

optimal timing for CABG, especially in the era of clopidogrel, ticagrelor or prasugrel.

Timing of CABG in ACS appears a critical factor in predicting outcomes after emergency CABG. Caceres et al.⁶ surmised that CABG had relatively similar outcomes in NSTEMI and STEMI though they maintained STEMI as a risk factor for CABG.⁶

But in 2017, quite a contrary view was noted by workers in Germany.

In the absence of CS, Grothusen et al. (2017)² found superior short- and long-term outcomes for STEMI patients vis-a-vis NSTEMI patients. STEMI patients were significantly younger with lower risk profiles and shorter referral times. The NSTEMI patients were older, had diabetes, hypertension, renal dysfunction, and multivessel involvement and were referred later in the course of their hospital stay.

OUTCOME OF SURGERY WITHIN 6 HOURS

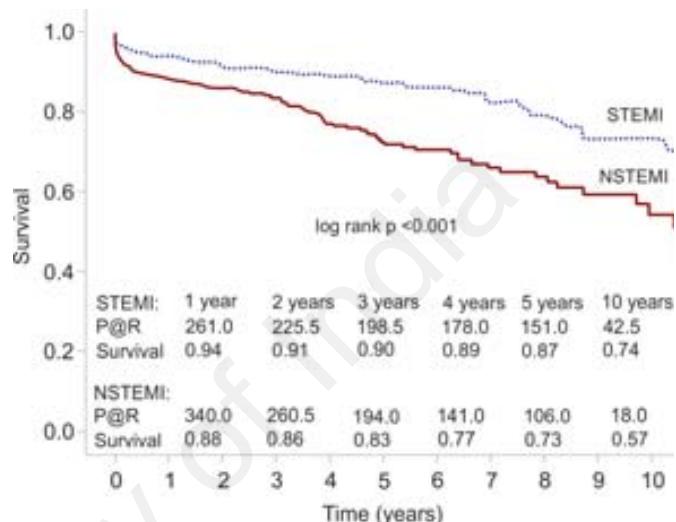

Grothusen et al. noted that 56% patients of STEMI were operated within 6 hours whereas only 20% of NSTEMI underwent CABG within 6 hours.

Presumably, the NSTEMI patients were sicker as evidenced by higher lactate levels, the higher incidence of preoperative balloon pump insertions. They observed that increased lactate level in excess of 2 mmol/L was associated with higher morbidity and mortality.

Some previous studies indicated that delayed surgery may improve outcomes because of the “proinflammatory” state of these patients causing a “shock”-like state.

Until recently, majority of surgical data indicated that it was indeed worthwhile to wait after AMI for the proinflammatory state to cool off.

Caceres et al. in 2013 was one of the first authors to differentiate between STEMI and NSTEMI as outcomes appeared different.⁶ STEMI was considered an incremental

STEMI, ST-segment elevation myocardial infarction; NSTEMI, non-ST-segment elevation myocardial infarction; P@R, patients at risk.

FIG. 1: Ten-year survival after acute myocardial infarction and coronary artery bypass. Kaplan-Meier survival curves for STEMI and NSTEMI patients showed significant survival differences.

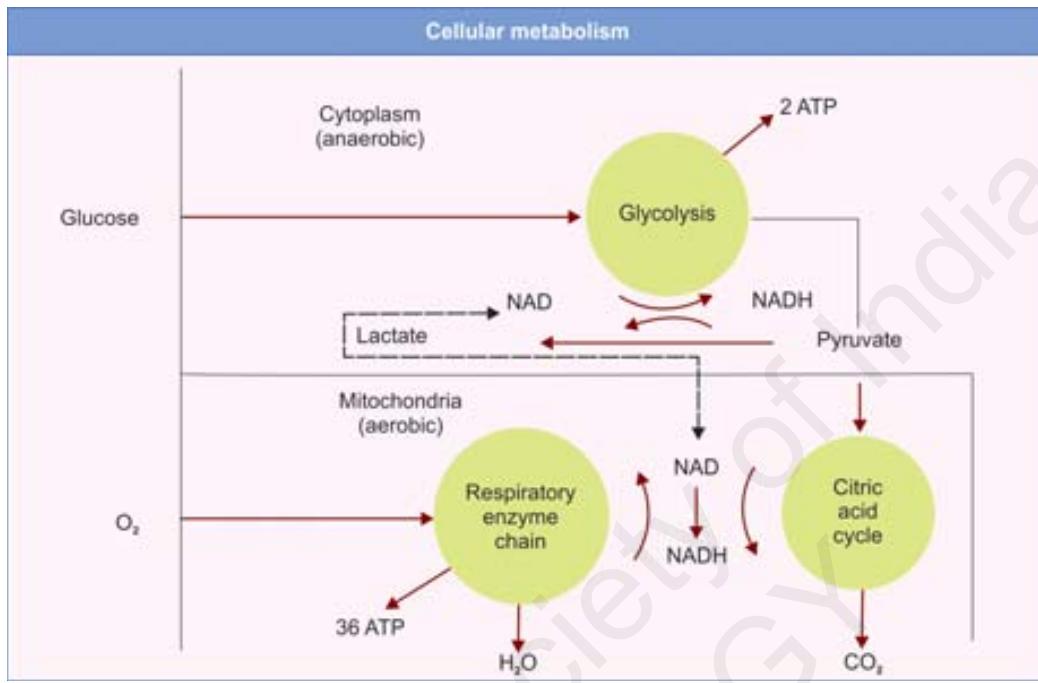

Source: Grothusen C, Friedrich C, Loehr J, et al. Outcome of Stable Patients With Acute Myocardial Infarction and Coronary Artery Bypass Surgery Within 48 Hours: A Single-Center, Retrospective Experience. *J Am Heart Assoc*. 2017;6(10). pii: e005498.

risk factor (because of thrombolytics or other antiplatelet drugs on board). However, subsequent data from Grothusen et al. in 2017 indicate that hemodynamically stable STEMI patients can safely undergo early revascularization. In contrast, the surgical NSTEMI population described in this study consisted of older and sicker patients with consequently higher preoperative risk! The ACC/AHA guidelines advice seem to be in line with this experience in NSTEMI.

However, contrary to expectations, Grothusen observed that the CABG after STEMI fared better in the short-term as well as long-term! Survival of STEMI and NSTEMI at 1-year was 94% versus 88% ($p <0.001$), 87% versus 73% after 5 years ($p <0.001$), and 74% versus 57% after 10 years ($p <0.001$). Thus they concluded that STEMI patients (not in CS) fared better than NSTEMI patients when subjected to CABG within 48 hours. This observation of outcome in STEMI patients after CABG somewhat challenges the guidelines which have hitherto recommended surgery only after the cooling off of the proinflammatory state (Fig. 1).

OPTIMAL TIMING OF CORONARY ARTERY BYPASS SURGERY IN ACUTE MYOCARDIAL INFARCTION

Nichols et al. 2017⁹ found that crude in-hospital mortality was higher for those whose MI to CABG time was less than 24 hours (5.1%) compared to 1–2 days (1.6%) or 6–7 days (1.6%). These results were similar to those of Parikh et al. 2010¹⁰ whose analysis showed no difference in mortality rates between patients undergoing CABG less than 48 hours or more than 48 hours.

NAD, nicotinamide adenine dinucleotide.

FIG. 2: Beating heart techniques maintain the myocardium in an aerobic state and thereby preserve 18 times more adenosine triphosphate (ATP) than the arrested heart which maintains the myocardium in an anaerobic state.

OPERATIVE STRATEGY (ARRESTED OR BEATING HEART?)

Chikara Ueki et al. 2016¹¹ postulated that on-pump beating heart CABG (On-BH-CABG) is associated with significantly lower morbidity and mortality (45%) as a result of lesser incidence of perioperative myocardial infarction ($p < 0.001$), lesser renal failure ($p < 0.001$) and lesser low output syndromes ($p < 0.001$).

The On-BH-CABG could be an attractive planned alternative to conventional cardioplegic arrest CABG in this high-risk patient population.

However, they observed that it was important to maintain a high arterial pressure during perfusion as it ensured better results.

The myocardial metabolism is maintained in an aerobic state during both off-pump coronary artery bypass graft (OPCABG) as well as On-BH-CABG which is essentially a nonischemic surgery. The preservation of mitochondrial adenosine triphosphate (ATP) could be the reason for less myocardial stunning and thereby better outcomes (Fig. 2).

PERSONAL EXPERIENCE

Though we have had a vast experience of over 15,000 CABGs (1985 to date), we concede that suboptimal record-keeping has precluded the publishing of our results! About 600 CABGs would have been done so far by us within 48 hours after AMI

in the last 33 years. Of these, over 300 would have been done by beating heart technique (on-pump or off-pump). The unit policies have changed over the last three decades and so have clinical strategies.

The recent unified "Heart Team" strategy is offering the best option to the ischemic myocardium in AMI. It has been our current policy that CABG is first option in left main stem disease. However, in severe triple vessel disease, stabilizing hemodynamics with plain old balloon angioplasty (POBA) to restore some flow in the culprit artery and wheeling the patient at the earliest to the operating room possibly preserves myocardium better. Intra-aortic balloon pump (IABP) support is particularly valuable if the operation is planned on a beating heart. However, we have readily put the patient on cardiopulmonary bypass whenever hemodynamics were compromised. Before 2000, almost all these operations were done with anoxia and cardioplegia. But since 2000 onwards, all emergency CABGs whether done "off-pump" or "on-pump" were done on beating heart.

Excessive bleeding consequent to the recent use of reteplase and ticagrelor have been managed with cell saver assisted autotransfusion, fractionated blood products, and pharmacological agents like tranexamic acid.

However, a more detailed study comparing surgical outcomes in urgent and delayed CABG in AMI and those of CABG in STEMI and NSTEMI is warranted before we establish that both PCI or CABG emerge to have the same therapeutic value in AMI.

CONCLUSION

Surgery in AMI (excluding postinfarction VSD, acute MR, impending cardiac rupture) is an area where cardiac surgery was not routinely envisaged due to former erroneous attitudes of permitting “cooling off” of a proinflammatory clinical condition following AMI. Contemporary experiences of authors have busted this myth!

The presence of CS (if effectively managed by timely institution of IABP) is no longer a contraindication to CABG and has infarct become an indication.

Though earlier cancers in 2013 had observed that NSTEMI patients fared better⁶ after CABG, more recently Grothusen in 2017 has shown that STEMI without CS actually fared better!²

If logistics are favorable, CABG should be undertaken (if necessary with IABP support) as early as possible, though this subset needs specialized care of blood pressure and arrhythmia. However, usually, one may have to wait till next day for logistic reasons. As per all literature reviewed there is no further advantage by waiting further to “cool” the patient as perceived earlier.

Though most of the Western literature pertains to CABG on the arrested heart, there have been some recent reports favoring off-pump.⁸ On-pump beating heart CABG,¹¹ our own personal experience supports the view that nonischemic technique (avoiding cardioplegic arrest) is a safer option in an already ischemic heart.

RECOMMENDED GUIDELINES

In India, in the middle of 2018, the possible recommended guidelines for revascularization in AMI would be:

- Percutaneous coronary intervention of culprit artery whenever possible
- Heart team to decide early for CABG whenever PCI is not possible
- In the presence of ongoing ischemia in triple vessel disease, culprit artery dilatation (POBA) and insertion of IABP could be done in cath laboratory as “bridge to CABG”.
- Early CABG can safely be undertaken in both STEMI and NSTEMI
- Avoiding ischemic cardioplegic arrest may be an advantage in this subset
- Ventricular septal defect repair or mitral valve replacement is necessarily done by on-pump cardioplegic strategies only and has not been addressed in this chapter.

Patients with biochemical values of creatine phosphokinase MB >100, and lactate level >2 mmol are higher risk patients and appropriate consents are advisable. Intra-aortic balloon pump is valuable adjunct and preferable to catecholamines and facilitates OPCABG. Though CABG on arrested heart is the prevalent therapeutic modality in the West, OPCABG (maintaining a higher mean arterial pressure during perfusion) seems to have superior outcomes.

EPILOGUE

The last word is yet to be written and that may alter the ACC/AHA and ESC/EACTS guidelines of the future.^{12,13} However as of the June 2018, CABG is indicated in AMI whenever PCI cannot be done. Beating heart surgery on IABP support and adjunctive cell saver support offers an equally safe option be it STEMI or NSTEMI. If ventricular arrhythmia or extremely unstable hemodynamics prevail despite IABP counterpulsation, off-pump or on-pump beating heart CABG should be the “standard of care” for revascularizing the ischemic or infarcting myocardium.

In any case, in LMD or severe triple vessel disease, present day strategies tend to equalize the outcomes of emergency CABG to elective CABG (and PCI)!

Recent Advances in Coronary Artery Bypass Graft

OP Yadava

INTRODUCTION

1965 was a revolutionary year in the field of coronary artery disease (CAD) when sutured anastomosis for coronary artery bypass graft (CABG) surgery was first performed by Kolessov and Potashov. Such was the impact of CABG that it surpassed any other cardiac surgery in numbers. Basking in the glory of the initial success, cardiac surgeons developed a

kind of inertia and coronary surgery remained static in the 1970s and 1980s. However, challenged and egged on by the advances in percutaneous coronary interventions (PCI), surgeons too started innovating both as means of improving patient outcomes and experiences as also to protect their turf and advances came fast and furious in 1990s and thereafter in the millennium (Fig. 1).

OPCAB, off-pump coronary artery bypass; MVST, Multivessel sternotomy NSCAB, Non sternotomy coronary artery bypass; TECAB, total endoscopic coronary artery bypass.

FIG. 1: Evolution of coronary artery bypass surgery.

MINIMALLY INVASIVE CABG

Minimally invasive cardiac surgery (MICS) envisages avoidance of both the cardiopulmonary bypass (CPB) and the sternotomy as its primary objective and reduction in the size of the incision as its secondary objective. Another advantage of MICS is avoidance of aortic manipulation thereby leading to a reduction of the stroke rates.¹ By avoiding sternotomy, respiratory functions are maintained better and the dreaded complication of mediastinitis can be eliminated. Avoidance of CPB prevents the whole body inflammatory response and its attendant side effects.² All this leads to fast tracking of the patients, besides improved cosmesis, as a small anterior or lateral thoracotomy is used for MICS.³ Left internal mammary artery (LIMA) can be harvested endoscopically, but is now being replaced with robotically assisted LIMA harvest. Simple LIMA to left anterior descending (LAD) coronary artery through an anterior thoracotomy (Figs. 2A and B) has been labeled minimally invasive direct coronary artery bypass (MIDCAB) but even multiple bypasses can be performed with use of nonsternotomy stabilizer and positioner.⁴ Excellent results have been demonstrated in skilled hands,⁵ with reduced need for blood transfusion, reduced atrial fibrillation, and postoperative strokes. MICS-CABG has been validated against PCI⁶ and conventional CABG.⁷ However, Rabindranauth et al. found less number of grafts being performed with a MICS-CABG than with sternotomy off-pump coronary artery bypass (OPCAB)—(2.1 vs. 3.2%, respectively)⁸ and graft patency too has been a matter of concern in some studies.⁹

Future is likely to witness increased penetration of MICS-CABG in the surgical fraternity as the surgical instrumentation and techniques improve. Robotically assisted CABG is another new development which is likely to see more traction going forwards. In fact Ishikawa et al.¹⁰ performed robotically assisted awake CABG—ultra MICS, under

epidural anesthesia and even day care MICS—CABG have been reported. Though currently, robotically assisted total endoscopic CABG (TECAB) may be inferior to MIDCAB,¹¹ but this may change as more and more experience is gained. As it stands today, MICS-CABG is a niche area meant for a limited few but with new anastomotic automated devices,^{12,13} these techniques are going to percolate widely as they have mass appeal to the patients too. Coronary-conduit coupling devices, magnetic couplers, and even glues and laser welding are being evaluated and may fructify in the future.

Simulation-based learning in the skills labs too would help matters going forward. Even bilateral internal mammary artery (IMA) can be harvested through a left mini thoracotomy using direct vision.¹⁴ In a limited survey carried out in India, 69% of the cardiac surgeons confirmed undertaking minimally invasive work, with a majority carrying 5–20% of their cardiac procedures using MICS techniques. However, only one-third of surgeons doing minimally invasive work were undertaking MICS-CABG.³ Future is going to witness personalized medicine and customized operations with “one size fit all” operations—a paradigm of the gone by era.

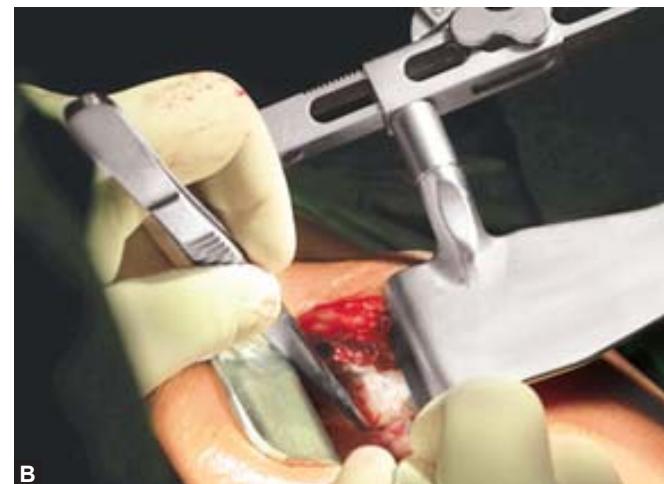

CONDUITS—IMPROVING PATENCY

Though arterial grafts have superior patency and total arterial revascularization (TAR) improves long-term survival rates (10 years survival 85.4% for TAR and 81.2% for non-TAR— $p <0.001$),¹⁵ almost 80% of all conduits used in CABG are saphenous vein (SV) grafts. Newer molecular targets involved in smooth muscle proliferation are being targeted to enhance SV patency.¹⁶ Even external vein graft support stents¹⁷ are being developed and gene and cell-based therapies too are being tried.¹⁸ Alternative conduits in form of nonautologous umbilical vein grafts, long SV homografts, treated bovine IMA, 3D printing of conduits, and tissue engineered conduits, available off the shelf, are on the horizon.

ON VERSUS OFF-PUMP CABG

Like any new technology, off-pump CABG came into vogue in 1990s with a lot of promise¹⁹ with the hope that avoidance of CPB will ameliorate all the systemic inflammatory ill effects of conventional CABG.² However, ROOBY (Randomized On/Off Bypass) trial²⁰ challenged it and even 5 years results showed higher mortality, myocardial infarction (MI), and lower graft patency with off-pump vs. on-pump CABG [relative risk (RR) 1.14; p = 0.046].²¹

However, the CORONARY (CABG Off- or On-Pump Revascularization Study) trial²² and Afilalo's meta-analysis²³ could not demonstrate any difference in the mortality, stroke, MI or quality of life measures between the two techniques. Even the patency rates²⁴ and survival up to 6–8 years²⁵ were same in the BHACAS I and II trials. Recent meta-analysis by Deppe et al.²⁶ and Luo et al.²⁷ too failed to demonstrate any difference in early mortality at 30 days and 6 months, respectively, between the two techniques.

Off-pump CABG may be associated with incomplete myocardial revascularization as suggested by the CORONARY trial.²² To the contrary, Palmer et al.²⁸ found that the ratio of anastomosis to lesions was same, thereby implicating patient selection for less number of grafts off-pump, i.e., probably patients needing less number of grafts were chosen for off-pump CABG.

With the use of anaortic, off-pump techniques, the perioperative stroke rates is likely to come down²⁹ and high-risk patients tend to benefit more from off-pump CABG³⁰ with less postoperative renal dysfunction, less bleeding and use of blood products, and early mobilization and discharge from hospital.

This raging controversy therefore seems to be surreal and those committed to off-pump ideology are likely to continue performing this procedure. In our experience of 3500 CABGs, off-pump CABG reduced mortality, specially in women, from 4.5% on-pump to 1.4% off-pump (p = 0.01).³¹

HYBRID MYOCARDIAL REVASCULARIZATION

Though a noble intent, of harnessing the survival benefits of the gold standard surgical LIMA to LAD anastomosis, and the use of PCI with drug-eluting stents for non-LAD vessels, with a view to lowering periprocedural complications, hybrid myocardial revascularization (HMR) has till date not lived up to the hype generated. HMR may be performed sequentially, with either CABG first, or PCI first, or it can be performed simultaneously in a hybrid theater. Though the safety and the feasibility of HMR is fully established, the POL-MIDES study³² failed to demonstrate any hard end-point advantage of HMR over CABG (all-cause mortality—CABG 2.9% vs. HMR 2% and 1 year survival CABG 92.2% vs. HMR 89.8%). Similarly, the HREVS (Hybrid Revascularization Versus Standards) study³³ found that residual myocardial ischemia and major adverse cardiac and cerebrovascular event (MACCE) were the same in the three study arms, viz. CABG, PCI, and HMR. Multicenter observational study by John Puskas et al.³⁴ again

failed to demonstrate any advantage of HMR over multivessel PCI. Even in a meta-analysis by Zhu et al.,³⁵ feasibility and safety of HMR was demonstrated along with reduced need for transfusion of blood products and faster recovery, but there was no difference with regards to in-hospital mortality or 1 year survival. To the contrary, Kahn et al.³⁶ found HMR superior in terms of only 1 stent failure in the HMR group vs. 7 SV graft failures in the CABG group with MACE occurring in 7% of HMR patients versus 23% in the CABG group (p = 0.05). Excellent results using fractional flow results-guided HMR have been demonstrated by Davidavicius et al.³⁷

The costs and the logistics of hybrid operating theater may be a barrier for its use, specially in a developing country like India. However, randomized controlled trials for diligent scientific scrutiny of the hard end-points are called for and likely to be launched in the future. HMR with robotically assisted LIMA harvest seems a promising prospect.³⁸

NO OPTION CORONARY ARTERY DISEASE

Transmyocardial Laser Revascularization

For patients with diffused coronary atherosclerosis and sub-optimum targets for conventional myocardial revascularization in form of CABG or PCI, transmyocardial laser revascularization (TMLR) is an approved form of therapy. Two kinds of laser systems, the holmium "yttrium-aluminum-garnet" and the carbon dioxide laser systems have been approved by the United States FDA. TMLR can be performed either as a standalone procedure (Sole Therapy) or in conjunction with CABG.³⁹ In these patients, TMLR has been shown to improve symptoms, reduce hospitalization, and increase event-free survival,^{40,41} which sustained over long term.⁴² In fact even in a very recent study, improved survival was demonstrated in these patients (65% vs. 52% p = 0.05).⁴³ The mechanism of action of TMLR is debatable and the postulations are that it works through either laser-induced sympathetic regional denervation, angiogenesis, and neovascularization or increased blood flow through patent channels.⁴⁴ It may even be a placebo effect. Probably the effects are multifactorial.

Cell-based Therapies

Cell therapies, till now, have flattered only to deceive, but the use of embryonic stem cells, induced pluripotent stem cells, bone marrow mononuclear cells and most recently, cardiac stem cells⁴⁵ are likely to bring this form of therapy into clinical realm. They can even be combined and delivered through TMLR.

Bone marrow laser revascularization involves delivery of autologous bone marrow cells through TMLR with a view to using their paracrine effects of secreting growth factors and cytokines and thereby potentiating the neoangiogenesis of TMLR.⁴⁶ However, the results are equivocal.

Besides TMLR, coronary venous bypass grafting in form of arterialization of the great and middle cardiac veins using a

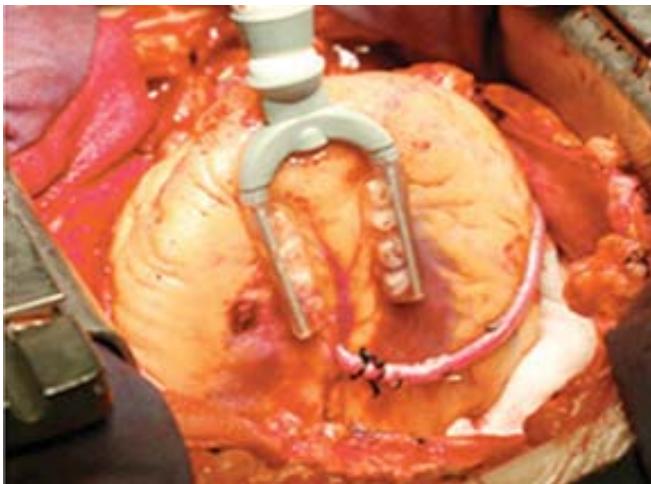

FIG. 3: Flow limiting coronary venous bypass graft.⁴⁷

pedicled IMA and its various iterations, including flow limited coronary venous bypass graft, are being explored⁴⁷ (Fig. 3).

QUALITY INITIATIVES

Contemporary CABG relies on qualitative cine coronary angiography for assessment of the coronary artery stenosis. However, the importance of looking at the physiological impact of an anatomical stenosis has been adequately demonstrated by the FAME (Fractional Flow Reserve Versus Angiography for Multivessel Evaluation) study. Though there were no mortality benefits, other clinical outcomes were superior with fractional flow reserve (FFR)-based revascularization as compared to conventional angiography based PCI.⁴⁸ Already some centers are using noninvasively assessed FFR measurements in CABG and GRAFFITI (Graft Patency After FFR-guided Versus Angio-guided CABG) trial is comparing angiographically driven CABG versus FFR driven CABG. Physiologically driven surgical myocardial revascularization is likely to become a routine and a normative quality matrix to avoid unnecessary grafting and to improve the outcomes of CABG.

In future, it is likely that intraoperative graft validation will become mandatory and in fact a norm for quality initiatives. Though cine angiography is the gold standard, however, in absence of free availability of hybrid operation theatres, noninvasive graft validation in form of either transit time flowmetry (TTFM) or indocyanine fluorescence imaging, thermal coronary angiography or high-resolution epicardial coronary ultrasonography (HR-ECUS) are likely to find greater application. In fact, DiGiammarco et al. recommend combining TTFM with HR-ECUS as it increases the positive predictive value of TTFM to virtually 100%.⁴⁹

MISCELLANEOUS

Advancements in CPB technology in form of biocompatible and miniaturized circuits, as also better myocardial protection, will make the surgeries safer. Artificial intelligence

may make the protocol-dictated delivery of intensive care safer and computers and mathematical modeling too will help in planning and execution of surgery.

Future is going to see increased cooperation between the interventional cardiologist and the cardiac surgeons to the point of may be amalgamation of the two, with the surgeons learning catheter-based skills.

A more holistic view is being taken currently with a realization that no single form of therapy is panacea to all the attendant ills of CAD. Therefore, heart-team concept assumes increasing importance and amalgamation of alternative forms of therapy—AYUSH with allopathy is likely to give better long-term outcomes. The development of the new specialty of “vascular psychiatry” with a view to bringing about behavioral change is again a futuristic well-intended trend. A “Heart Team”, indeed a “Platonic illusion”⁵⁰ till date, is likely to see more traction and patient and his personal physicians will form an integral part of decision making, thereby making treatment of CAD more organic and socially relevant. With the launch of social insurance schemes like “AYUSHMAN BHARAT” as also with deeper penetration of other health insurance schemes, the availability and affordability of coronary interventions, both percutaneous and surgical, will improve.

CONCLUSION

Total arterial revascularization and miniaturization of incision using minimally invasive and robotically assisted techniques and off the shelf, tissue engineered or biological conduits will make the surgery customized to each patients’ needs. There is a need for increased cooperation and collaboration between the family physician, interventional cardiologist, and the cardiac surgeon for an organic approach to the problem.

However, final answer to the woes of CAD will lie in molecular biology, genetics, and behavioral change with a view to preventing the disease rather than treating it.

Redo Coronary Artery Bypass Grafting: Challenges and Outcomes

Ramakanta Panda, Muzil Munshi

INTRODUCTION

A patient needs redo coronary artery bypass grafting (CABG) when there is graft occlusion or progression of their native coronary artery disease (CAD) or a combination of both. Redo CABG is far more challenging than primary CABG because the patients are older, have more compromised ventricular function, more comorbid conditions, severe and diffuse native distal coronary atherosclerosis and frequently have more advanced atherosclerosis in aortic and noncardiac arteries. Moreover, adhesions from previous operations predisposing the patient to higher risk of injury to cardiac structures or a patent arterial graft as well as saphenous vein graft (SVG) atherosclerosis with its attendant higher risk of distal embolization of atherosclerotic material adds up to the higher risk to patient and technical challenge to the surgical team. The availability of conduits if both internal thoracic arteries (ITAs) and saphenous veins were used up in first operation adds up to the challenge.

INCIDENCE

Likelihood of patient needing reoperation depends on variables related to patient, variables related to first time surgery and strict control of risk factors postprimary surgery. Patient-related variables are young age at first operation, preserved left ventricular (LV) function, single or double vessel disease, class III or IV symptoms at primary operation. Variables related to first time surgery predicting reoperation are: not using an ITA especially to left anterior descending (LAD) coronary artery and incomplete revascularization.

Even though Cosgrove et al.¹ have reported a cumulative incidence of reoperation of 3% at 5 years, 10% by 10 years, and 25% by 20 years, over last three decades, there has been a gradual decline in the total number of patients undergoing isolated repeat CABG as well as frequency of redo CABG relative to total CABG performed. This is due partly to universal use of at least one ITA especially to LAD compared to earlier decades, more use of arterial conduits, improved

surgical technique, possibly more effective risk factor control, optimal medical therapy with universal use of statins as well as antiplatelet therapy and more use of catheter interventions in patients with prior CABG.

Cleveland Clinic, one of the highest volume redo surgery centers, saw their numbers decline from 37% in 1990 to 30% in 2000² and more dramatically in current decade to 4.6% of all isolated CABG operations. This is similar to a decline from 6.0% in 2000 to 3.4% in 2009 from analysis of 72,322 isolated redo CABG patients from 1,035 institutions from Society of Thoracic Surgeons (STS) Adult Cardiac Surgery Database.³ Spiliotopoulos et al.⁴ from Toronto General Hospital, in a most recent largest single center study of changing pattern of redo CABG of 1,204 patients, among 25,347 patients undergoing isolated CABG procedure, reported a decline from 7.2% (1990–1994) to 2.2% (2005–2009). The Japanese Association for Thoracic Surgery (JATS) also reported⁵ a significant decline of ratio of redo CABG to total number of CABG from 10% in 2001 to 2% in 2010. The prevalence of redo CABG among elderly patients who undergo CABG is very uncommon.⁶ Fosbol et al. in a review of STS database of 723,134 patients older than 65 years who underwent isolated CABG between 1991 and 2007 found repeat revascularization incidence of 0.1, 0.6, 1.3, and 1.7% at 1, 5, 10 and 18 years, respectively. Mode of repeat revascularization among these patients was mostly percutaneous coronary intervention (PCI) (93%).

Emphasis on medical therapy over revascularization in patients with stable angina⁷ and improved medical management with use of beta-blockers, statins, and angiotensin-converting enzyme (ACE) inhibitors that can slow the progression of coronary disease delays or obviates the need for surgical revascularization.⁸ Among the patients in STS database, more patients were receiving statin and ACE inhibitors in 2009 than in 2004.³ PCI on native arteries or the grafts of re-operated patients, before redo CABG significantly increased from 14.5% (1990 through 1994) to 26.6% (2005 through 2009).⁴ Similar increase was reported

by Riley et al.⁹ who reported an increase of 31% among US Medicare population from 2001 to 2004 but decreased by 20% thereafter presumably from clinical trials demonstrating of lack of benefit of additional PCI (above optimal medical therapy) in stable CAD. Among the patients in the STS database of 72,431 patients undergoing reoperative CABG, incidence of patients treated with previous PCI had increased from 35% in 2000 to 53% in 2009.³

During past few decades, there has been universal use of a left internal thoracic artery (LITA) graft to LAD combined with an increase in use of arterial grafts during primary operation,¹⁰ possibly contributing to higher graft patency of arterial grafts thus decreased need for reoperation.^{3,11-14}

PATIENT RISK PROFILE

Patients undergoing coronary reoperation exhibit significantly worse risk profile. They are older, have more comorbidities, more unstable angina, higher New York Heart association (NYHA) class, worse LV function, previous myocardial infarction (MI), higher incidence of peripheral vascular disease.^{2,15} In the study of STS database from 2000 to 2009, though there was no significant change in age or gender of reoperation patients, there were significant prevalence of comorbidities like diabetes (42.5% vs. 31.7%), hypertension (90.9% vs. 73.4%), hypercholesterolemia (93.0% vs. 71.8%), renal failure (2.2% vs. 0.7%), chronic obstructive pulmonary disease (25.5% vs. 16.6%), cerebrovascular disease (12.4% vs. 8.5%) in 2009 than 2000.³ They had worse presentation like congestive failure (18.4 vs. 14.2%), left main disease (35.1% vs. 25.7%), MI (60.9% vs. 55.9%), renal failure (2.2% vs. 0.7%), and cerebrovascular disease (12.4% vs. 8.5%). They more likely needed an urgent procedure than a routine one. The study of risk profile from Toronto General Hospital⁴ showed similar increase over the years from 1990 to 2009. The patients were significantly older, had higher incidence of diabetes, hypertension, dyslipidemia, left main disease, peripheral vascular disease, and cerebrovascular accidents. The mean interval between first operation and reoperation had increased.

INDICATIONS

Unlike the randomized trials of bypass surgeries versus medical management in the 1970s and subsequent studies that provided information that formed the basis of indication for first time bypass surgeries, no such information exists for decision making regarding redo CABG. The coronary pathology of patients with prior CABG especially with vein graft, that progresses more rapidly and erratically, are different from that of patients with native CAD. The natural history of both cannot be equated to behave similarly.

The pathology of SVG to coronary arteries is different at various time intervals after surgery.¹⁶⁻²⁰ Most vein grafts develop proliferative intimal fibroplasia within 2–3 months which evolves with time to a nonfriable fibrous lesion. This may or may not cause stenosis or occlusion. This is completely different from vein graft atherosclerosis which starts as early

as 3–4 years after surgery and is due to lipid infiltration into areas of intimal hyperplasia. Vein graft atherosclerosis is a friable, diffuse, superficial lesion and is often associated with overlying mural thrombus. This is different from native coronary atherosclerosis which is segmental, and proximal, eccentric, encapsulated, and is usually not friable or associated with mural thrombus.

Because of above and greater surgical risk of redo CABG compared to primary CABG, indications for the former are stricter and based on careful assessment of risk benefit ratio. Patients with early (<5 years after operation) vein graft stenosis (mostly intimal hyperplasia and nonatherosclerotic) have approximately the same outcomes as those with no stenosis^{19,20} and can be managed medically. However, patients with late (>5 years after operation) vein graft stenosis, especially to that of LAD has poor long-term prognosis.^{19,20} Patients with late stenosis in SVG to LAD associated with other risk factors have an abysmal late survival. Patients with 50–99% stenosis in SVG-LAD who had additional impaired ventricular function or left main stenosis or triple vessel disease (TVD) had only 46% survival at 2 years. Patients with stenosis in SVG to LAD had far worse long-term survival than native LAD coronary atherosclerosis and should be treated with PCI or redo CABG.

Percutaneous Coronary Interventions Versus Redo Coronary Artery Bypass Grafting

Percutaneous coronary intervention of stenosed vein graft or native coronary artery is an alternative anatomical treatment for symptomatic post-CABG patients. PCI on native arteries or the grafts of operated patients, before redo CABG, significantly increased from 14.5% (1990 through 1994) to 26.6% (2005 through 2009).⁴ Similar increase was reported by Riley et al.⁹ who reported an increase of 31% among US Medicare population from 2001 to 2004 but decreased by 20% thereafter presumably from clinical trials demonstrating of lack of benefit of additional PCI (above optimal medical therapy) in stable CAD. Among the patients in the STS database of 72,431 patients undergoing reoperative CABG, incidence of patients treated with previous PCI had increased from 35% in 2000 to 53% in 2009.³

However, PCI for SVGs is associated with an increased risk of distal coronary embolization from more friable SVG atheroma, resulting in perioperative MI. Glycoprotein (GP) IIb/IIIa inhibitors are less effective in the intervention of SVG compared to native coronary artery.²¹ Compared to occlusive devices, distal embolic protection devices using filters during SVG PCI seem to offer better protection.^{22,23}

Symptomatic patients with prior CABG are a very heterogeneous group with a group at one end considered low-risk group who do not need any anatomic treatment (redo CABG or PCI) and a group at other end who are at high risk without the above therapy. Whether PCI or redo CABG is the most effective form of therapy must be based on multiple factors.

Some of the factors favoring PCI over redo CABG are listed in table 1.

TABLE 1: Indications of coronary artery bypass grafting versus percutaneous coronary intervention

Redo CABG	PCI
Late (>5 years) SVG stenosis	Early (<5 years) SVG stenosis
Diffusely atherosclerotic vein graft	Other patent non-stenotic vein grafts
Stenotic LAD vein graft especially diffuse disease	Focal stenotic LAD vein graft
Multiple stenotic vein graft	Single stenotic vein graft
No patent ITA graft especially to LAD	Patent ITA-LAD graft
Abnormal left ventricular function	Normal ventricular function

CABG, coronary artery bypass grafting; ITA, internal thoracic artery; LAD, left anterior descending; PCI, percutaneous coronary intervention; SVG, saphenous vein graft.

PREOPERATIVE EVALUATION AND PLANNING

As complete understanding of the patient's native coronary and bypass graft anatomy is very essential before undertaking redo CABG, preoperative planning (Table 2) is more important in coronary reoperations than it is in primary CABG. The patient's history and previous operation note must be reviewed thoroughly including any relevant procedures or comorbidities that may affect surgeon's approach to the reoperation. For example, a patient with history of mediastinitis following primary operations may be better to operate through lateral thoracotomy if coronary anatomy is favorable to this approach.

TABLE 2: Indications for redo coronary artery bypass grafting from the European guidelines for revascularization

	Class of recommendation	Level of evidence
In early graft failure:		
Coronary angiography is indicated for highly symptomatic patients, or in the event of postoperative instability, or with abnormal biomarkers/ECG suggestive of perioperative MI	I	C
Decision of redo CABG or PCI should be made by the Heart Team	I	C
In late graft failure following CABG:		
PCI or redo CABG is indicated in patients with severe symptoms or extensive ischemia despite OMT	I	B
PCI is preferred over CABG if considered safe	I	C
Revascularization modalities:		
ITA is the conduit of choice for redo CABG when available/ Not used earlier	I	B
Redo CABG is considered for patients without patent ITA graft to LAD	IIa	B
Distal protection devices is considered for PCI of SVG lesions	IIa	B
PCI of the bypassed native artery should be considered over PCI of the bypass graft	IIa	C
In Stent Restenosis:		
In patients with recurrent events of diffuse in-stent restenosis, CABG should be considered by the Heart Team over a new PCI attempt	IIa	C

CABG, coronary artery bypass grafting; ECG, electrocardiography; ITA, internal thoracic artery; MI, myocardial infarction; OMT, optimal medical therapy; PCI, percutaneous coronary intervention; SVG, saphenous vein graft.

Preoperative Assessment

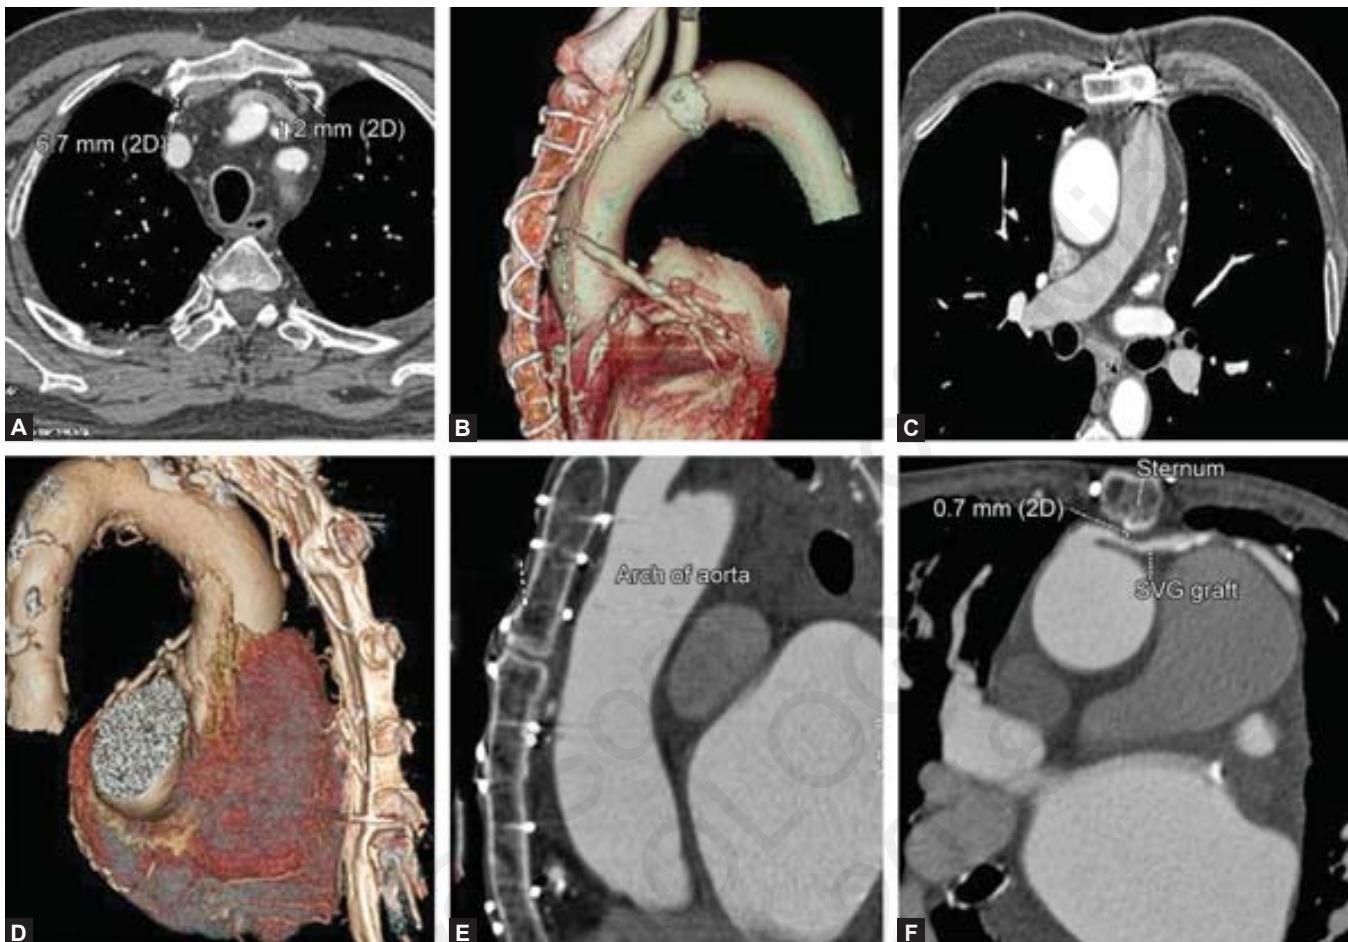

- *Review of available conduits:*
 - Physical examination
 - Inferior thoracic artery (ITA) shoot
 - Radial artery (RA) ultrasound and Doppler.
- X-ray posterior-anterior (PA) and left lateral view
- Vascular Doppler imaging of Carotid Arteries and lower extremities
- Dobutamine echocardiography/thallium scintigraphy
- Computed tomography of chest
- Coronary angiography
- Review of previous operation note
- Review old angiograms before previous operations
- Adequate blood arrangement.

Availability of Conduits for Bypass Grafting

The importance of preoperative physical examination and testing to assess the availability and quality of conduits cannot be overstated. ITA angiography during coronary angiography provides a more complete evaluation of these arteries and should be done whenever possible. Venous Doppler studies are often used to determine the size and quality of greater and lesser saphenous vein segments. Arterial Doppler studies of the radial arteries combined with modified Doppler Allen's test to assess adequacy of flow to digits should be done whenever RA harvesting is contemplated.

Chest X-ray and Computed Tomography

A posteroanterior and lateral chest X-ray can give an idea of the proximity of important cardiac structures to the sternum

SVG, saphenous vein graft.

FIG. 1: Computed tomography (CT) angiogram. Preoperative CT angiogram to detect proximity of vascular structures and previous grafts to sternum. CT images showing proximity of cardiovascular structures to sternum: A, Left internal thoracic artery; B, Aorta; C, Brachiocephalic vein; D, Right ventricle; E, Aorta; F, Saphenous vein graft.

and helps the surgeon in evaluating the risk of sternal reentry. Steel clips, used in the harvest of ITA graft, visible on chest radiograph give information about risk of injury during sternotomy. Routine use of multi-detector computed tomographic angiography (CTA) (Fig. 1) is recommended in redo CABG to detect proximity of cardiovascular structures and conduits to the posterior surface of sternum, any patent grafts missed out during coronary angiography, ascending aorta calcification, and pseudoaneurysms. It is also helpful in assessing unused ITA if not demonstrated during conventional coronary angiography.

Coronary Angiography

A complete and well-performed angiography is a necessary step in the preoperative assessment of patients undergoing redo CABG. Review of previous angiogram and operation notes are invaluable tools for the surgeon as well as the interventional cardiologist performing angiogram to gain a better understanding of the patient's coronary anatomy. Multiple views, injecting all relevant branches and grafts

as well as allowing enough time for filling of the coronaries by collaterals are critical to identify potential targets. Non-demonstration of bypass graft, venous or arterial, usually means that they are occluded but it is also possible that the angiogram had failed to demonstrate their location.

Assessment of Viable Myocardium

Because of the increased morbidity and mortality in patients undergoing coronary reoperations especially those with impaired ventricular function, it is important to be reasonably sure that there is a matchup between the patient's graftable arteries and viable myocardium to provide some long-term benefits. This is especially so in patients with patent LITA-to-LAD who have non-LAD territory disease. Because these patients derive no survival benefit from reintervention, viability assessment is important to verify a substantial non-LAD territory at jeopardy. The commonly used diagnostic tools are dobutamine echocardiography, thallium scintigraphy, positron-emission tomography (PET), and cardiac magnetic resonance imaging (cMRI).

TECHNICAL ASPECTS AND CHALLENGES ASSOCIATED WITH REDO CORONARY ARTERY BYPASS GRAFTING

Coronary reoperations are technically more difficult and challenging than primary CABG for various reasons,²⁴ and recognition of all pitfalls and a thorough planning is essential. They are:

- Sternotomy and dissection
- Myocardial protection
- Stenotic or patent vein or arterial graft
- Aortic atherosclerosis
- Availability of conduits for bypass
- Identification of coronary arteries.

Detailed preoperative evaluation as mentioned earlier and operative planning are key to minimizing complications and their importance cannot be overemphasized in achieving superior results.

Sternotomy and Dissection

Unlike primary CABG, opening the sternum during redo CABG is always risky because the pericardium has been opened in earlier operation and the heart, major vessels or bypass grafts may be close or adherent to under surface of sternum. The most common re-entry injury is to a patent bypass graft,²⁵ i.e., a patent graft to right coronary artery (RCA) or a patent LITA to left side artery close to sternum or a right ITA graft to left coronary artery. The sternotomy is performed with an oscillating saw. In high-risk cases, alternative access to go on emergency cardiopulmonary bypass like prior exposure of femoral vein and axillary artery or wire access of femoral artery and vein for percutaneous cannulation must be planned out before sternotomy. In extremely high-risk cases, prior cannulation (femoral vein and preferably axillary artery) may be required before commencing sternotomy. Axillary artery cannulation is

preferred over femoral artery because of risk of retrograde atherosclerotic embolization from femoral artery. Sternal wires are divided anteriorly and not removed to protect the underlying structures. The sternotomy is performed till the posterior table, at which stage the ventilation is stopped temporarily. While the posterior table is cut, the assistant lifts up both ends of the cut wires thus elevating the posterior surface of sternum from cardiac structures (Fig. 2). Once the posterior table is divided, the wires are removed and the heart is carefully dissected away from under surface of sternum, first on right side and then left side. Once the heart is freed from the posterior table and chest wall, the dissection of heart starts from diaphragmatic surface of heart (where there is very little risk of injuring any critical structure) and carried cranially first dissecting out the right atrium and aorta for central aortic and venous cannulation if needed. The right ITA is dissected first followed by dissection of left side of heart. One must be extremely careful while dissecting patent ITA, especially near second and third rib. The risk of injury to a patent ITA can be reduced significantly if the ITA is routed posterior to the lung (Fig. 3) through a

FIG. 2: Sternotomy lifting. Lifting of the anterior sternal wires during sternotomy reduces the risk of injury to underlying structures.

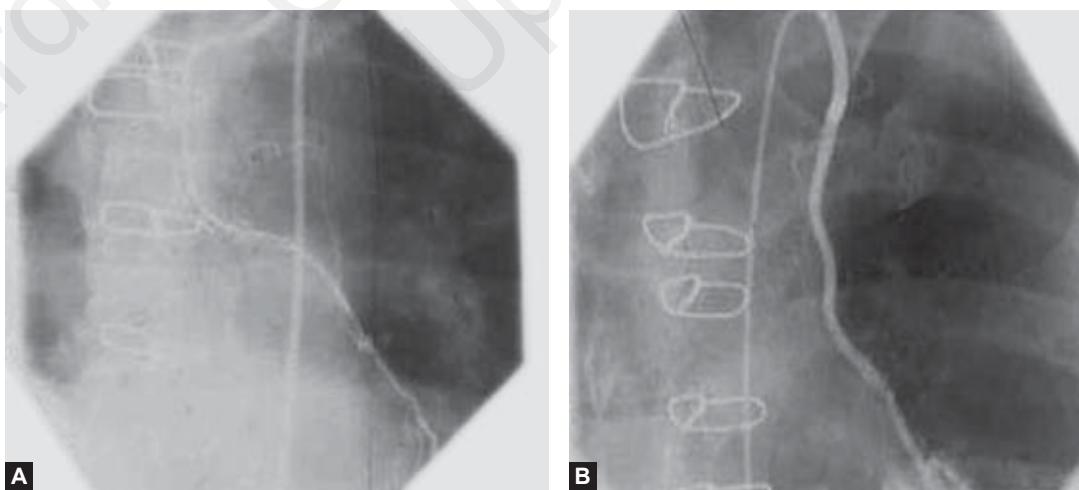

FIG. 3: Left internal thoracic artery (LITA) position. LITA position with **A**, closed pleura; **B**, pleura open.

cut in pericardium during primary CABG. One should do minimum dissection of atherosclerotic vein grafts just away from pericardium to prevent athero-embolism.

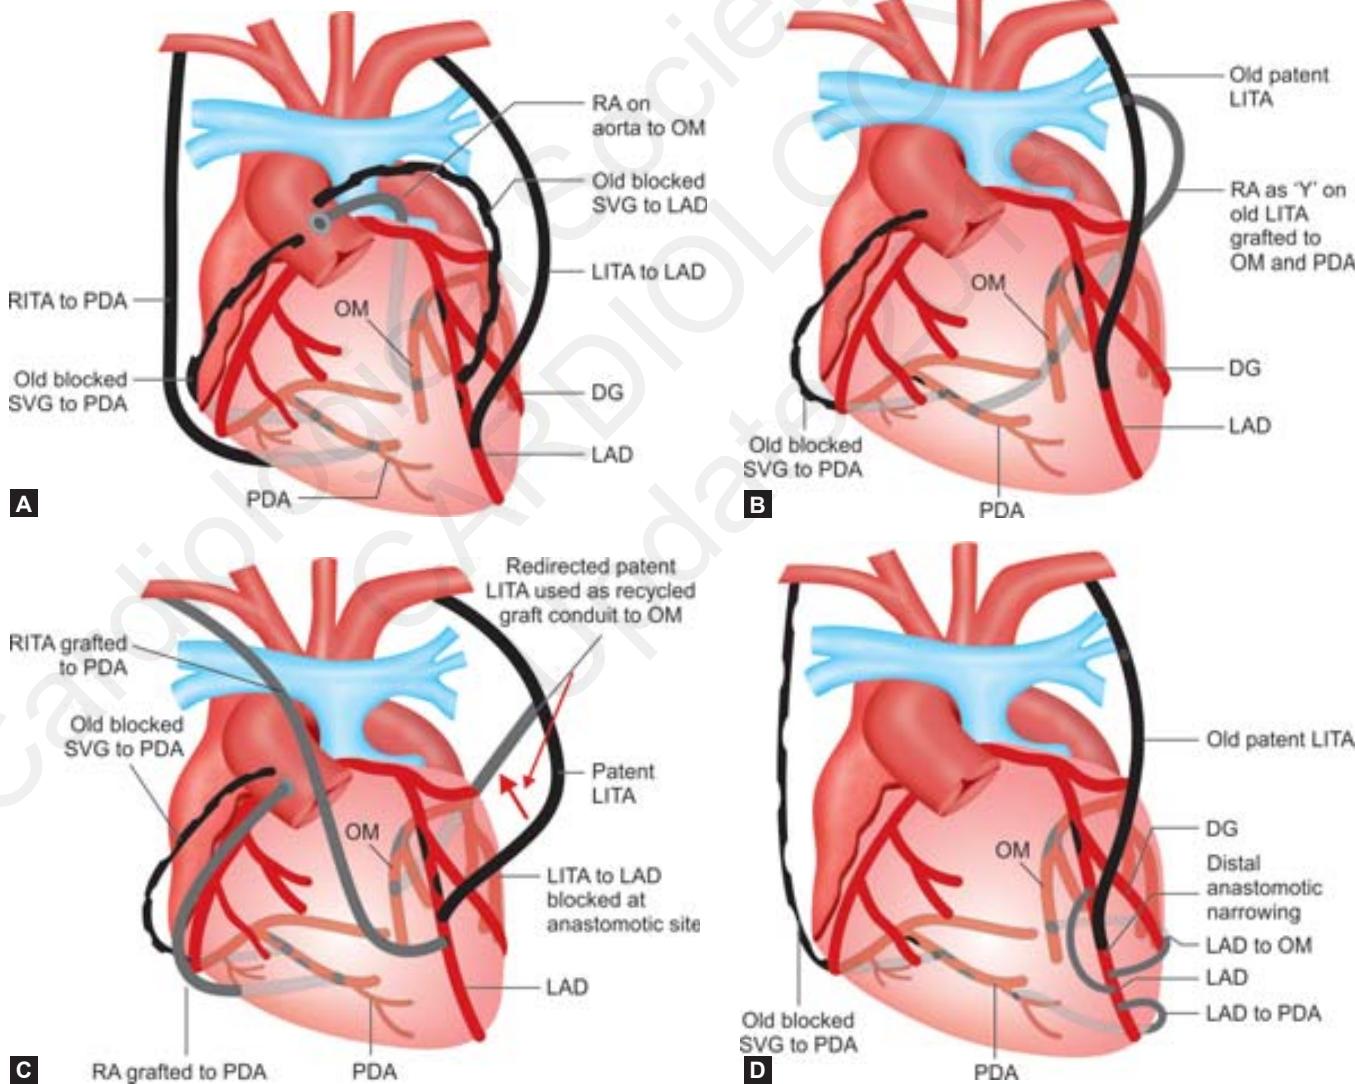

Myocardial Protection

Redo CABG patients with more diffuse distal atherosclerosis in coronary arteries, totally occluded vessels, patent arterial graft supplying an occluded coronary artery, friable vein graft atherosclerosis pose a more difficult myocardial protection challenge compared to primary operation, with perioperative MI being the most common cause of in-hospital death.^{26,27} Conventional antegrade cardioplegia may not be effective in above situations and may be dangerous because of risk of embolization from atherosclerotic vein grafts. A combination of antegrade and retrograde cardioplegia seems to be a better option. Retrograde cardioplegia delivered through the

coronary sinus is extremely useful not only in reaching areas not protected by antegrade cardioplegia like areas supplied by patent arterial grafts or occluded coronary arteries which significantly decreases hospital mortality²⁸ but, also can be helpful in removing embolized atherosclerotic debris from diseased vein grafts or air from coronary arteries. This can also be combined with cardioplegia through newly constructed vein graft, if any.

Choice of Conduits and Grafting Pattern (Fig. 4)

The basic concept of conduit selection for coronary reoperations is same as primary CABG and arterial conduits should be the first choice wherever possible, especially in younger patients or older patients with reasonable life expectancy. Vein grafts are less suitable in redo CABG

RITA, right internal thoracic artery; PDA, posterior descending artery; LITA, left internal thoracic artery; RA, radial artery; LAD, left anterior descending artery; DG, diagonal artery; SVG, saphenous vein graft; OM, obtuse marginal.

FIG. 4: Graft configurations. Examples of arterial conduit permutations in redo to achieve total arterial revascularization.

because patients have more diffuse and distal atherosclerosis and better quality vein grafts are utilized during primary operation leaving poor quality veins for reoperations. If only SVG was used in the primary CABG, then either one ITA or both ITAs should be the conduit of choice. Like primary operation, revascularization of LAD with LITA in reoperation is associated with increase in early and late survival compared to use of SVG to LAD.²⁹

In patients with patent LITA-to-LAD and non-grafted or occluded grafts to circumflex and RCA, using the right internal thoracic artery (RITA) does not increase the risk of deep sternal wound infection.³⁰ The right ITA can be used as in situ or as a free graft anastomosed to the side of patent left ITA in a T or Y fashion to graft circumflex and RCA branches. Such graft arrangements using bilateral ITAs may have a survival benefit as in primary operations.³¹ RA is a good alternative conduit that can be used in conjunction with right ITA or alone and is associated with improved outcomes,³² but this should only be used in native vessels with severe stenosis to avoid competitive flow and graft attrition.³³

The right gastroepiploic artery (RGEA) can be a good option to graft inferior wall especially to isolated RCA disease through a sternal-sparing transabdominal approach with good short-term and mid-term outcomes.³⁴ However, the RGEA has limited length, small diameter, vulnerable to spasm and is being infrequently used especially since the resurgence of RA as a conduit.

Handling Saphenous Vein Grafts

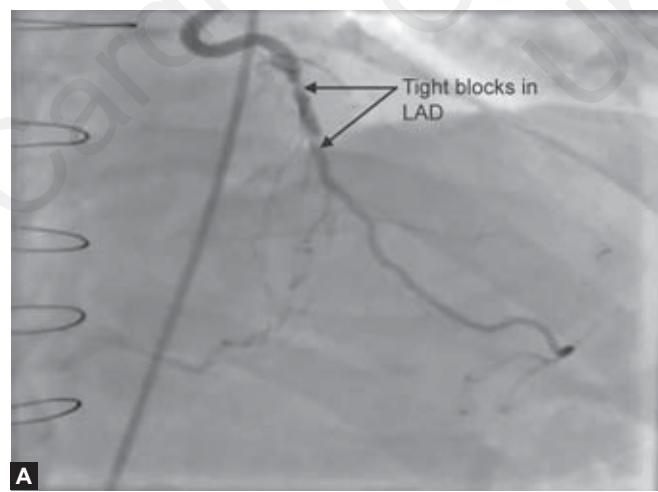

Whether a patent or stenotic vein graft be left alone or replaced and if replaced, should it be with a vein or arterial graft are difficult technical decisions that need to be taken during coronary reoperations. Vein grafts more than 5 years old are more likely to be atherosclerosed and need to be replaced. If using an arterial conduit to revascularize a coronary artery with a pre-existing patent SVG, the old venous

graft flow must be interrupted (unless critically stenosed) to avoid competitive flow and possible graft closure. If the LAD was not grafted during primary operation or a SVG was used, every effort must be made to revascularize it with an ITA as there is evidence of increase in early and late survival when at reoperation, LAD is bypassed with an ITA compared to SVG-to-LAD.²⁹ However, when a patent vein graft is replaced with an arterial graft, especially supplying a large territory, patient may develop a hypoperfusion syndrome³⁵ resulting in myocardial ischemia or infarction because of lesser flow through a smaller diameter arterial graft compared to a vein graft, even if stenosed. RA may be more suitable in this situation because of larger diameter. A skeletonized ITA has better flow than pedicled ITA³⁶ and may be used to replace a diseased vein graft. Every effort must be made to use multiple arterial grafts at reoperation to improve long-term survival and event-free survival. However, if there is shortage of arterial conduits or available venous conduits are of poor quality, any existing SVG free of atherosclerosis (both angiographically and on inspection) especially if less than 5 years, old grafts should be left alone.

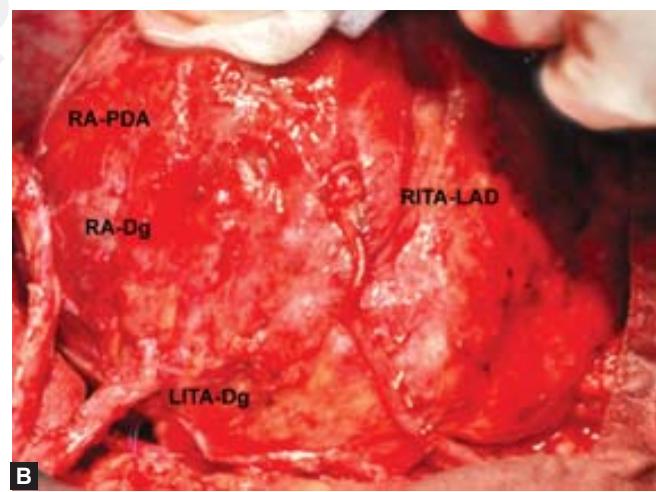

Lack of Conduits and Recycling Conduits

Poor quality of conduits or lack of conduit²⁴ is a common problem in redo CABG patient populations due to older age, obesity, calcification of RAs, use of ITAs or better quality veins in prior CABG leaving no or poor quality veins. When conduit shortage is an issue and anatomy is suitable, recycling arterial grafts previously used is a good adjunct to performing redo CABG. A distal stenosis in a LITA-to-LAD can be managed by dividing distally and anastomosing to a diagonal or early obtuse marginal and grafting RITA to LAD (Fig. 5).

A proximal stenosis in an in situ LITA can be managed by using as a free graft off the hood RA or an old vein graft. A free RITA can be used in Y or T fashion to the side of existing patent

A

LAD, left anterior descending artery; LITA, left internal thoracic artery; PDA, posterior descending artery; RA, radial artery; RITA, right internal thoracic artery.

Recycling of conduit with right internal thoracic artery to LAD and LITA to diagonal and sequential radial artery to intermediate (inter) and posterior descending artery.

LITA to revascularize rest of myocardium. Combination of arterial conduits to optimize usage in situations of limited availability of conduits is depicted in Fig. 4. The RGEA or inferior epigastric arteries (IEA) can be used in extreme situations of non-availability of conduits.

Off-pump Versus On-pump

Though there have been concerns related to perceived greater threat of atherosclerotic vein graft embolization, incomplete revascularization, and poor outcomes in patients converted to on pump, there is increasing evidence that off-pump coronary artery bypass (OPCAB) grafting may provide superior early results especially in high-risk patients and prospective randomized trials as well as large retrospective reviews have shown that compared to on pump CABG, OPCAB is associated with improved early risk adjusted morbidity and mortality.^{37,38} A meta-analysis of 12 studies from Imperial College, London showed that in selected patients undergoing coronary reoperations off-pump technique significantly reduced early mortality.³⁹

The advantages of off-pump technique in coronary reoperations are:

- Elimination of cardiopulmonary bypass-induced complications
- Reducing or eliminating aortic manipulation and attendant reduction in cerebrovascular accident by avoiding aortic cannulation or cross clamp and basing grafts off ITA inflow
- Elimination of concerns relating to effective protection of myocardium by cardioplegia.

In spite of evidence of superior early results of off-pump redo CABG, use of the technique for coronary reoperations varies widely between various centers. An analysis of STS database revealed an increase prevalence of off-pump reoperative CABG from 12% in 2000 to 18% in 2009 among 72,431 patients undergoing isolated coronary reoperations.³ However, Maltais et al.⁴⁰ from Mayo Clinic, recently reported use of only cardiopulmonary bypass among 748 patients undergoing redo CABG with a 6% perioperative mortality. On the other hand, Dohi et al.⁴¹ in an analysis of Japanese Cardiovascular Surgery Database reported 59% use of off-pump technique among 617 patients undergoing coronary reoperations. Whether to use OPCAB technique in coronary reoperations and success of off-pump technique depends on skill and experience of surgeon and anesthesiologist as well as number and location of target coronary arteries, aortic atherosclerosis, and patient's hemodynamics. However, the primary goal should always be to achieve complete revascularization with lowest perioperative morbidity.

In patients with hemodynamic instability, dilated heart with impaired ventricular function, insertion of an intra-aortic balloon pump (IABP) is helpful in improving hemodynamics and avoiding cardiopulmonary bypass. One should have a low threshold for its use. In patients undergoing on pump redo CABG, its use also helps ease perioperative hemodynamic instability and postoperative recovery and has been used as high as in 20% patients.⁴⁰

To avoid hemodynamic instability during dissection of lateral wall, it is important to graft LAD and RCA with minimal dissection and perform circumflex area dissection and anastomosis last. One should complete the proximal anastomosis first, as this has the advantage of supplying blood to ischemic myocardium immediately upon completion of distal grafting and stabilizing an unstable patient.

Alternative Approaches

Although vast majority of patients undergoing redo CABG need grafts to multiple vessels and the procedure is performed through a median sternotomy, alternative approaches may be useful especially if a limited target area revascularization is needed or if combined with PCI (hybrid approach). A thoracotomy⁴² may be an alternative route to avoid injury to underlying structures especially if a patent graft is adherent to sternum or a patent ITA is crossing midline and has the additional advantage of less blood loss and wound complications. This is risky in patients who are obese, need grafts to multiple regions of the heart or cannot tolerate single lung ventilation. This is performed through a muscle-sparing lateral thoracotomy through the fourth, fifth or sixth interspace and provide good exposure of entire anterolateral wall and the LITA if not used previously. The proximal end of the conduit can be anastomosed to descending aorta or the subclavian artery, if the patient only needs grafts to LAD territory and/or intermediate, minimally invasive direct coronary artery bypass grafting (MIDCAB) approach with a small anterior thoracotomy may be a preferable approach. If the patient needs revascularization of RCA, a transabdominal approach may be preferable using RGEA³⁴ as described earlier. Hybrid procedure with robotic left thoracotomy LITA graft to LAD combined with PCI has been described,⁴³ although its usefulness is yet to be determined.

Early Results

Technically redo CABG operations are far more complex than primary operations and the patient populations are more vulnerable resulting in a higher operative mortality and morbidity than primary operations. The early mortality of redo CABG is reported to be 2–5 times higher than expected for primary CABG and associated with increased stroke, renal failure, reoperation for bleeding, and deep sternal wound infection.³ However, over past few decades, there has been a steady improvement in early operative mortality despite an increase in risk profile of patient populations undergoing reoperations. Cleveland Clinic reported an operative mortality of 3.4%²⁶ between 1967 and 1994 which continued to decrease to 2.5% in 2002.²⁹ Similar results were reported by Ghanta et al.³ in an analysis of STS database of 72,431 patients undergoing reoperations between 2000 and 2009, at 1,035 institutions. They reported a 23.7% reduction in the relative risk of redo CABG mortality during the period, despite increase in morbidity like more left main disease, MI, heart failure, renal failure, and cerebrovascular disease. The risk-adjusted

mortality decreased from 6.0 to 4.7%. In 2013, the mortality had further reduced to 3.5% among the STS participants institutions. This is attributed to increase in surgical team experience resulting in better patient management pre- and postoperative, better myocardial protection, handling of atherosclerotic vein graft, avoiding injury to patent vein graft, frequent use of arterial (especially ITA graft). In high-volume centers, the risk of redo CABG approaches that of primary CABG.² However, hospital risks increase with number of previous operations. Sabik et al.² reported operative mortality of 4.3% for first reoperations, 5.1% for second reoperations, and 6.4% for three or more reoperations.

The two most important factors that determine the outcome of redo CABG are surgical team experience as mentioned earlier and patient risk profiles. While surgical experience especially in high-volume centers has neutralized the risk of operation due to technical difficulties, patient characteristics now has a greater influence on hospital mortality.²

The higher perioperative mortality in coronary reoperations is mostly because of an increased risk of perioperative MI. Causes of MI identified are incomplete revascularization from diffuse distal atherosclerosis, atherosclerotic emboli from old vein grafts, injury to bypass grafts including patent ITA and thrombosis of constructed vein graft. In Cleveland Clinic series, 85% of cause of perioperative death was cardiovascular, in contrast to mostly non-cardiac cause of death in primary CABG.^{26,44} The early in-hospital mortality was associated with a new perioperative MI in 67% cases. The higher incidence of perioperative MI may be attributable to multiple factors unique to coronary reoperations like incomplete revascularization due to diffuse distal atherosclerotic CAD, vein graft thrombosis, atherosclerotic embolization from diseased vein grafts, injury to earlier bypass grafts, ITA graft failure, hypoperfusion from new arterial grafts, perioperative MI, and complications of percutaneous transluminal coronary angioplasty (PTCA).

Predictors of in-hospital mortality of coronary reoperations identified in multiple studies are increased age, female gender, and emergency operations.^{27,45} Though by itself, advanced age does not increase the risk of operative mortality it does so when combined with other variables. Emergency operations are a strong predictor and the operative mortality is more than three times higher than that of elective coronary reoperations.^{26,27,45,46} Anatomic conditions specific to reoperations like presence of an ITA graft or atherosclerotic vein grafts or patent graft attached to undersurface of sternum in midline can increase the risk of reoperation but with experience, these technical factors can be neutralized.

Late Results

Patients undergoing redo CABG are older and at a later stage in the natural history of CAD than those undergoing primary CABG resulting in more diffuse atherosclerosis, inferior quality coronary revascularization. So the long-term results after coronary reoperations are not as favorable as that of

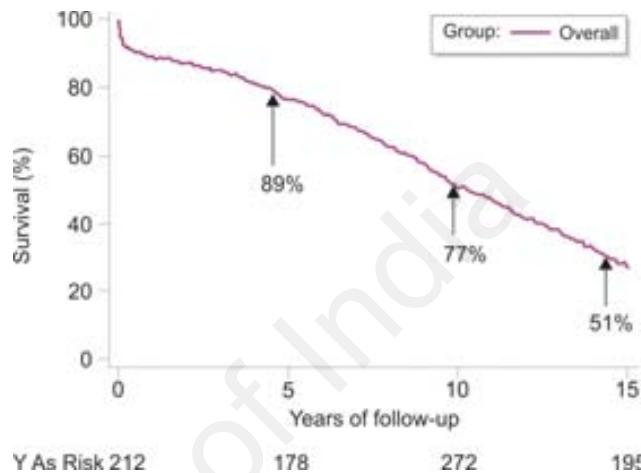

FIG. 6: Survival curve for redo. Kaplan–Meier survival curve for redo patients at 1, 5, and 10 years.

primary CABG, with more frequent recurrence of angina and inferior late survival. Weintraub et al.²⁷ have reported a 41% recurrence of angina at 4-year follow-up and 76% survival at 5-year, and 55% at 10-year. This is similar to 89%, 77%, and 51% survival at 1-, 5-, and 10-year respectively reported from Mayo Clinic⁴⁰ recently (Fig. 6). LV dysfunction, advanced age, and diabetes have been the consistent predictors of late survival in most studies, though current cigarette smoking, hypertension, TVD have been identified as decreasing late survival in some studies.⁴⁷ Unlike primary CABG, the influence of ITA graft on late survival has been difficult to determine for reoperation, probably due to non-LAD coronary artery grafting by ITA. However, extrapolating the positive influence of ITA grafts at least partially contributing to the dramatic reduction in coronary reoperations among STS participating institutions¹⁰ one could extrapolate a similar positive effect of ITA, especially multiple ITA, or arterial grafting on late survival.

Multiple Reoperations

Patients needing more than one coronary reoperations represent a very small fraction of all redo CABG patients. Of the 4518 patients undergoing coronary reoperations at Cleveland Clinic between 1990 and 2003, 3919 had first, 552 second, 43 third, 3 fourth, and 1 fifth reoperations.² Similarly Maltais et al.⁴⁰ from Mayo Clinic reported an incidence of 8% second reoperation, and 1% third reoperation. The indications for additional reoperations remain the same as first time redo CABG especially in patients with disabling angina unresponsive to medical therapy. In addition to having more complex and diffuse CAD, availability of conduits is a limiting factor in these patients. Even though the risk of first reoperation in high-volume experienced centers approaches that of primary CABG, the hospital risk of multiple re-operations still remains high with reported operative mortality of 4.3% for first reoperations, 5.1% for second reoperations, and 6.4% for three or more reoperations.² Age greater than 65 years and LV dysfunction with ejection

fraction less than 35% are predictors of early mortality, with 10% mortality in patients above 70 years.² Patients above 70 years who survived multiple reoperations have a poor late survival of 50% at 5 years.²

CONCLUSION

Redo CABG is a complicated procedure and far more technically challenging than primary CABG. The surgical team must recognize the challenges involved and careful pre-operative planning as well as meticulous surgical technique is essential to successful outcomes. Surgical outcomes of redo CABG are improving in spite of increasing high-risk patients and in high-volume experienced centers the operative mortality is nearing that of primary CABG.

LVAD—Should Indians Borrow to Afford Them?

Sachin Talwar, Harsha V Niraghatam

INTRODUCTION

Heart failure (HF) is a state characterized by reduced cardiac index, stroke volume, and mean arterial pressure with the heart unable to meet the circulatory demands of the body. Initially heart tries to meet the circulatory demands by various compensatory mechanisms. As one reaches the chronic phase due to remodeling the architecture of the ventricular musculature causes chamber dilatation causing the ventricle to attain spherical shape as a result of which, the cardiac myocytes are subjected to maximal stress leading to myocyte apoptosis which lead to progressive ventricular dysfunction and end-stage HF.¹

EPIDEMIOLOGY

The incidence of HF in the Western population is 1–5/1,000/year and it is 3–20/1,000 population.^{2,3} HF affects an estimated 4.7 million Americans, with 550,000 new patients diagnosed annually.^{4,5} The risk of HF in adults around 40 years of age in the US is 14–20%.⁶

Magnitude of Problem in Indian Scenario

Actual data and small studies suggest that the number of patients with HF in India is not less than 2–5 million patients with and at any point of time, 2–3/1,000 population suffers HF. In a study by Chaturvedi and Seth,⁷ 1.2/1,000 patients in rural areas suffer from HF. Approximately, 0.1–0.16 million patients die from HF annually. As per the AFAR study the patients enrolled were middle aged (mean 50.8 years) with an in-hospital mortality estimated to be 30.8% with a post-discharge 6-month rehospitalization and mortality rates of 39.5% and 26.3%. The mean age was lower than Western cohorts (ranging from 65 to 73 years) described in Euro-HF Study, the Acute Decompensated HF National Registry, the organized program to initiate life-saving treatment in hospitalized patients with HF and the effects of oral tolvaptan in patients hospitalized for worsening HF (EVEREST). The reason for mortality in the hospital was progression of HF in 92% patients, majority of in-hospital deaths were due

to progressive HF in 92%, refractory arrhythmias in 6% and/or renal failure in the remaining. One-month death rate in patients who were discharged from the hospital was 15.8% that approached 26.3% at 3 and 6 months.⁸ HF was found to be the cause of death in 2.4% of all deaths in around 50 villages in South India.⁹ These figures represent those patients in whom all medical therapeutic options have been exhausted. Heart transplantation has been considered to be the gold-standard in managing patients with end-stage HF and mechanical support using various devices is considered in the interim in patients awaiting heart transplant. In some patients these devices are used as the only final palliation. However, these devices come at a heavy cost to the patients, insurance companies and the health sector. In addition they are associated with many complications. In this chapter, we present the detailed indications, methods, complications of these devices and will attempt to perform a risk-benefit analysis of these devices and attempt to answer the question "Should Indians borrow to afford them?".

THE INDIAN SCENARIO

In another study of admitted patients of HF (as per Framingham criteria) from South India (Fig. 1),⁷ 94 consecutive patients aged more than 60 years were studied between 2003 and 2005. Mean age of these patients was 69 years and just less than half were females. Coronary artery disease was responsible for majority of these cases (55%) and diseases affecting single or multiple heart valves was the next most common cause (13%). The other causes were dilated cardiomyopathy in 10% and hypertension in 6% patients. In 12% patients, no causes could be ascertained.¹⁰

Disease-wise Heart Failure

Rheumatic Heart Disease

A previous estimate has shown that close to 200,000 deaths that account for 1% of all deaths are due to rheumatic heart disease in southeast Asia,¹¹ majority of these being due to HF. According to project carried out by the World Health

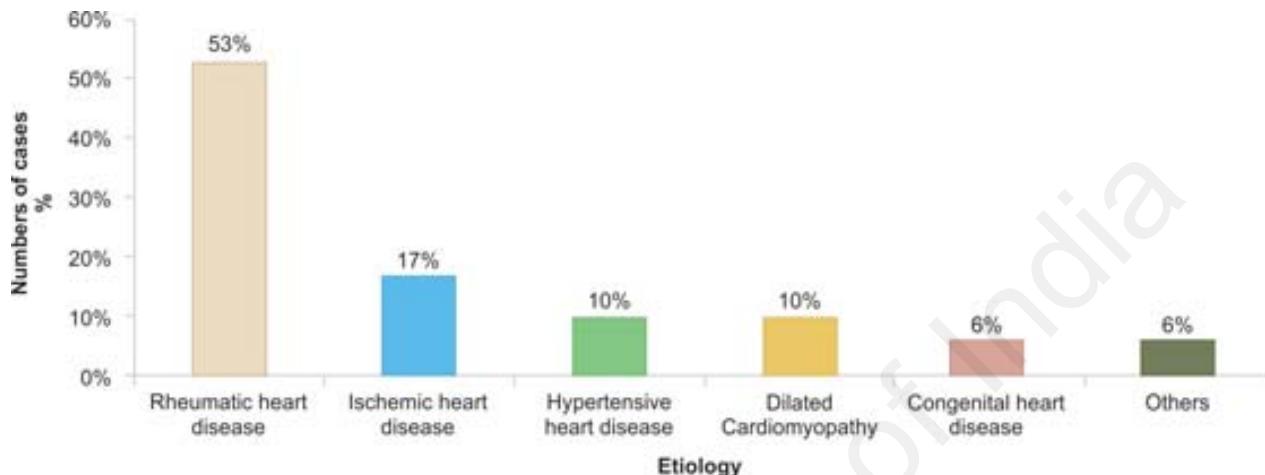

FIG. 1: Common etiologies of heart failure in India.

Source: Chaturvedi V, Parakh N, Seth S, et al. Heart failure in India: The Indus (India Utkari Study) study. J Pract Cardiovasc Sci. 2016;2:28.

Organization in seven developing nations including India, approximately 19% patients with rheumatic heart disease had congestive heart failure (CHF).¹² In a study by Arora et al. in the 1980s, 20% of the patients with rheumatic heart disease needed multiple hospitalizations.¹³ Grover et al. have estimated that 10% of patients with chronic rheumatic heart disease may die particularly in the presence of lesions that are not.¹⁴ Therefore, it is easily inferred that 20–30% patients with rheumatic heart disease may develop HF and it can easily account for 3% yearly deaths.

Ischemic Heart Disease

Jose and Gupta have shown that 5% patients may develop HF within 30 days of an ST-segment elevation myocardial infarction (STEMI).¹⁵ In the CREATE-ECLA study, 17% patients developed HF within 30 days and 10% died.¹⁶ In the OASIS 2 registry, that studied the outcome following acute coronary syndromes, HF was prevalent in 7.2% patients.¹⁷ In CREATE registry that was carried out in India, HF was documented in 1.6%.¹⁸

Hypertension and Heart Failure

As many as 90,000 patients per year are estimated die from consequences of hypertension in Southeast Asia and a large number of these have HF.¹⁹ In the LIFE study, as many as 8.8% patients may have HF of new onset with abnormal features on an electrocardiogram (ECG).²⁰ In study that was carried out in Mumbai, significant hypertension was present in 13.1% of males and 16.7% of females. On a yearly basis, it was estimated these accounted for 0.2% annual deaths. Of all deaths related to hypertension, 14% deaths in males and 25% in females resulted from cardiac disease and consequences of hypertension.²¹

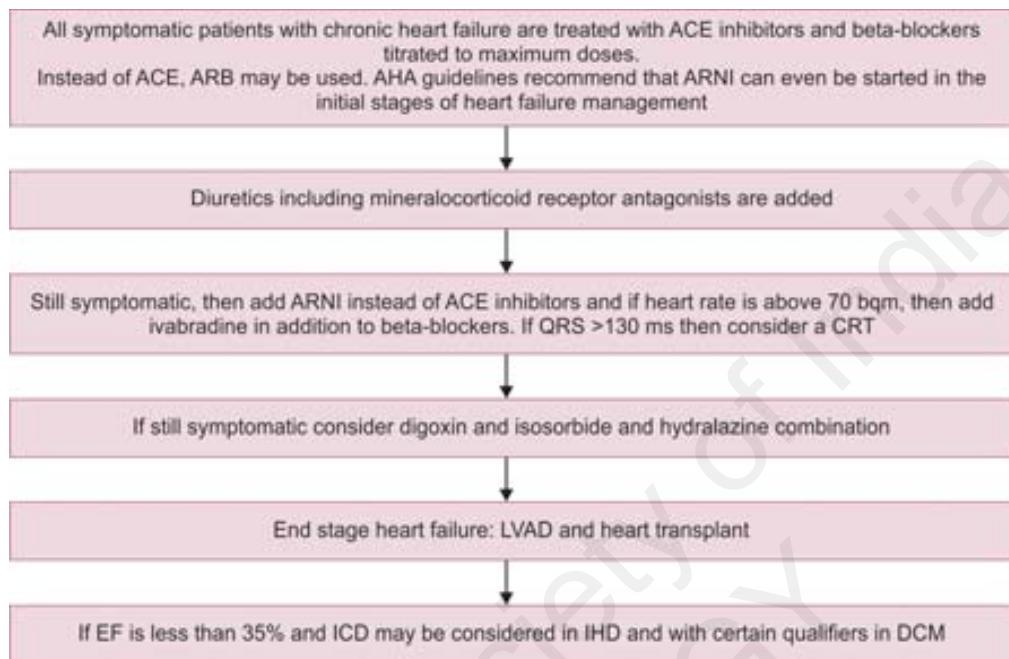

PROTOCOL FOR MANAGEMENT OF HEART FAILURE IN INDIA (FLOWCHART 1)²²

Ventricular Assist Devices

A ventricular assist device (VAD) helps patients with HF by (A) arresting the remodeling process; (B) by reversing the

remodeling process; (C) limiting or reducing dilatation of the heart due to HF. This is achieved by giving rest to the heart gradually helping improve its contractile function. The artificial heart program at the National Institute of Health (NIH) commenced in 1964 following which various mechanical devices were developed for use in patients with unresponsive and refractory HF. The Jarvik 7 artificial heart was first implanted in 1982 and the recipient survived for 112 days.²³ Domingo Liotta from Houston are credited with the development of the first left ventricular assist device (LVAD) in the early sixties.²⁴ These devices were approved as a bridge to heart transplantation in 1994 in the United States.

Heart transplantation is considered to be the final and desired management options for patients with refractory and unresponsive HF. However, the numbers of these procedures has remained stationary worldwide. The number of heart transplants performed annually in the United States has remained fairly constant at approximately 2,100 for many years (2001 heart and stroke update). The total number of heart transplants performed in India has not grown beyond 500 (number since 3rd August 1994) and only a few centers are equipped for this purpose. Due to these limitations there was a need to explore for alternative means of hemodynamic support and VADs play an important role as a "Bridge to transplant" because there is a shortfall of a sufficient number of donors. In about 5–15 % of transplant candidates the native ventricular function is restored by VAD support. Bridging to heart transplantation occurs in 300–400 patients annually in USA.²⁵ Transplantation is performed after VAD implantation in about 20% of patients.²⁶ The published total number of VAD implanted in India is approximately 25,²⁷ although current data suggests the number to be around 60 (data collected by means of telephonic conservation from Dr KR Balakrishnan, Chief Cardiothoracic, Fortis Malar Hospital, Adyar, Chennai, India). VADs also have a place in providing circulatory support in patients who have end stage HF who are ineligible for transplant (old age >65 years, renal dysfunction, pulmonary hypertension and high body mass index) as "Destination Therapy".²⁸ VADs have also been used in patients with

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; AHA, American Heart Association; ARNI, angiotensin receptor-neprilysin inhibitor; CRT, cardiac resynchronization therapy; LVAD, left ventricular assist device; EF, ejection fraction; ICD, implantable cardioverter-defibrillator; IHD, ischemic heart disease; DCM, dilated cardiomyopathy.

potentially reversible cardiomyopathy and in whom the candidacy for heart transplantation cannot be determined immediately and in order to buy time to make a judicious decision as "Bridge to Recovery or Decision".²⁹

Classification of Ventricular Assist Devices^{1,30}

Left Ventricular Assist Devices

They reduce the left ventricular wall stress by 80% and decreases the myocardial oxygen demand by 40% by left ventricle decompression and provide systemic perfusion.

Indications:

- Presence of a cardiac index less than 1.8 L/min/m² with a systolic blood pressure (BP) less than 80 mm Hg
- Pulmonary capillary wedge pressure (PCWP) or left atrial pressure (LAP) more than 20 mm Hg on maximal medical support
- An intra-aortic balloon pump, systemic vascular resistance (SVR) more than 2100 dyne-s/cm,⁵ urine output less than 20 mL/hour.

Technique

Drainage is provided from the left atrium or left ventricular apex with return of blood to the aorta and a left atrial catheter is inserted for accurate monitoring of left-sided filling pressures.

Evolution of Left Ventricular Assist Devices^{1,31}

First Generation

They are also known as pulsatile and volume displacement pumps. They are powered by pneumatic or electrical drive systems. Examples are Abiomed BVS 5000, Thoratec IVAD,

Novacor II, Worldheart Heart Saver, Arrow LionHeart are designed for long term support. Thoratec IVAD and Novacor II are para corporeal while Worldheart HeartSaver and Arrow LionHeart are totally implantable. Lion Heart is a totally implantable VAD without the need for a percutaneous drive line or external catheter but instead uses a transcutaneous energy transmission (TET) system. The LionHeart also has the potential for permanent use in patients not listed for transplantation, such as those with a history of cancer and advanced age. It has the advantage of preventing infection and improving patients' quality of life.

Second Generation

These are also known as continuous flow LVADs which are further classified as:

- *Axial flow pumps:* Nimbus HeartMate II/TCI, Jarvik 2000, (Fig. 2)³² DeBakey/Micromed VAD (Fig. 3),³² and Impella pump system
- *Centrifugal pumps:* AB 180, HeartMate II (Fig. 4),³² Cor Aide, Tandem Heart (PTVA), Heartware (HVAD) system (Fig. 5).³²

Third Generation

These are continuous flow devices which are being developed with an aim search for better material, longer battery life, and smaller size of the device. Examples are VentrAssist, DuraHeart, and HeartMate III LVAD (Fig. 6).³²

Volume unloading is better with pulsatile pumps EVAHEART 2, (Fig. 7),³² but left ventricular pressure unloading is similar with both pulsatile and non-pulsatile pumps.^{33,34}

Timing of Decision Strategies for Ventricular Assist Devices

With the worsening hemodynamic profile and advanced stage of HF, traditional New York Heart Association (NYHA) classification is not reliable (Flowchart 2). Thus, the Intergency Registry for Mechanically Assisted Circulatory Support (INTERMACS) profile system assigns a level depending on how severe the illness is (Figs. 8 and 9).^{28,35,36}

Patients classified under INTERMACS level 2 and 3 constitute about 66% of all LVAD patients. These classes HF are the ideal patients for durable LVAD implantation which could serve in the interim till they undergo heart transplant or for the remainder of the life of the patients. In the randomized evaluation of mechanical assistance for the treatment of congestive HF (REMATCH) trial out of 129 nontransplant patients of HF randomized into two arms one with ongoing medical therapy and in the other arm patients receiving HeartMate XVE implantation, those receiving circulatory device support showed 53% survival versus 25% survival in medical therapy arm at the end of 1 year.³⁵ Thus, LVAD implantation confers a definite survival benefit in the presence of end stage HF.

Preoperative Evaluation of Patients for LVAD²⁷

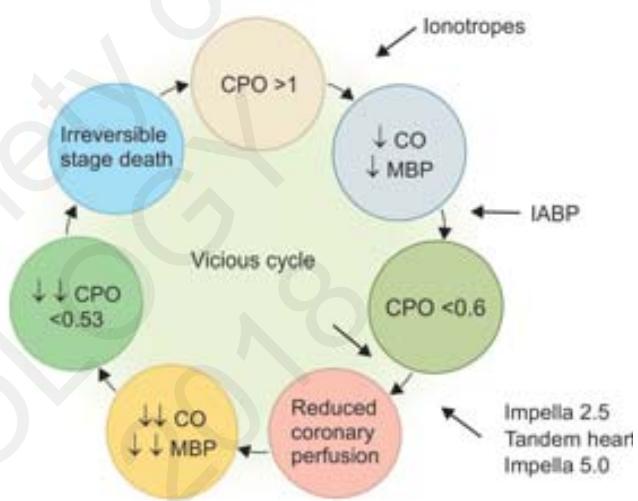

Issues that can jeopardize functioning of LVAD which needs to be assessed prior to implantation are:

- Patent foramen ovale (PFO) which cause severe hypoxemia post-LVAD implantation
- Presence of significant aortic regurgitation which increases further post-LVAD implantation as a result increases LVAD preload leading to increased pump flow and fall in systemic blood flow
- Right ventricular function and tricuspid regurgitation (TR) as high LVAD flow can distort inter ventricular septum and cause tethering of tricuspid valve and exacerbate pre-existing TR.

Post Ventricular Assist Device Implantation Management³¹

Left Ventricular Assist Device

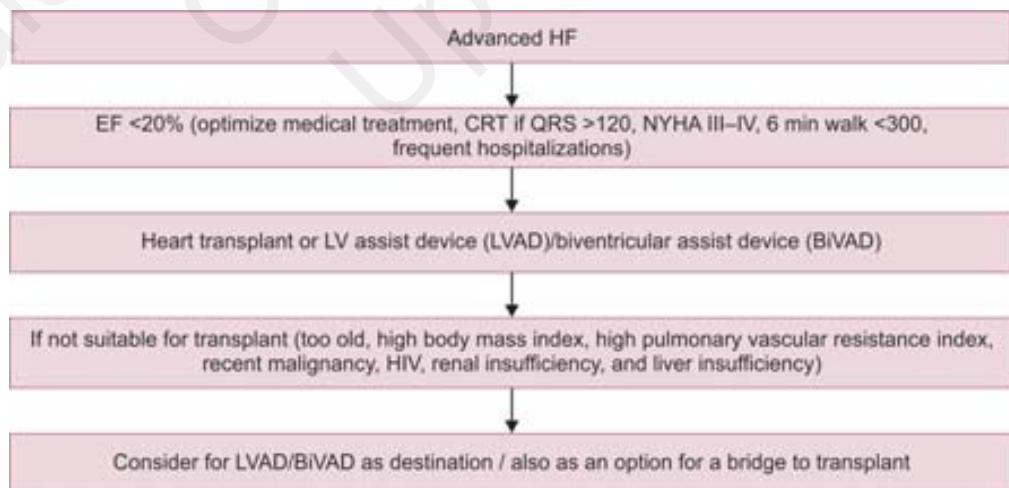

- Flows are initiated to achieve a systemic flow of 2.2 L/min/m² with a LAP maintained at 10–15 mm Hg
- Maintain mean BP of 75 mm Hg
- As LVAD patients manifest commonly with vasodilatory shock alpha agents and vasopressin infusions may be started
- Heparinization should be done to maintain activated partial thromboplastin time (aPTT) 2–2.5 times normal and activated clotting time (ACT) 185–200 s.

CPO, cardiac power output; CO, cardiac output; MBP, mean blood pressure.

Problems with LVAD: Post-LVAD Implantation Complications^{30,37}

A discussion of these is important as the frequent occurrence of these complications mandates that the patients either remain in the hospital for extended duration or live in close proximity or manage to return for follow-up at short intervals or in times of need. This is not difficult in the Western world because of wide awareness and because of multiple set-ups that are available within close distance of the patient's place of residence. However, this is practically impossible in countries like India where there are less than 10 setups for the entire country, which means that these patients have to be in the hospital for extended periods of time, significantly increasing the costs of health care.^{38,39}

Bleeding

As a result of anticoagulation with warfarin, shear stress from pump induced platelet dysfunction causes bleeding mostly from gastro intestinal tract at the rate of 8–23%.⁴⁰ Heyde's syndrome [a gastrointestinal (GI) bleeding initially described in patients with severe calcific aortic stenosis from angiodysplasias] is seen in candidates with continuous flow LVADs which results due to low pulsatility on micro circulation and increased oxidative stress.⁴¹

Up to 60% of patients require re-exploration for evacuation of mediastinal clots as a result of mediastinal bleeding that causes tamponade which manifests as improper drainage of the device.⁴²

Pump Thrombosis

This complication carries a high risk of death and may also lead to postoperative neurological events. Incidence rate of pump thrombosis is 6–12%.^{43,44} From the time of confirmed pump thrombosis, there is a two-fold increase in mortality at 30 days, 90 days, and 6 month.⁴⁵ Patients with suspected LVAD thrombosis who do not undergo LVAD exchange or cardiac transplantation have 48.2% mortality within 6 months.

Infection

Incidence of infection in post-VAD implantation patients is about 20% which manifests as sepsis, mediastinitis or a drive-line infection.⁴⁰ This data is from the Western world and the incidence of infectious complications is expected to be much higher in India. The most common organisms are *Staphylococcus aureus*, coagulase-negative staphylococci, *Candida* and *Pseudomonas aeruginosa*. Infection should be treated aggressively which may require long term antibiotics, antifungal agents unless the device is exchanged or the patient is considered for cardiac transplantation.

Cerebrovascular Complications

Thromboembolic events like stroke occur at a rate of 6%. Patients with mechanical aortic valves should have them covered with tissue or sewn shut to prevent thromboembolism.

Malignant Ventricular Arrhythmias

Ventricular arrhythmias occur as a result of myocardial ischemia, infarction, or the use of catecholamines. Fibrillation may lead to thrombus formation in the ventricle and it should be treated aggressively by early cardioversion to prevent RV injury from prolonged fibrillation.⁴⁶ Chest compressions can be used for percutaneous and continuous flow devices but are contraindicated for pulsatile devices.⁴⁷

Case Series on Ventricular Assist Device Implantation from India

A case series comprising of 11 patients implanted with LVAD as destination therapy was reported by Kumar et al. in 2015 from Fortis Malar Hospital Chennai⁴⁸ in 8 males and 3 females with a mean age of 47 years. Two models of LVADs HEARTMATE-II for patients weighing more than 70 kg in 3 patients and HeartWare (HVAD) for patients weighing less than 70 kg in 8 patients were implanted. Out of 11 patients primary diagnoses for 4 patients was ischemic cardiomyopathy, 3 had dilated cardiomyopathy, one patient had recent anterior wall myocardial infarction (AWMI) with recurrent VT and LV dysfunction and one had severe valvular aortic stenosis with severe LV dysfunction. Seven patients were classified as INTERMACS level 2, 3 patients in INTERMACS level 3 and one patient in INTERMACS level 4. Two patients were on prior ECMO and 8 patients were on inotropic support. In postoperative period 9 patients were successfully discharged. Two patients had in hospital mortality: one due to sepsis and intracerebral hemorrhage and other due to severe right heart and liver failure. There was one late mortality 18 months postoperatively due to fulminant hepatic failure. Remaining 7 patients are doing well with no signs of HF after a maximum of 3 years follow-up. Current Fortis experience is listed in table 1.

A case series of 3 patients of LVAD implantation was reported by Jayanth Kumar et al. in 2013 from Narayana Hrudayalaya Institute of Medical Sciences, Bangalore.⁴⁵ The average age was 42.3 years. Etiology of HF in 2 cases was ischemic cardiomyopathy and 1 was idiopathic cardiomyopathy. All 3 patients underwent LVAD implantation with VentrAssist model. All 3 patients underwent a cardiac rehabilitation program prior to discharge. All of them were in NYHA class I cardiac status at the time of discharge.

A case report was described by Singh et al. from AIIMS New Delhi⁴⁸ of a 35-year-old male with primary diagnoses of dilated cardiomyopathy who underwent LVAD implantation with HeartWare (HVAD). During the postoperative period patient developed hematuria on second postoperative day and acute kidney injury in the first postoperative week. This patient underwent mediastinal exploration on day 11 and bilateral pleural drains were placed for pleural effusion which did not subside by repeated tapping during the first week.

TABLE 1: LVAD: The Chennai experience

Variable	Values
• Duration	2012–2018
• Number of cases	55
• Type of LVAD	
◦ HeartMate III	20
◦ Heartware	25
◦ HeartMatell	10
• Cost per case	80–90 lakh rupees
• Survival rates	
◦ At 1 year	>80%
◦ At the end of 5 years	<40%
• Number of cases who ended in transplantation	4

In addition, Centrimag was used in 28 patients in 2016, 55 patients in 2017 and in 50 patients so far in 2018. Majority of these patients were postcardiotomy and 10 were done as bridge to transplant.

LVAD, left ventricular assist device.

TABLE 2: LVAD AIIMS experience

Variable	Value
Number of cases	8
Median age	41.5 (range 34–49) years
Etiology of heart failure	DCM (N = T), Post-transplant: 1

Planned as bridge to transplant in all patients except one, with only one patient receiving the transplant.

LVAD, left ventricular assist device; AIIMS, All India Institute of Medical Sciences; DCM, dilated cardiomyopathy.

Patient also developed depression due to prolonged ICU stay. Mean hospital stay was 45 days. Postdischarge patient developed driveline site infection leading to formation of granulation tissue. During follow-up visit 6 months postoperative, patient developed severe RV dysfunction and hepatomegaly. Current AIIMS experience is listed in table 2.

HEART TRANSPLANTATION VERSUS VAD'S FOR END STAGE HEART FAILURE

Cardiac transplantation is the desired optimal management for patients with end stage HF, but compatible donor availability is a major limiting factor.⁴⁹ Optimal patient selection determines is important to get good results. Heart transplantation is contraindicated in the presence of significant pulmonary hypertension; however mechanical support is considered in these patients.⁵⁰ Patients with end-stage right-sided HF are suitable for mechanical LV assist. In these patients cardiac transplantation is useful.^{51–53} Mechanical assist of the left ventricle improves renal function.⁵⁴ Contraindications are infection, older age, and significant aortic insufficiency.^{55–58} Mechanical LV assist may however lead to ventricular arrhythmias.⁵⁹ In addition, many

patients on LV assist may not remain suitable candidates or may never undergo cardiac transplantation due to scarcity of a suitable donor.⁵²

Theochari et al.,⁶⁰ conducted a meta-analysis of eight multi-centric studies involving close to 8,000 patients. Almost 5,000 of these received a cardiac transplant whereas a LV assist device was implanted in 92 as the final palliation. In more than 2,500 patients, the mechanical assist was used while these patients awaited a transplant. The follow-up in patients undergoing transplant was 12–50 months and for those on assist, awaiting transplant, it was 9.4–30 months. The average LVEF was 14–24% in the transplant group, 15.6–20.4% in the bridge to transplant group and 13–20% in the destination group 1-year death rates in all groups were similar. Stroke rate was 0–4.3% in those undergoing cardiac transplantation, 0–6.1% those undergoing mechanical assist as a bridge to transplant and 4.3–6.1% in patients where the mechanical assist was used as a destination therapy. Infection occurred in 0.5–25.5% undergoing transplant, 21.1–26.5% with destination mechanical assist and 0–32% with bridge mechanical assist. The total cost per-patient for the transplantation group was 128,474–230,009 US Dollars, for the mechanical assist as a bridge, it was 95,428–166,415 US Dollars and in patients where mechanical LV assist was the final palliation, it was 152,931–174,165 US Dollars. On comparing 1-year survival following heart transplantation after a period of mechanical

circulatory assist with mechanical assist as a final therapy, both strategies carried similar results.

Retrospective Study by Mishra et al.⁶¹ showed that 1- and 5-year survival rates were 96% and 83% in the bridging to HTx (LVADHTx group), 92% and 81% in heart transplant (HTx group), 48% and 36% in those who were treated by LVAD alone (LVAD group). Total hospital cost at 1 year was \$151,685 ± 86,892 for HTx, \$427,337 ± 365,154 for LVAD, and \$600,897 ± 198,109 for LVADHTx. The study concluded that LVADHTx and HTx groups showed excellent 1- and 5-year survival rates and the expenses per patient was almost four times in LVADHTx group. However, as these devices are not indigenous, it is apparent that these costs are prohibitive and not within reach of even 0.5% of the population. The average per capita income in India was \$1,410 in 2011, in some states it was as low as \$ 294–436 (“India Country Overview 2013”. World Bank. 2014. Retrieved 28 July 2014.)—World Bank: India Country Overview 2013.

India is a developing mixed economy.⁶² It is the world's sixth largest economy by nominal gross domestic product (GDP) and the third largest by purchasing power parity (PPP). The country ranks 139th in per capita GDP (nominal) with \$2,134 and 122nd in per capita GDP (PPP) with \$7,783 as of 2018.⁶²

A study by Garbade J et al.⁶³ compared the two therapeutic options VAD versus heart transplantation for end stage HF (Table 3).⁶³

TABLE 3: Comparing questions and challenges between the two end-stage heart failure treatment modalities

Feature	Ventricular assist devices	Heart transplantation
Availability	Immediately	Unmet needs with waiting list
2 years survival benefit	80%	80%
5 years survival benefit	40%	70%
QoL and functional capacity	Proven up to 2 years	Proven
Showering and bathing	Very limited	Unrestricted
Long-term stability	Proven	Proven
Complications	<ul style="list-style-type: none"> • Thrombo embolic events • Bleedings • Drive-line infections 	<ul style="list-style-type: none"> • Drug toxicities • Allograft vasculopathy • Malignancies
Drug monitoring	Required, anticoagulation, different protocols	Required, immunosuppression, multiple protocols
Myocardial biopsy	No	Yes, different protocols
Infrastructure, outstanding, and hospital care	Under construction and development	Available
Team and coordinator	Yes	Yes
Remote monitoring	Under development	Not available
Organ supply	–	Limited, despite newer conservation technique and organ care systems
VAD development and new technique, peripherals	Stringent development	–
Reimbursement	Unclear	Defined
Public policy	Insurance & costs	Insurance and costs
Ethical aspects	Undefined, decision making: device selection for individual patients not defined clearly (e.g., considering age, comorbidities, palliative care)	Regulated by different societies

VAD, ventricular assist device; QoL, quality of life.

A retrospective single center study by Marasco SF et al.⁶⁴ comparing costs of 35 post-heart transplantation patients with 33 post-LVAD implantation patients, demonstrated the significantly increased costs of VAD implantation compared to HTx over the first 12 months of care. The total costs of care during the index admission, procurement, blood products, and subsequent admissions were approximately \$411,414 per patient in the VAD group which is almost double versus \$189,988 per patient in the heart transplant group. Procurement costs for the current generation VAD in our country are approximately 27 times higher than for a donor heart as they are not indigenously manufactured. Emergency admissions for duration of several days in the subsequent periods are also high for VAD implantation group culminating in very high postoperative management expenditures.

Patel et al.⁶⁵ compared costs over 12 months of LVAD treatment versus heart transplantation including follow-up with immunosuppressive drugs and surveillance biopsies, it was found that the index admission and postoperative management costs for 1 year were higher in LVAD implantation by approximately 15%, but the overall costs were almost similar in both the groups balanced by the higher outpatient costs in the transplant group.

In a study by Mullooy et al.,⁶⁶ in-hospital deaths following mechanical LV assist occurred in 17% compared to 6.5% following cardiac transplant. The mean cost per patient increased for both orthotopic heart transplantation and LV assist device placement which were 40% and 17%, respectively. With the observed increase in both device usage and cost per patient, the cumulative LV assist device cost increased 232% within 5 years from \$143 million to \$479 million.

PROS AND CONS OF LVADS IN INDIA (TABLE 4)

Made in India Ventricular Assist Device⁶⁷

On May 23rd 2016, Cherian from Frontier Lifeline, Chennai signed entered into collaboration with Russian scientists to manufacture a low-cost VAD which potentially fulfil the objectives of LV assist. This is proposed to be manufactured in India and may cost only around Rs 30 lakh, one-third of the

TABLE 4: Pros and cons of ventricular assist devices in India

Pros	Cons
Off the shelf availability	Prohibitive costs
Size not an issue	Risk of complications: bleeding, infection, thromboembolism
Blood group not an issue	Need and risks of anticoagulation
No need to wait for donors	May unmask right ventricular failure with need of ventricular assist
No need for immunosuppressants	Technical issues with implantation
Can be used as bridge to transplant/destination therapy	Patient mobility (flexibility with newer modules)

market prices of other devices. The device called Sputnik, in envisaged to be manufactured in a facility near Chennai. India will be the first Asian country and the third in the world to manufacture VADs, after US and Germany. Currently this device is still in the testing phase in various preclinical animal studies.

CONCLUSION

The cost of VAD implant is approx. US\$ 100,000 and in India Rs. 9,000,000.^{27,67,68} The cost of implant is obviously a factor in slow growth of VADs assistance programs for patients. VAD costs as well as perioperative care need to reduce substantially in order to make this treatment option a more available alternative for larger groups of the severe HF patients. It is likely that this will happen, as results improve and complications reduce. Favorable reimbursement policies even in developing countries like India are expected to trigger the entry of these devices penetration into the health care in the near future. However, at the moment this remains a costly treatment option despite an expanding pool of recipients and probably does not justify the need to borrow to afford them.^{69,70}

Heart Transplantation in India: Successes and Challenges

Balram Airan, Milind Hote

INTRODUCTION

The events that led to the first human heart transplant and the relevant history of this phenomenal surgical feat is fascinating. Cardiac surgery progressed from the days of Stephen Paget in 1890s who condemned any contemplation of surgery on a human heart as being beyond the “limit set by nature” to controlled cross-circulation and first-oxygenator based open-heart surgeries in 1950s.¹ The next big leap in this field came from a teaching hospital near Devil’s peak in Cape Town, South Africa when a young surgeon named Christiaan Barnard captured public imagination all over the world by doing the first human heart transplant in 1967.² Many thought this was flattery only to deceive, when several successive attempts at heart transplantation failed worldwide. Essentially the field went into hibernation and only very few determined pioneers at Stanford University persisted with this daring undertaking.³

There have been significant advances in medical and device therapies for heart failure (HF) in the last two decades. However, for patients in stage D HF (established end-stage HF), heart transplantation is the gold standard option for suitable candidates.⁴

This chapter is an attempt to look back into the journey of the heart transplant procedure in India, its successes and the challenges to be faced in the road ahead.

SUCCESSES

Overcoming Difficulties in Performing the First Heart Transplant in India

While major experimental work was going on at Stanford, Indian efforts were also on at King Edward Memorial (KEM) hospital in Mumbai, in early 1960s. Professor PK Sen was actively harvesting and transplanting canine hearts (dogs) in his laboratory, worth reasonable success.⁵ Having gained strong insight into surgical technique required and donor organ function after transplant, Professor Sen awaited

permission from the Maharashtra state medical board to carry out the first human heart transplant since 1965. However, the permission did not come until the first such operation was done in South Africa. In February 1968 (the sixth heart transplant operation in the world) and then again in September 1968, Dr Sen performed two human heart transplants, in both, hearts were retrieved from severe head injury patients.⁵ Both the patients succumbed within the first 24 hours of their surgery; first one due to graft dysfunction and the other due to severe pulmonary hypertension in recipient. It is interesting to note here that even in South Africa, in 1967, there had been no set guidelines for diagnosis of death in beating heart potential donors.

These initial failures and the lack of a robust medicolegal document (act pertaining to human organ transplantation) put a mental block in the minds of other surgeons about performing this procedure. By early 1990s All India Institute of Medical Sciences (AIIMS), New Delhi and Madras Medical Mission (MMM), Chennai were ready to perform their own cases of heart transplantation. However, even up to this time, the laws defining organ donation in India were not crystal clear. Major efforts to convince the governmental bodies about the feasibility of this procedure, need for the organ donation, and examples of successful systems in the west, were finally sufficient to convince the regulatory bodies of that time, to come up with a set of rules [THOA (Transplantation of Human Organs Act, 1994)]. The act defined for the first time, the concept of brain stem death (BSD), organ donation, and set forth the regulations governing such organ donation and transplantation for the various hospital setups in India. This was a major breakthrough which kick started the program of solid organ transplant in 1990s. With this major roadblock gone, Professor Venugopal did the first successful heart transplant in India on 3rd August 1994.⁶ This was soon followed by several heart transplants both at AIIMS and at MMM, Chennai (Dr KM Cherian). Dr Cherian is credited with our country’s first pediatric heart transplant and also the first heart-lung transplant operation.⁷ At KEM, where

this operation was first attempted in 1968, no further heart transplant operation was done until 2015.

Number of Heart Transplant Centers in Our Country

For almost 14 years since 1994, there were only three to four active centers doing heart transplants in the country. However, since 2008, there has been a rapid increase in the number of centers certified to do heart transplant operation. This increase has been mostly in the metro and large tier-II cities. With a continuous increase in the number of qualified surgeons with more than 2,000 cases surgical experience of open-heart surgery and also the establishment of various multidisciplinary facilities in both government and private sector hospitals, the requirements of certification of an applying center are usually met with and hence the increase in the number of certified centers has materialized. The concern here remains that of the 87 odd centers now certified (Fig. 1),⁸ only about 10 are actively doing heart transplants frequently (>5 cases a year), and the other centers have yet to cross a cumulative figure of five.

Number of Operations⁸

Paralleling the increase in the number of centers, there has been an encouraging increase in the number of operations also year-wise, as can be seen in fig. 2. With increase in the experience of transplant teams, the initial teething problems of a successful program are frequently over after the third or fourth operation and subsequent limitation to number is only related to the availability of donor heart. There are three centers which have experience of more than 50 transplants (AIIMS, New Delhi >60, Fortis Malar, Chennai >200 and Fortis Mulund, Mumbai >50). The number of organ donations is increasing especially in some states in our country and more and more surgical teams are geared up to utilize the available donor hearts. The evolution of HF teams (especially cardiologists, cardiac surgeons) enables increasing referrals of end-stage HF patients to heart transplant registries. In addition, there are increasing numbers of pediatric heart transplants also which is very encouraging.

Availability of Standard Immunosuppressive Drugs

Cyclosporin was introduced to the world in early 1980s and the success of solid organ transplants increased exponentially thereafter. There is standard immunosuppression protocol followed across heart transplant centers in India, and there is no dearth of the availability of common drugs used including cyclosporine, tacrolimus, mycophenolate mofetil, and OKT 3. The spectrum of Indian patients varies widely compared to the west in terms of our patients' nutrition, pre-existing latent infections and external environmental hygiene. This has mandated the titration of dosages of steroids and immunosuppressive drugs in Indian patients, these doses being different from western heart transplant recipients. It is a tightrope walk between achieving adequate immune

suppression versus inviting infection in Indian setup. With increasing experience in our country, these long-term immunosuppressive drug dosage regimes also have been standardized, as different from Western dosages.

Good Survival and Heart Transplant Outcomes

The standard 1-year survival in busy centers in our country is more than 80%. This compares very favorably with the International Society for Heart and Lung Transplantation (ISHLT) Western data (88%).⁹ The main losses previously have been due to flaring up of latent infections or patients who were in extremis preoperatively (on extracorporeal membrane oxygenation, etc.). The problem of flaring up of subclinical infection has been minimized due to aggressive tapering of steroid therapy administered postoperatively, to the minimum required dosage. In terms of long-term recovery, patients are becoming more aware about the possibilities after this major surgery and they are able to actively participate in their cardiac rehabilitation program which enables their return to routine work and lifestyle. Many long-term survivors (>10 years) are inspiring motivators to preoperative HF patients. Good long-term survival also depends significantly on the regular and routine follow-up of these recipients in specialized heart transplant clinics managed mainly by intensivists and cardiologists with important support from radiologists, nephrologists, pathologists and physiotherapists, and counselors.

Increase in Organ Donation, Heart Utilization⁸

Till 2008, the number of organ donations overall in India was abysmally low. If we compare the organ donation rates (number per million population) following 2008, there has been a significant increase. The leading state in terms of organ donation has been Tamil Nadu and the regions of Maharashtra, Chandigarh, Indore, and Kerala also have picked up encouragingly (Fig. 3). Primary cause of increased donation is the increased awareness amongst people about the benefits of organ donation and removal of taboos from their minds (about possible deficiencies in future lives following organ donation), etc. The states starting with Tamil Nadu have taken good corrective action in minimizing red tapes related to organ donation following accident (medicolegal case) deaths, in the sense that no further postmortem is necessary. The forensic team arrives in the operation theatre itself whilst organ harvesting process is underway. In addition, some of the states have taken commendable action toward promoting organ donation by giving ethical soft incentives like government job to one member of a donor family, health insurance to all close family members of a donor family for 5 years, special recognition and thanksgiving functions organized periodically to honor the family of organ donors, and special status to family member of a donor if he/she needs any organ donation. Various states adopt these various measures and the response has definitely been encouraging.

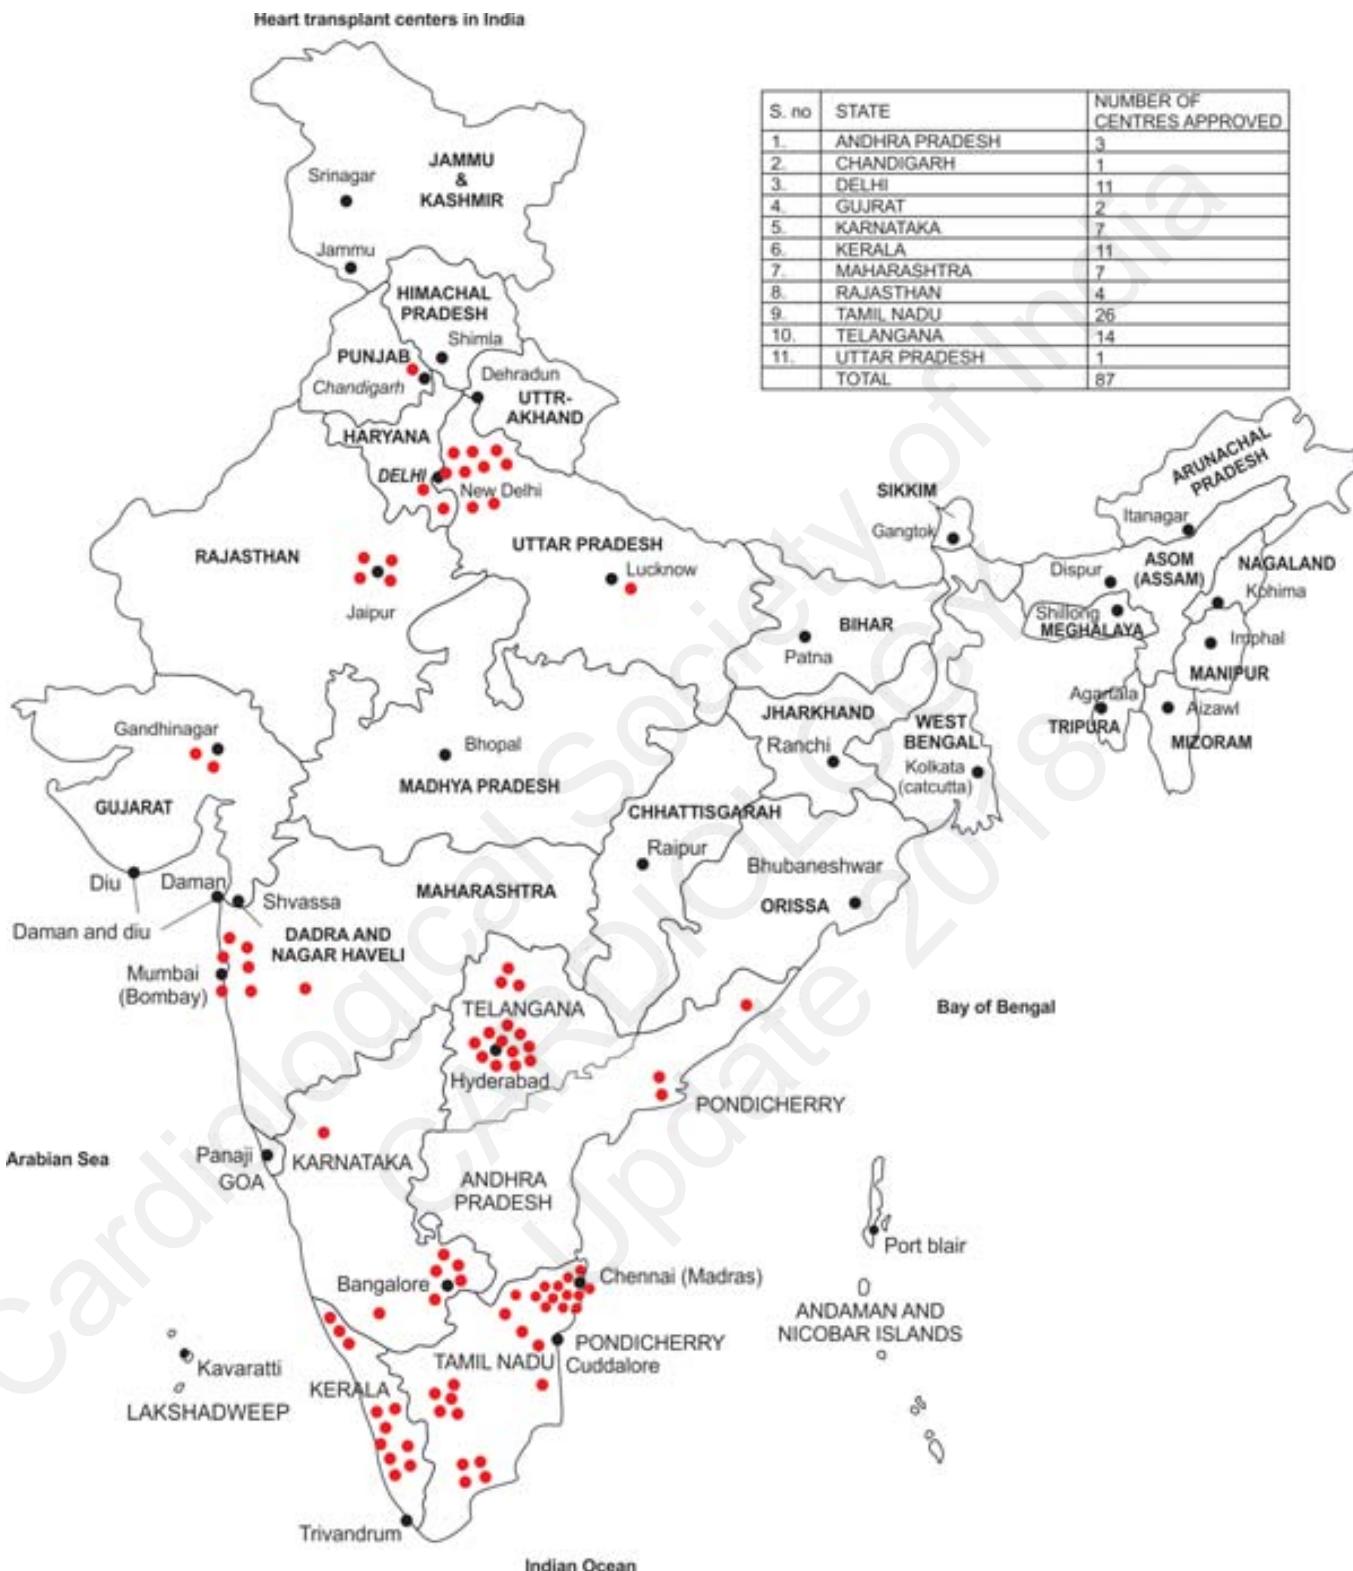

FIG. 1: Red dots on map show the cities with hospitals licensed to perform heart transplants.

Recipient Characteristics and Pediatric Heart Transplant

In recent years and in experienced centers, the patient profile is visibly changing. All patients on waiting list for heart

transplant are New York Heart Association Class IV, but in addition, several patients are now being taken up whilst being on heavy inotropic support with additional mechanical support (intra-aortic balloon pump or left ventricular assist device) frequently. It becomes a real emergency to offer a

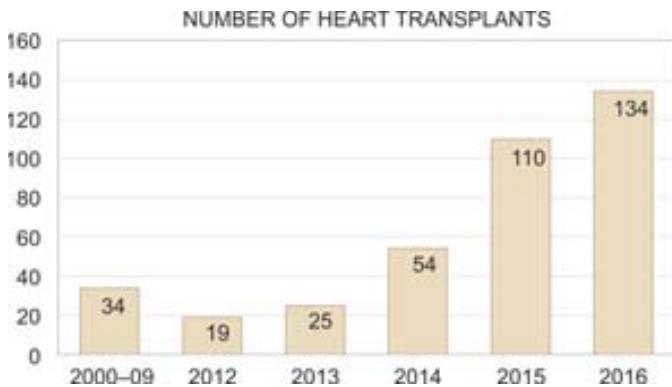

FIG. 2: Yearwise figures - number of heart transplants in India.

donor heart to such patients who are in extremis and are not expected to survive for more than a week in the absence of a donor heart. In these patients, even borderline donor hearts have been transplanted as a desperate measure. Centers are also taking up transplant in the pediatric age group (<14 years). Pediatric age group patients usually belong to the subset having late ventricular failures following some primary operation (usually Fontan operation). There are a very large number of patients in our country who have undergone a Fontan procedure and many of them are gradually returning back with increasing HF. The complexity of surgery increases many times in both the above subsets but outcomes have been gratifying.

National Organ and Tissue Transplant Organization Coordination and Outstation Harvests

With a limited pool of recipients registered in a city, it is a frequent happening that a donor available in a city has no takers for the heart in that city. In the initial years (1995–2008), there was no central organization in the field of coordinating organ donation. Important regional players were nongovernmental organizations (NGOs) like Mohan foundation in South India, Organ Retrieval Banking Organization (ORBO) in AIIMS, New Delhi, and others. Later there was formation of Tamil Nadu Network for Organ Sharing (TNOS) and Transplant Authority of Tamil Nadu (TRANSTAN), and the organ donation rates were significantly increased. Recently, a robust central coordination system is being gradually put into place by National Organ and Tissue Transplant Organization (NOTTO) and it has been instrumental in judicious utilization of available donor hearts nationwide. Nowadays, most of the transplants are happening with donor heart harvesting being done in some other city. NOTTO informs various transplant teams across the country about the availability of a donor heart with all the details. The allocated recipient hospital then makes arrangement to retrieve the donor heart from another city. Use of both chartered flights (air ambulances, cost 6–10 lakh rupees) and routine commercial flights (Indigo, Jet airways, Air India, etc.) has been done to procure the precious donor hearts. The cooperation extended by the flight staff, airport security officials, and traffic police in creating a green

corridor in both cities has always been magnanimous, and this concept of outstation harvests is primarily responsible for the recent spurt in the number of heart transplants being done in India.

Experienced Transplant Teams

Surgical technique for heart transplantation is simple. Essentially it involves good myocardial protection while harvesting the heart (give cardioplegia, pack it properly in cold cardioplegia solution—ice), ensure transport of donor heart back to recipient OT within 4 hours, and perform five structural anastomoses—left atrial cuff, inferior vena cava (IVC), superior vena cava (SVC), pulmonary artery and aorta. Any cardiac surgeon with an open-heart surgery experience of more than 1,000 cases can perform the above steps without difficulty. The real challenge comes in the postoperative management in the intensive care unit (ICU) and ward. Many patients go into low renal output and a good all-around team care—from the cardiologist, intensivist, anesthesiologist, nephrologist, physiotherapist, transplant nurses, pathologist, psychologist and others—is mandatory for a successful outcome following this major surgery. This close model of care needs to be followed up even after discharge and late after transplant. Having a successful transplant program essentially depends on having a competent, cohesive, committed core team comprising the above. These are now available in many hospitals and many cities in India, that is, an important factor in the success of the transplant program in India.

CHALLENGES

In India, there still are several challenges faced by the specialty of heart transplantation. We are still not performing as many number of transplants as needed and the factors determining postoperative outcome here are slightly different from what is seen in the western data. Herein we briefly look at the factors that cause still a suboptimal heart transplant program in India.

Low Donation Rate⁸

The bar graph (Fig. 4) shows the organ donation rate per million population in various countries. It is amply clear that India stands way far behind in terms of national average donation rate.

About 10 states and two union territories only are reasonably active in the field of organ donation. Many states are large states like UP, Bihar, Chhattisgarh, Himachal Pradesh (Fig. 5), etc. but have not yet seen a single organ donation. If we see the road traffic figures, we had 1% (of the world) road vehicles and 6% of road traffic accidents (in the world). By 2006, these accident figures have swelled to 10%. In absolute numbers, 137,572 people died on Indian roads due to accidents (1.1% of world's total death figure). If even 5–10% of these deaths are converted into organ donating individuals,¹⁰ it will largely suffice the need for donors for heart and lung transplants in our country. We need to have more number and enthusiastic transplant coordinators

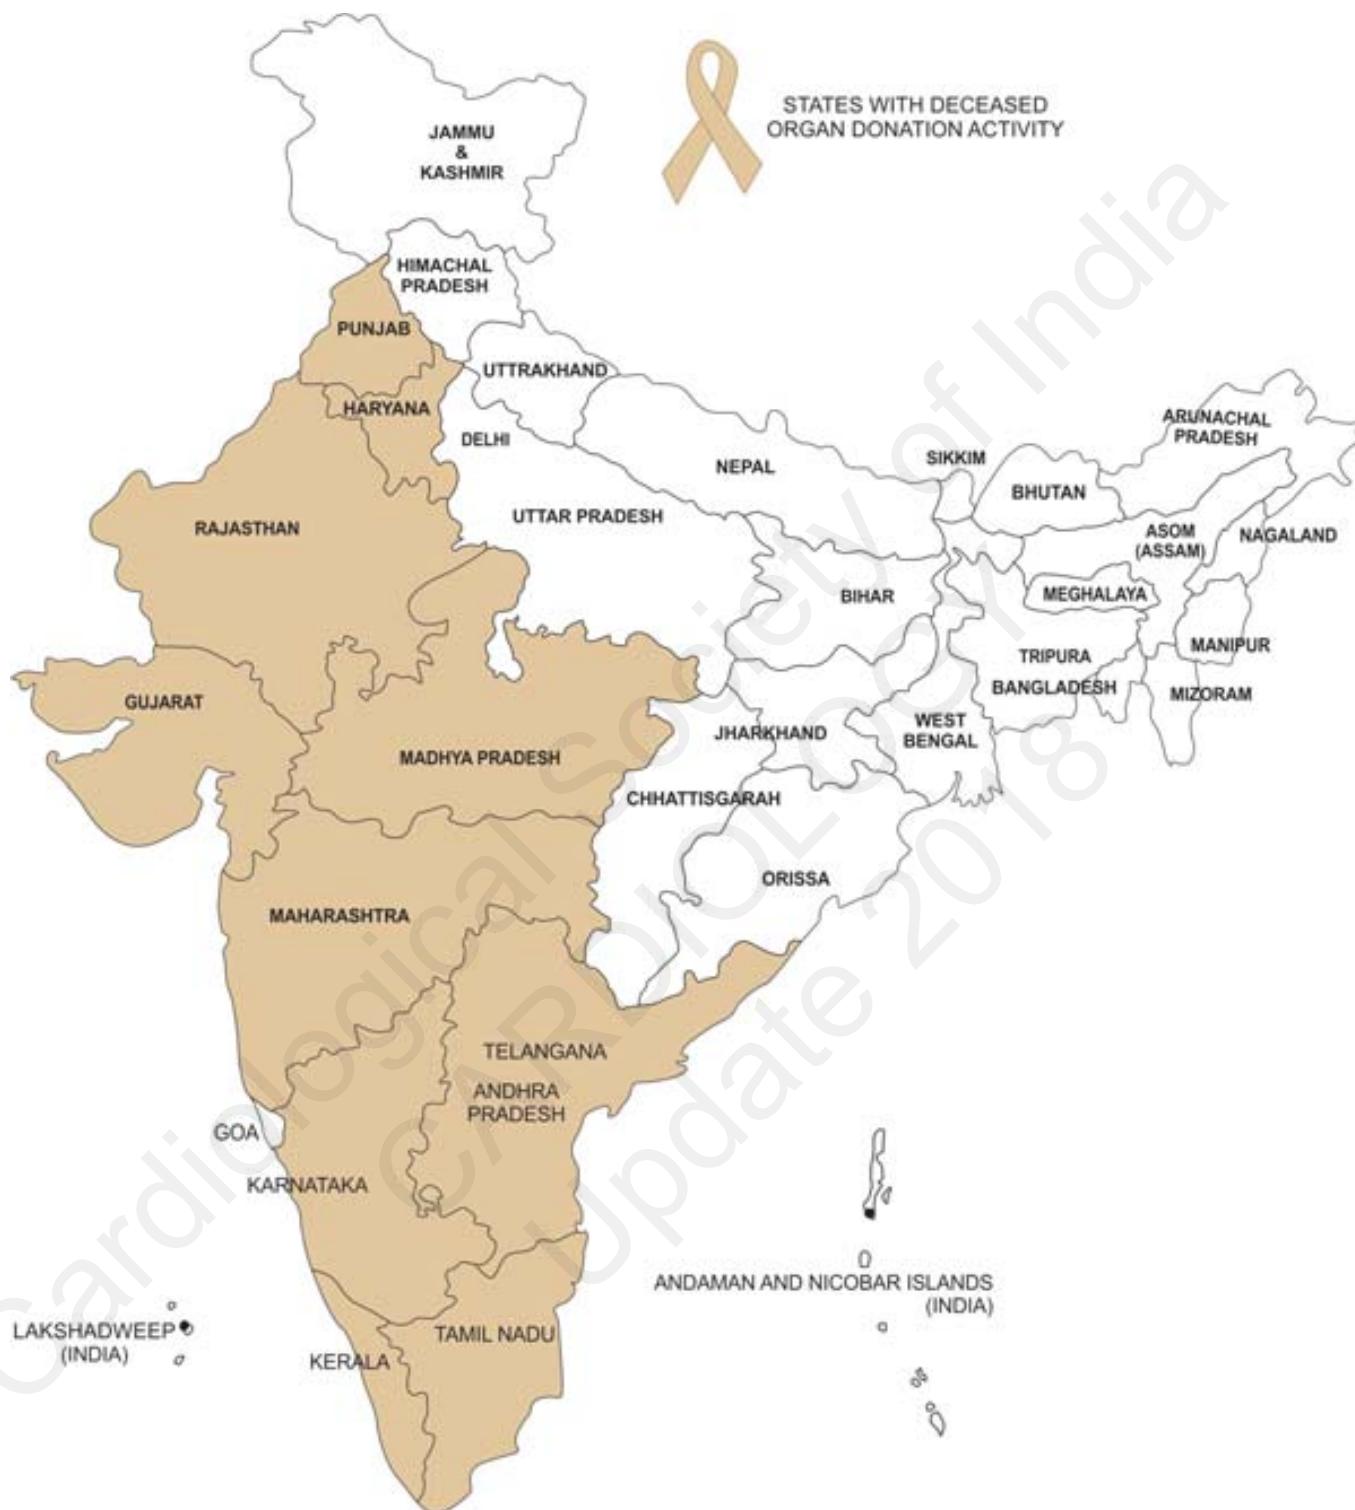

FIG. 3: States active in organ donation.

who can empathize with such road traffic accident victims' families and can coordinate with the treating neurosurgeons or intensivists to motivate the families for organ donation.

The reasons for low convincing rate for donation in donor's family are manifold: cultural beliefs amongst people of various religions about incomplete next-birth form;

multiplicity of family people involved in decision-making process; fear of mutilation of body; delay in cremation process, etc. Several recent attempts by religious leaders and prominent sports and political personalities (including Prime Minister himself) to convince the people about organ donation are working to reduce this sociocultural factor.

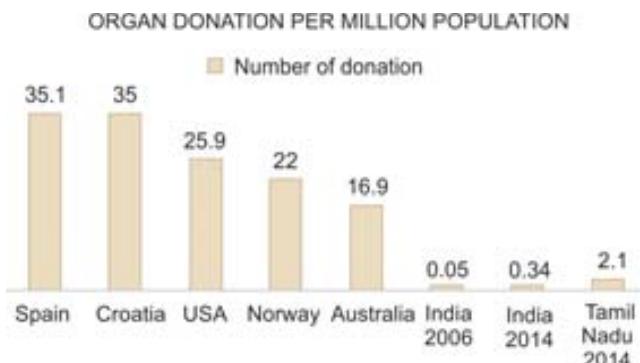

FIG. 4: Abysmally low levels of donation in India.

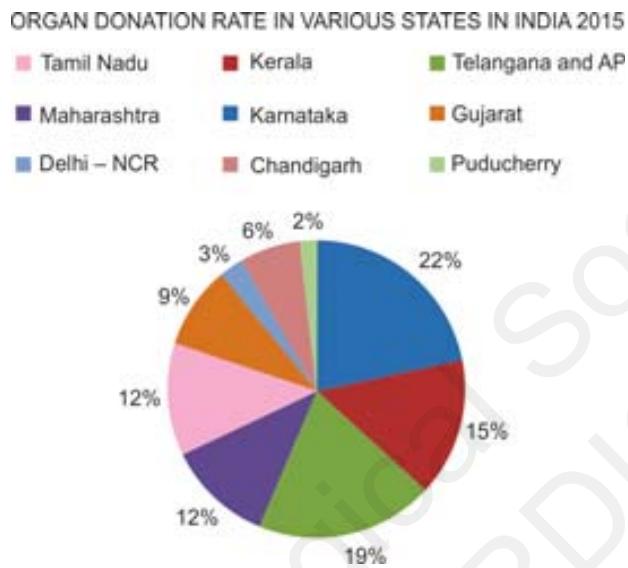

FIG. 5: States where most donors have come from.⁸

Recipient Attrition

Sometimes, the patients on the waiting list get “used to” their class IV status and relegate themselves to this bedridden life. Their motivation levels are low. Many patients when offered the option of heart transplantation refuse because the high costs involve. At AIIMS, New Delhi, most of the heart transplants were done at a very nominal cost of 1 lakh rupees, but recently, the commitment toward lifelong immunosuppression has made it necessary to give higher estimate for this surgery (Rs 10 lakhs). In most corporate hospitals, the package rates for heart transplant are between 15 and 22 lakhs. In addition, sometimes the recipients refuse when informed about availability of a donor heart by giving reasons as upcoming festival or family event scheduled shortly, etc. Several others die while in the waiting list.

Not Identifying or Notifying Brain Stem Death

Many centers in metro cities and especially in tier-II cities are inexperienced in handling all aspects of BSD. Even if they have identified a patient of head injury or spontaneous

subarachnoid hemorrhage with Glasgow Coma Scale (GCS) of 3 and absent brain stem reflexes, they are hesitant to declare BSD. The common reasons for not identifying BSD include:

- They do not have the BSD certification panel
- It is cumbersome for them to arrange the logistics for organ donation
- They are not clear about who will bear the costs of “maintaining” a BSD patient in ICU who is willing for organ donation
- They are not having forensic medicine backup and hence unable to tackle the medicolegal aspects of organ donation
- They do not have the advanced surgical facilities for facilitating multiorgan harvest. In several cases the families are willing to donate organs, but the hospital lacks the infrastructure to enable this donation of organs.

Stronger implementation of the legislation that mandates the notification of BSD in any ICU/hospital to the state transplant organization is necessary. Donor management programs for these smaller hospitals are necessary to enable them to allay their hesitations about the complexities of organ donation process.

Poor Donor Management Equal to Waste of Heart

A small hospital or nursing home does not have good facilities either for monitoring a BSD patient’s hemodynamics, nor the expertise of intensivist or anesthetist available to expertly manage the turbulent changes in hemodynamics of a possible donor after BSD. Many times, even the most basic screening (echocardiography) is not available to assess the suitability of a donor heart. Neither the machine, nor an echocardiographer is available. No arterial pressure monitoring line or arterial blood gas (ABG) analysis is in records. The person managing the BSD patient is not sensitive to understanding the protective aspect of ideal volume and inotropic management for the health of organs to be harvested. Often very high doses of vasopressors are being administered which can be detrimental to the sensitive function of the heart. The volume status is also not optimized. There is a tussle between the lung and liver teams about sufficiency of volume infusion. These points indicate that there is a need to adequately train at least two people from all possible donor centers in the country about ideal donor management. In our country with acute scarcity of donor organs, these precious organs should not be wasted.

Inconstant Transplant Teams

Due to various reasons, the faculty at institutes or corporate hospitals performing heart transplant operations is not constant. As mentioned above, the postoperative care of a recipient is the real Achilles’ heel over which the final outcome critically depends. Loss of even one member of the team can seriously compromise the results of a transplant program at any institute unless very standard protocols are set in and uniformly followed all over the country. However,

since there is no database in the country of the transplants done and their final outcome, development and vetting of such a protocol is not even in a nascent stage. The transplant teams need to get their act together on this issue about the database so that their own success can be replicated elsewhere and the chain reaction of one transplant leading to at least three more by other teams will materialize.

Lack of Flights

Many a times there is a call from a center far away from the recipient center. In the absence of affordable air ambulance flights, commercial flights have to be utilized for this critical transfer. The whole harvesting process has to be coordinated between three to four teams and appropriate harvest time decided. Many a times, the flight distance or timings preclude harvesting of the available organ and these precious hearts are lost.¹⁰ The government needs to eke out a policy wherein a special status is made available to chartered flights for the purpose of organ transplantation. This is routine in European and other western countries where all donor organ transfers are done through chartered flights. There is a pleasant collaboration between the private aircraft owners who perform these "transfer helps" as a part of their corporate social responsibility.

Postoperative Problems in Indian Scenario

The results of heart transplantation have been uniformly encouraging. There is however scope for improvement. We need to bring further down the 1 year mortality of 1-25%. This mortality is due to the fact that ours is a developing country, usually people are from middle to poor socioeconomic backgrounds, average education, minimum sense about hygiene, poor self-discipline, dry dusty climate that throws up a battery of environmental pathogens attacking the immunocompromised steroid-dependent heart transplant recipient. The 1 year results range between 70 and 90% survival across the country. There are many more than 5 years and more than 10 years survival too. The common complications seen in the Indian scenario include infections (fungal and bacterial pulmonary infections, cytomegalovirus—neurological infection), early prosthetic graft dysfunction, reversible renal compromise, psychological disturbances, and rarely cardiac allograft vasculopathy. Common cause of death in the Indian scenario has been infection and not rejection as is prevalent in the western literature. At any individual center, with more experience, the complications reduce and overall recoveries are faster.

ROADMAP FOR THE FUTURE

Some important steps which may help to make the heart transplant program more robust in our country include:

- Stronger legislation making notification of brain death mandatory in all hospitals. It must be ensured and documented that reasonable efforts were made to counsel

the family of a BSD patient for organ donation before the final certification of death

- Gradual shift of THOA laws to "opt out" policy. This is consistent with the standards of organ donation in many Western countries
- Hiring of trained and enthusiastic transplant coordinators who can strongly educate and motivate families to donate organs in the setting of BSD. They should be continuously upgraded with continuing medical education and periodic seminars
- Ensuring ideal donor management and facilitation of organ harvesting by NOTTO or regional coordinating authority
- Cost support to any hospital enabling the organ donation process
- Increasing the awareness amongst public that heart transplant is a good viable option with excellent quality of life after surgery
- Covering the heart (and other solid organ) transplant surgery under the proposed national healthcare insurance scheme. Majority of our citizens cannot afford the operation costs and hence, it is high time the government took up financing this program under its mantle. Similarly, cost subsidy to post-transplant recipients for lifelong immunosuppression
- Robust national, regional and state organ and tissue transplant organizations (NOTTO, ROTTO, and SOTTO). The coordination activity should be efficient, organ allocation process should be fair and transparent and there should be no wastage of any available donor heart
- A continuous and comprehensive pool of end-stage HF patients should be available waitlisted with all hospitals who are licensed to do heart transplants. The active participation of cardiologists here is important to ensure the same
- Initiating special and ethical incentives for donor families to encourage organ donation
- Audit of centers dealing with BSD patients to ensure they are encouraging organ donation. Audit of centers performing heart transplants to ensure that centers of transplant excellence are there, at least one per state so that the overall results continually improve
- All above measures should seek to improve the annual transplant rate to at least 1,000 operations per year, distributed equally in all geographical regions of our country.

CONCLUSION

The progress made in the field of heart transplantation in India has been slow & steady but is now seeing robust growth. There still are many challenges to be overcome, but as India makes a transition towards a more developed country, it is only to be expected that over the next two decades, the advances in science and the combined efforts of the state, medical personnel and the society will make the option of heart transplantation for our large end-stage heart failure population a very feasible and viable choice.

Stroke

Atrial Fibrillation and Stroke: An Update

Rohit Bhatia, Rimpy Joseph

INTRODUCTION

Atrial fibrillation (AF), the most prevalent sustained disorder of cardiac rhythm, has in recent times emerged as a major global public health concern, in terms of substantial morbidity and mortality.¹ Global estimates indicate 20–25% of all strokes to be cardio embolic in origin; of these, nearly one-half cases are caused by nonvalvular AF, one-fourth by valvular heart disease, and one-third by left ventricular (LV) thrombi.² Thus, worldwide, AF contributes to almost 80% of cardioembolic strokes and approximately 33% of all ischemic strokes.^{2,3} While the risk of stroke is increased by 4–5 fold, the mortality is almost doubled compared to age-matched controls in the presence of AF.^{4–6} Although, the annual risk of stroke related to AF alone is 0.2%, it rises exponentially to more than 10% in the presence of additional risk factors.⁷ Significantly, in as many as 25% of AF-related strokes, stroke is the presenting manifestation of a hitherto undetected AF. Regardless to say, AF-related strokes are significantly more disabling and fatal. Fortunately, AF is an eminently preventable and treatable cause of stroke. There has been a surge in the evidence available with newer avenues for tackling several issues concerning concomitant AF and stroke management. This chapter envisages to provide a lucid and comprehensive overview on AF and stroke, with particular emphasis on thromboprophylactic and therapeutic strategies.

EPIDEMIOLOGY AND GLOBAL BURDEN

Data suggest that globally nearly 33 million individuals are affected with AF. This figure is a gross underestimation of sorts, as evidenced by the fact that majority of AF patients (1 in 12 paroxysms) remain asymptomatic. The lifetime risk of developing AF stands at 25%. Available data indicate 1–2% AF prevalence in the general population.⁸ The prevalence of AF rises with age steadily, affecting 2% patients less than 65 years of age and nearly 9% of patients more than 65 years of age. The risk of stroke in AF is also age-dependent, rising exponentially from 1.5% in the fifth decade to 23.5% in the eighth decade.⁹

This translates to a 1.5-fold increase in the risk of AF-related stroke for every decade of life. In the western world, the median age of patients with AF is 75 years, with nearly 70% being in 65–75 years age group.¹⁰ It is estimated that by 2050, nearly 50% of those affected in US will be aged 80 years and above.¹¹ As regards the Asian population which is rapidly aging, estimates suggest a staggering 72 million AF-afflicted patients by 2050, of which nearly 2.9 million would have AF-related stroke.¹² Valvular AF confers a 17-fold higher risk of stroke compared to 5-fold higher risk with nonvalvular AF.¹³ Available data also suggest that AF-related stroke translates to a high mortality (20%) and substantial morbidity (60%).

There remains paucity of epidemiological data pertaining to AF from India. Regional population based registries from India have estimated AF prevalence of 8–10%.^{14,15} Recent data from the Indian population indicate AF to be associated with 15% of all strokes.¹⁶ Indian Heart Rhythm Society (IHRS-AF) registry – till date, the single largest epidemiological study of its kind from the Indian subcontinent, was a prospective, multicenter observational study conducted over 24 centers across India, enrolling 1,537 AF patients during the time period 2011–2012. The salient observations were that the annual stroke rate was 1%; mean age of AF in the Indian population was 54.7 years, which is at least a decade lesser than the western counterparts and females constituted 51.5% while males were 48.5%. In contrast to the west, rheumatic heart disease (RHD)-related AF constituted a significant proportion (47.6%) in the Indian population. The younger age of onset of RHD AF is attributed to higher prevalence of RHD, hypertension, diabetes, and coronary artery disease among the young population of India.¹⁷ Regional registries such as Ludhiana-based urban population stroke registry, which found an AF-related stroke prevalence of 10% (203/1,942 patients) have corroborated the findings of IHRS-AF registry except that nonvalvular AF constituted 97% of cases.¹⁵ However, most of the Indian studies, albeit done on small scale, have found RHD-related valvular AF to be the most common cause of AF related stroke in our

Indian population.^{18,19} In addition, AF-related strokes are more common in women (F:M 1.2 to 1.38:1) in contrast to western studies (F:M = 1:1.5). This again is speculated to be due to larger proportion of causative RHD cases in India which in turn are more common in women. Also in deviation to the global trends, only one-third cases of AF in India are constituted by paroxysmal AF.

UPDATED MODEL FOR STROKE MECHANISM IN ATRIAL FIBRILLATION AND CONCEPT OF ATRIAL CARDIOPATHY

Atrial cardiopathy refers to structural remodeling of the heart resulting in changes in the atrial tissue properties (chiefly fibrosis), size [left atrial (LA) enlargement and cellular ultrastructure (alterations in sarcoplasmic reticulum, nuclear chromatin, redistribution of mitochondria, glycogen accumulation, myolysis, proteolysis due to calcium dependent calpain activation, etc.)]. This leads to reduced and ineffective atrial contractility underlying AF, which further contributes to atrial dilatation and the vicious cycle continues. Atrial fibrosis with resultant conduction slowing, could either be reactive interstitial fibrosis where the individual muscle bundles are separated by fibrous tissue or reparative fibrosis wherein, there is replacement of the dead cardiac myocytes. The resultant increased fibroblast coupling to the cardiac myocytes promotes re-entry and focal ectopic firing. Since, atrial fibrosis predicts progression to permanent AF, it has become a potential target for suppression of arrhythmogenesis as well as predicting response to treatment.²⁰⁻²² It is interesting to note that, atrial cardiopathy can occur independent of AF. In fact, the surrogate markers of atrial dysfunction such as premature atrial contractions, paroxysmal supraventricular tachycardia, LA size, and ECG-defined LA enlargement, etc. can result in stroke (embolic/cryptogenic), independent of AF.²³⁻²⁶

Kamel et al. proposed the updated model for stroke in AF which highlights the causative role of systemic and atrial abnormal substrates, in addition to abnormal rhythm in AF-related strokes. They proposed that atrial cardiopathy or abnormal atrial tissue substrate which underlies both AF and thromboembolism is predisposed to by ageing and other systemic vascular risk factors; either of which can also predispose to stroke independently via nonatrial stroke mechanisms (such as large artery atherosclerosis, small vessel occlusion, ventricular dysfunction, etc.). Conversely, AF per se, by causing reduced atrial contractility resulting in atrial stretch, dilatation and remodeling, also contributes to atrial cardiopathy over a period of weeks which further increases the risk of stroke and thromboembolism. Moreover, AF also leads to ventricular dysfunction due to fast ventricular rate with irregular rhythm, loss of atrial kick, and reduced coronary flow reserve. This model could explain the fact that nearly 25% cases of AF and stroke manifest AF only after stroke occurrence and brief AF periods could result in strokes several months later. In addition, the occurrence of nonembolic strokes in AF patients is also explained by this

model which suggests that AF acts as a marker for upstream vascular risk factors. It also provides plausible explanation to the fact that rhythm controlling therapies (including catheter ablation of AF) alone cannot by itself eliminate stroke risk. In particular, among the systemic vascular risk factors, obesity needs special mention as concurrent local epicardial fat accumulation leads to local atrial inflammation and also by increasing propensity to obstructive sleep apnea (OSA), elevates intra-arterial pressures resulting in atrial cardiopathy. A major therapeutic implication of this model is that strategies aimed at reversing atrial cardiopathy are essential for reducing thromboembolic risk. Future trials are anticipated to specifically address this issue. Not all strokes in AF are due to left atrial appendage (LAA) thromboembolism. While two-thirds of stroke in AF patients are postulated to be due to embolism arising from thrombi lodged within the LAA; a significant one-third cases are due to alternative stroke mechanisms such as carotid atherosclerosis, complex aortic arch plaque, small vessel disease, LV origin thrombi, etc.^{27,28}

The need of the hour is thus concomitant global risk factor reduction rather than tunneled focus on anticoagulation alone.

ATRIAL FIBRILLATION DETECTION IN STROKE

Atrial Fibrillation Detected after Stroke and Transient Ischemic Attack

Cerasuolo et al. coined the term AFDAS [AF diagnosed or detected after stroke and transient ischemic attack (TIA)] in 2017. The term encompasses all forms of AF (paroxysmal/persistent/permanent) detected by any ECG monitoring technology and could either be prestroke AF which was hitherto undiagnosed/asymptomatic and detected only after stroke (cardiogenic origin) or incident AF which has developed after stroke/TIA (neurogenic origin)—new onset AF. It is estimated that AFDAS constitutes nearly 25% of AF cases and approximately 50% of AFDAS are asymptomatic.²⁹

Till date, whether poststroke AF is a cause or consequence of stroke remains unclear. A plausible hypothesis for AFDAS suggests an interplay of autonomic dysregulation and systemic inflammation. Normally, the extrinsic or cerebral autonomic nervous system (ANS) (comprising of cerebral cortex, especially insula, cingulate, and prefrontal regions with projections to the hypothalamus, limbic, and brainstem nuclei) exerts control over the intrinsic ANS constituted by the ganglionated plexi within the pulmonary vein (PV) endings and pericardium. In acute ischemic strokes affecting the aforesaid regions, the central modulation is lost, with consequent activation of intrinsic ANS resulting in ectopic firing from PV and non-PV foci, and paroxysmal AF ensues. Following acute cardioembolic strokes, there also exists a brief lasting inflammatory response with release of cytokines [interleukin (IL)-6, tumor necrosis factor (TNF) alpha, IL-1 antagonists], chemokines (CXCL16), and adhesion molecules [intercellular adhesion molecule (ICAM) 1, E/P

selectins)] which can trigger AF either by focal ectopic firing via the autonomic cascade or re-entry circuits located in the atrial myocardium. Other contributing factors in AFDAS include sleep-disordered breathing (SDB) which confers 4 times higher risk of AF and AF per se, doubles the risk of developing SDB in the poststroke period.^{29,30}

Compared to known AF patients, those with poststroke AF are younger (median age 72 vs. 79 years, $p = 0.058$); have significantly lesser proportion of LA enlargement (60.9 vs. 91.2, $p = 0.001$), and overall 4 cm² lesser median LA area.³¹ A study identified 3 positive clinical predictors of poststroke paroxysmal AF which would warrant intensive work up including 7 days prolonged Holter. These included advanced age [74 ± 10.5 vs. 67 ± 13 , $p < 0.001$; odds ratio (OR) 1.05; 95% confidence interval (CI) 1.01–1.08], clinical symptoms more than 24 hours (OR 5.17, 95% CI 1.73–15.48), and a history of coronary artery disease (OR 3.14, 95% CI 1.35–7.28).³² Since, the peaks of inflammation and autonomic dysfunction occur in the initial few days of stroke onset, majority of neurogenic poststroke AF is manifest in the initial few days (71% in first 3 days; 75% in 1–2 weeks)—emphasizing the need for early Holter monitoring to get better diagnostic yield. Targeted strategies to reduce myocardial inflammation and thus reduce poststroke AF recurrence are being extensively studied.

Occult Atrial Fibrillation Detection in Stroke

The commonly available tools for detection of AF include ECG, continuous ECG monitoring with Holter recording (both routine short term: 24 hours and long-term recording using efficient memory Holter and patch monitors), intermittent long-term monitoring using loop recorders (external and implantable), and event monitors; and telemetry systems (inpatient and outpatient). Digital innovations including apps for easy detection of AF have also entered into the foray.

The 2016 European Society of Cardiology (ESC) guidelines for management of AF has placed class I recommendation for AF screening by short-term ECG followed by at least 72-hour Holter monitoring for all patients with ischemic stroke and TIA.³³

Find-AF is a recently published open label randomized control trial (RCT), based on the premise that enhanced and prolonged Holter recording would increase the odds of AF detection in poststroke patients. The study which was conducted on 398 patients of acute ischemic stroke (AIS) (within 7 days of onset and aged ≥ 60 years) across four German centers, found a significantly higher AF detection rate of 14% in the enhanced and prolonged monitoring group (10 days Holter monitoring at 0, 3, and 6 months) compared to 5% in control group (95% CI 3.4–14.5, $p = 0.002$).³⁴

Cryptogenic stroke and underlying AF (Crystal AF study) was a RCT done on 441 patients with stroke aged more than or equal to 40 years, without pre-enrolment evidence of AF during 24 hours of ECG monitoring, who were then randomized to insertable cardiac monitor (ICM) group (221 patients) and control group (220 patients). The results indicated a higher AF (>30 s duration) detection rate in the

ICM group at 6 months [8.9% vs. 1.4%; hazard ratio (HR): 6.4; 95% CI 1.9–21.7; $p < 0.001$]. Also, ICM group registered a significantly higher AF detection rate at 12 months (12.4% vs. 2%; HR 7.3; 95% CI 2.6–20.8; $p < 0.001$) and 36 months, 30% (ICM group vs. 3%; HR 8.8, 95% CI 3.5–22.2, $p < 0.001$).³⁵

Event Monitoring Belt for Recording Atrial fibrillation after a Cerebral ischemic Event (EMBRACE)-AF trial observed that 30-day event triggered loop recorder (intervention group) was superior than conventional 24-hour Holter recording: control group (AF detection rates 16.1% vs. 3.2%; 95% CI 1–17.6; $p < 0.001$, number needed to screen 8); also AF with duration more than or equal to 2.5 minutes was detected more in the intervention group (9.9% vs. 2.5%; 95% CI 3.4–11.3; $p < 0.001$) and the rate of anticoagulant treatment nearly doubled in the intervention arm.³⁶

Importantly, brief subclinical AF acts as an important predictor of AF recurrence and subsequent stroke, as corroborated by the ASSERT study (ASymptomatic atrial fibrillation and Stroke Evaluation in pacemaker patients and the atrial fibrillation Reduction atrial pacing Trial); subclinical atrial tachyarrhythmia more than 6 minutes predicts clinical AF (HR 5.56; 95% CI 3.78–8.17, $p < 0.001$) and MOST (Mode Selection Trial) trial (atrial high rate episode) more than 5 minutes predicted clinical AF (HR 5.9).^{37,38}

However, the minimum duration or frequency of AF that necessitates anticoagulation remains controversial. Nevertheless, the frequency of atrial premature beats (APBs) detected on routine 24-hour Holter monitoring serves as a marker for subclinical AF, especially among older cryptogenic stroke and TIA patients, as evidenced by the EMBRACE-AF³⁶ trial, which suggested a cutoff of more than 500 APBs or 24 hours for defining frequent APBs.³⁹ This study also proposed a minimum of 2 weeks of targeted noninvasive ECG monitoring with mobile outpatient telemetry or autodetect loop recorder for patients with infrequent APBs less than 500 or 24 hours; 4 weeks for frequent APBs more than 500 or 24 hours and longer monitoring with implantable loop recorders for those with excessive APBs more than 1,000 or 24 hours.³⁹

Another AF prediction score is STAF score (Score for the Targeting of Atrial Fibrillation) which takes into account 4 factors—age more than 62 years (2 points), NIHSS (The National Institutes of Health Stroke Scale) more than or equal to 8 (1 point), LA dilatation (2 points), absence of symptomatic intracranial or extracranial stenosis more than or equal to 50% or clinical radiological lacunar syndrome (3 points). The STAF score more than or equal to 5 had a high sensitivity (89%) and specificity (88%) of having underlying AF.⁴⁰

Recently, Yoshioka et al. developed the iPAB score [acronym for—Identified by Past history of arrhythmia or antiarrhythmic agent use, Atrial (left) dilatation and Brain natriuretic peptide (BNP) elevation] to predict the presence of AF in acute stroke patients. In this scoring system, a score of 3 is given if there is a past history of arrhythmia or antiarrhythmic agent use; LA dilatation more than or equal to 40 mm gets a score of 1 while BNP elevation (pg/mL) is sub classified into 3 groups—levels more than or equal to 50 are scored 1, levels more than or equal to 90 are given a score of 2,

and levels more than or equal to 150 get a score of 3. Score of more than or equal to 2 was found to have a sensitivity of 93% and specificity of 71% while scores of more than or equal to 4 had sensitivity of 60% and specificity of 95% in predicting paroxysmal AF in acute stroke patients.⁴¹

Other ongoing RCTs in this direction include SAFFO trial⁴² (Silent AF detection aFter ischemic strOke) in patients more than or equal to 65 years, with first ever atherothrombotic or lacunar stroke, using implantable loop recorders at first diagnosis and MonDAFIS trial (Impact of standardized MONitoring for Detection of AF in Ischemic Stroke), largest of its kind RCT, which aims to evaluate whether initial prolonged 7-day Holter recording has impact on secondary stroke prevention.⁴³

STROKE RISK STRATIFICATION SCORES

Over the past few decades, several scores for prediction of stroke risk in AF have been devised, aimed at aiding in decision making regarding initiation of antithrombotic strategies.⁴⁴⁻⁴⁹ The major scores used for stroke risk stratification are outlined in table 1.

ARE TYPE OF ATRIAL FIBRILLATION AND DURATION OF EPISODES PREDICTIVE OF STROKE RISK?

Published data provide conflicting results on the association between type of AF and stroke risk prediction, although

TABLE 1: Stroke risk stratification scores among patients with atrial fibrillation

*CHADS₂—acronym for Congestive cardiac failure, Hypertension, Age ≥75 years, Diabetes and prior Stroke/transient ischemic attack (TIA).

**CHA₂DS₂VASc score—acronym for Congestive cardiac failure, Hypertension, Age (≥75 years and 65–74 years) , Diabetes, prior Stroke/TIA, Vascular disease [prior myocardial infarction (MI), peripheral arterial disease or aortic plaque] and Sex category (female).

CHF, congestive heart failure; ESRD, end stage renal disease; eGFR, estimated glomerular filtration rate; MI, myocardial infarction; TIA, transient ischemic attack.

the odds of thromboembolism are more in favor toward permanent or persistent AF vis-a-vis paroxysmal AF. The ACTIVE-W trial (Atrial Fibrillation Clopidogrel Trial with Irbesartan for Prevention of Vascular Events) was equipoised as regards the risk of stroke or systemic embolism in paroxysmal AF versus persistent AF [relative risk (RR) 0.7; 95% CI 0.59–1.30].⁵⁰ However, the recent evidence obtained from ENGAGE-AF (Edoxaban versus warfarin in patients with Atrial Fibrillation) trial, *ROCKET-AF (Rivaroxaban-Once-daily, oral, direct Factor Xa inhibition Compared with vitamin K antagonism for prevention of stroke and Embolism Trial in Atrial Fibrillation) trial*, and meta-analysis by Ganesan et al. proves that the risk of thromboembolism is much higher in nonparoxysmal forms of AF.^{51–53}

The establishment of correlation, if any, between duration of AF episodes and stroke risk has been the focus of numerous studies. The ASSERT study (ASymptomatic atrial fibrillation and Stroke Evaluation in pacemaker patients and the atrial fibrillation Reduction atrial pacing Trial) was conducted on 2,580 elderly hypertensive patients (≥ 65 years), without previous AF history, who had undergone pacemaker or defibrillator implantation recently. It was found that during the initial 3 months postprocedure, 10% patients developed subclinical tachyarrhythmias lasting at least 6 minutes, and this was associated with 2.5-fold higher risk of stroke or systemic embolism in the 2.5 years follow-up period (HR 2.49; 95% CI 1.28–4.85; $p = 0.007$).³⁷ These findings were corroborated by the SOS-AF study (Stroke PreventiOn Strategies based on Atrial Fibrillation information from implanted devices) which found a statistically significant association between AF episodes more than or equal to 5 minutes and stroke (HR 1.76; 95% CI 1.02–3.02); the highest HR was observed for more than or equal to 1 hour duration AF burden (HR 2.11, 95% CI 1.22–3.64, $p = 0.008$); also there was a 3% increase in the relative risk for stroke for every additional hour in the daily maximum AF burden.⁵⁴ The RATE study (RAte control Therapy Evaluation in permanent atrial fibrillation) observed that the risk of stroke or TIA in brief lasting AF episodes less than 20 seconds is similar to that in non-AF patients while episodes more than or equal to 20 seconds have 1.5 times higher risk of developing stroke or TIA (HR 1.51, 95% CI 1.03–2.21).⁵⁵

SERUM BIOMARKERS AS PREDICTORS OF STROKE RISK IN ATRIAL FIBRILLATION?

Current evidence suggests high sensitivity cardiac troponins and NT-proBNP as positive predictors of stroke risk in AF patients. The RE-LY trial⁵⁶ (Randomized Evaluation of Long-term Anticoagulation Therapy) observed that Trop I levels more than or equal to 0.040 were associated with highest annual stroke risk rate of 2.09% (HR 1.99, 95% CI 1.17–3.39; $p = 0.0040$) and elevated NT-proBNP levels more than 1,402 ng/L were associated with 2.3% annual stroke risk rate (HR 2.40, 95% CI 1.41–4.07; $p = 0.0014$) while levels between 801 ng/L and 1,402 ng/L had HR of 1.31 (95% CI 0.76–2.27,

$p = 0.0014$) and for levels 387–800 ng/L, HR was 1.35 (95% CI 0.80–2.27, $p = 0.0014$).⁵⁶ The results of ARISTOTLE trial add impetus to the value of elevated high sensitivity troponin (≥ 24 ng/L) and NT-proBNP in predicting stroke and systemic embolism (HR 1.98; 95% CI 1.42–2.78).^{57,58} The role of inflammatory biomarkers such as C-reactive protein (CRP) and IL-6 in stroke prediction remain controversial.^{59–61} The ABC stroke risk score (acronym for Age, Biomarkers-high sensitivity troponin and NT-proBNP and Clinical history, i.e., prior stroke/TIA) is a recent biomarker-based score for 1 year and 3 years stroke risk prediction in AF which has demonstrated benefit over all clinical stroke risk scores recommended by current guidelines.⁶² Modifications of ABC score like ABC death risk score (additionally incorporates GDF-15, i.e., growth differentiation factor 15 and congestive heart failure as variables) and ABC bleeding risk scores have also been proposed recently and validated.^{63,64}

STRUCTURAL AND FUNCTIONAL MARKERS OF LEFT ATRIAL AND LEFT ATRIAL APPENDAGE AS STROKE PREDICTORS IN ATRIAL FIBRILLATION

Available evidence suggests moderate-to-severe LA enlargement as predictor of recurrent embolic or cryptogenic stroke, irrespective of AF.⁶⁵ Studies on AF patients have shown convincing evidence on association between LA enlargement and stroke; in addition to correlating strongly with surrogate markers of stroke risk such as LAA thrombus and spontaneous echocardiographic contrasts (SECs).^{66,67} Also, LA function markers such as decreased myocardial strain rate, MRI evidence of atrial fibrosis, higher CHADS₂ (Congestive cardiac failure, Hypertension, Age ≥ 75 years, Diabetes and prior Stroke/TIA) score, presence of persistent or permanent AF, mitral valve inflow, and atrial electromechanical delay also serve as markers of thromboembolic risk.⁶⁷

Left atrial appendage is a major source of thrombus formation in AF and has been the focus of continuing research. Echocardiographic evidence of reduced LAA antegrade flow velocities is taken as marker of stasis within LAA; a cross-sectional study on nonvalvular AF showed that LAA velocities less than 36 cm/sec had significant association with prior stroke than those without stroke who had LAA velocity of 55 cm/sec ($p < 0.001$).⁶⁸ Also, post-hoc analysis of 721 patients from SPAF (the Stroke Prevention in Atrial Fibrillation) III trial showed LAA velocities less than 20 cm/sec as independent predictor of LAA thrombus (RR 2.6, $p = 0.02$).⁶⁹

Spontaneous echocardiographic contrasts are also taken as markers of stroke risk, these refer to the echocardiographic dynamic smoke-like appearance, secondary to stasis, hypercoagulability and RBC aggregation, and is strongly associated with LAA thrombus and thromboembolic risk.^{67,70} Morphological appearance of LAA serves as a structural marker of stroke risk. Amongst the four morphologies of LAA (chicken wing-48%, windsock-19%, cactus-30%, and cauliflower-3%), most studies suggest nonchicken wing

morphologies to have higher odds of stroke risk. This is attributed to lower LAA flow velocities in nonchicken wing LAA morphologies and extensive trabeculation specifically in the cauliflower morphology. Other structural LAA markers include larger LAA orifice size and greater number of lobes.⁷¹⁻⁷³

ASSESSMENT OF BLEEDING RISK (TABLE 2)

Although bleeding risk in AF is much less than the thromboembolic risk, assessment of bleeding risk assumes significance as it decides the net clinical benefit of anticoagulation. Several bleeding risk prediction scores exist for AF patients such as HEMORR₂AGES [Hepatic or Renal disease, Ethanol abuse, Malignancy, Older age (>75 years), Reduced platelet number/function, Rebleeding, Anemia, Genetic factors, Excessive fall risk and Stroke]⁷⁴, HAS-BLED [Hypertension, Abnormal renal and liver function, Stroke, Bleeding, Labile international normalized ratio (INR), Elderly (>65 years) and Drugs (antiplatelets or NSAIDs or Alcohol)],⁷⁵ ATRIA (Anticoagulation and Risk factors In Atrial fibrillation)⁷⁶, ORBIT (Outcomes Registry for Better Informed

Treatment of AF)⁷⁷ and ABC-bleeding risk score, which is biomarker based.⁶⁴ The major scores are summarized in table 2. In the universally recommended HAS-BLED score, the annual bleeding rate steadily increased from 1.13% for 0 score, to 1.88% for score 2, 3.74% for score 3, 8.7% for score 4, and 12.5% for score 5.⁷⁵ The HAS-BLED score more than or equal to 3 predicts major bleeding during bridging of chronic anticoagulant therapy. The AMADEUS trial of 2012, which compared the performances of HEMORR₂AGES, ATRIA, and HAS-BLED scores, concluded that HAS-BLED score has better predictive value for intracranial haemorrhage.⁷⁸ While validation studies have proven superiority of ORBIT score over HAS-BLED for predicting major bleeding, it is the recent ABC-bleeding risk score which has outperformed all previous bleeding scores.⁶⁴

MANAGEMENT STRATEGIES

The management of AF primarily revolves around a three pronged strategy of rate control, rhythm control (which includes both acute rhythm restoration strategies in the form of pharmacological cardioversion, electrical cardioversion and pill in the pocket cardioversion using self-administered

TABLE 2: Bleeding risk prediction scores for patients with atrial fibrillation

HEMORR ₂ AGES*	HAS-BLED**	ATRIA***	ORBIT****	ABC-bleeding risk score #
Hepatic/renal disease	1	Hypertension	1	Anemia
Ethanol abuse	1	Abnormal renal and liver function	1+1	Severe renal disease
Malignancy	1	Stroke	1	Age ≥75
Older age(>75)	1	Bleeding	1	Any prior hemorrhage
Reduced platelet no./function	1	Labile INR	1	Hypertension
Rebleeding	2	Elderly (>65)	1	–
Anemia	1	Drugs (antiplatelets or NSAIDs/alcohol)	1+1	–
Genetic factors	1	–	–	–
Excessive fall risk	1	–	–	–
Stroke	1	–	–	–

*HEMORR₂AGES: acronym for Hepatic or Renal disease, Ethanol abuse, Malignancy, Older age (>75 years), Reduced platelet number/function, Rebleeding, Anemia, Genetic factors, Excessive fall risk and Stroke.

**HAS-BLED: acronym for Hypertension, Abnormal renal and liver function, Stroke, Bleeding, Labile INR, Elderly (>65 years) and Drugs (antiplatelets or NSAIDs or Alcohol).

***ATRIA: acronym for Anticoagulation and Risk factors In Atrial fibrillation.

****ORBIT: acronym for Older (≥75), Reduced hemoglobin, Bleeding history, Insufficient renal function and Treatment with antiplatelet.

ABC-bleeding risk score: acronym for Age, Biomarkers and Clinical history.

Hct, hematocrit; GDF-15, growth differentiation factor 15; eGFR, growth differentiation factor 15; INR, international normalized ratio; NSAIDs, nonsteroidal anti-inflammatory drugs.

oral flecainide 200–300 mg or propafenone 400–600 mg and long-term antiarrhythmic measures), and prevention of thromboembolism; alongside prompt management of vascular risk factors implicated in atrial cardiopathy which can beget AF. We shall focus on thromboprophylactic strategies in AF, which are core to prevention of AF-related stroke and its recurrence.

Primary Prevention of Stroke in Atrial Fibrillation

Oral Anticoagulation Therapy

The best form of stroke prevention and avoidance of consequent stroke-related disability is primary prevention. Oral anticoagulation therapy comprising vitamin K antagonists (VKA), and non-vitamin K newer or directly acting oral anticoagulants (NOACs or DOACs) is currently the standard of care for thromboprophylaxis in AF. Irrespective of the stroke risk, antiplatelets are not recommended for stroke prevention in AF.

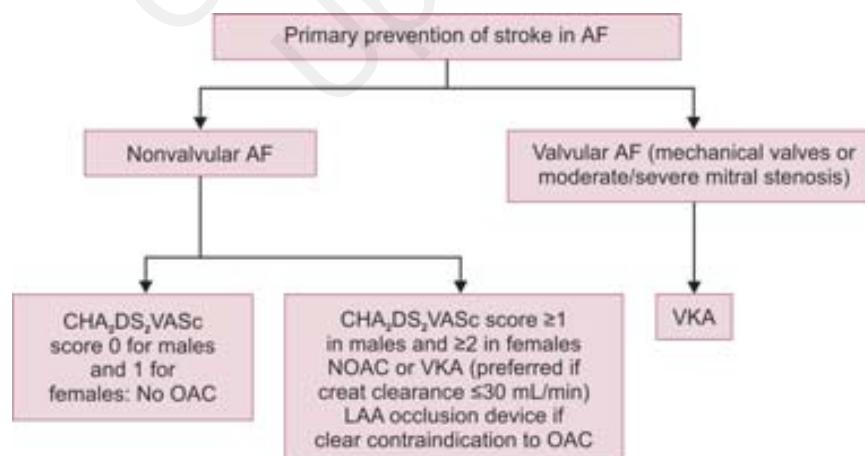

While VKAs form the sole thromboprophylactic option in valvular AF (mechanical heart valves or rheumatic moderate and severe mitral stenosis), nonvalvular AF offers a choice between VKAs and NOACs. High-bleeding risk is one of the reasons cited for deferring oral anticoagulants (OACs). However, there is concrete evidence to suggest that while bleeding risk of OACs is similar to antiplatelets, it is only the OACs which are effective in stroke prevention.^{79–82}

Recently, in 2017, a functional EHRA classification (Evaluated Heart valves, Rheumatic or Artificial) was proposed based on the type of OAC use in patients with AF. The EHRA Type I refers to valvular heart disease patient, especially rheumatic moderate; severe MS and mechanical prosthetic valves who need VKA therapy while EHRA Type 2 refers to all other native valvular disease along with mitral valve repair, bioprosthetic valves, and transaortic valve

interventions, where either VKAs or NOACs would suffice.⁸³ All current guidelines advocate a thromboembolic risk-based antithrombotic strategy for stroke prevention in nonvalvular AF. Flowchart 1 summarizes the current guidelines-based recommendations for primary prevention of stroke in AF.^{33,46,84}

Vitamin K Antagonists

There is sufficient evidence to prove that VKAs reduce stroke risk by 64% while reducing mortality by 26%, when compared to either aspirin or no treatment, provided the INR is within therapeutic range (2.0–3.0).⁸⁵ The clinical superiority of warfarin over aspirin, with similar risk of intracranial hemorrhage was also corroborated by the BAFTA (Birmingham Atrial Fibrillation Treatment of the Aged) study which showed a 52% risk reduction with warfarin.⁸⁶ VKA therapy is associated with a 0.2% increase in absolute risk of intracranial hemorrhage (ICH). Notable among the various limitations of VKA therapy include a narrow therapeutic window (with resultant frequent monitoring and adjustments in dose), varied drug and food interactions, unpredictable response, slow onset and offset of action, warfarin resistance, and increased baseline ICH risk. However, if administered with adequate time in therapeutic range (TTR >70%), they provide effective and cheaper thromboprophylaxis in AF. In 2013, using the AFFIRM trial (Atrial Fibrillation Follow Up Investigation of Rhythm Management) data, authors put forth a simple predictive score, SAME-TT₂R₂ [acronym for Sex, female; Age <60 years; Medical history (atleast 2 of the following – hypertension/diabetes/CAD/peripheral arterial disease/CCF/previous stroke /pulmonary disease/hepatic or renal disease); Treatment (warfarin interacting drugs, e.g., amiodarone); current Tobacco use (within 2 years) and Race, noncaucasians] for likelihood of INR control. Except for current tobacco use and race which are scored 2, all others

AF, atrial fibrillation; CHA₂DS₂VASC score, Congestive Heart Failure, Hypertension, Age ≥75 (Doubled), Diabetes Mellitus, Prior Stroke or Transient Ischemic Attack (Doubled), Vascular Disease, Age 65–74, Female; LAA, left atrial appendage; NOAC, newer oral anticoagulants; OAC, oral anticoagulants; VKA, vitamin K antagonists.

FLOWCHART 1: Summary of primary prevention of stroke in atrial fibrillation.

are scored 1. Higher the SAMe-TT₂R₂ score, poorer will be the INR control and more will be the rationale to choose NOACs over VKA.⁸⁷ A SAMe-TT₂R₂ score of less than or equal to 2 (which translates to an adequate time in therapeutic range, i.e., >70%) may be used as a reasonable cutoff to choose between either NOACs or VKAs as stroke thromboprophylactic strategies in nonvalvular AF with CHA₂DS₂VASC scores more than or equal to 1 in males or more than or equal to 2 in females. However, the presence of SAMe-TT₂R₂ score of more than or equal to 3 precludes the use of VKAs and necessitates exclusive NOAC usage.⁴⁶

Nevertheless, VKAs are the only thromboprophylactic strategy available for valvular AF (rheumatic disease and mechanical heart valves) and stage V chronic kidney disease (CKD) (creatinine clearance ≤15 mL/min).

Novel Oral Anticoagulants

These have emerged in recent years as an effective and safer alternative to VKAs in the field of stroke prevention in nonvalvular AF. In all AF patients who are otherwise eligible for NOACs, ESC 2016 guidelines places class Ia recommendation for choosing NOACs over VKAs.³³ As of

TABLE 3: Novel anticoagulants used in clinical practice for primary and secondary stroke prevention

	Dabigatran	Apixaban	Rivaroxaban	Edoxaban
Prodrug	+	-	-	-
Bioavailability	3–7% (not affected by food)	60% (not affected by food)	66% (in fasting state and higher with food, up to 100%)	50% (6–22% more absorption with food)
Time to peak plasma concentration	0.5–2 hours	1–4 h	2–4 h	1–2 h
Renal clearance	80%	27%	35%	50%
Half-life	12–14 h (in normal renal function) 18 h, creatinine clearance 30–50 mL/min >24 h, creatinine clearance <30 mL/min	12 h	7–11 h	8–10 h
Drug interactions	P-glycoprotein inhibitors (e.g., ketoconazole)	P-glycoprotein and CYP3A4 inhibitors	P-glycoprotein and CYP3A4 inhibitors	P-glycoprotein inhibitors and CYP3A4 inhibitors (<4%)
Adverse effect other than bleeding	Dyspepsia (due to acidic coating on capsule)	Nil	Nil	Nil
Dosing frequency	Twice daily	Twice daily	Once daily	Once daily
Intake with food	No interaction	No interaction	Mandatory	No guidelines
Administration through Ryle's tube	Cannot be given*	Yes	Cannot be given**	Yes
NOAC	Standard dose		Dose modification	
Apixaban	5 mg bd		2.5 mg bd if two out of the following three criteria present: • Serum creatinine ≥1.5 mg/dL (or creatinine clearance 15–29 mL/min) • Weight <60 kg • Age >80 years	
Dabigatran	150 mg bd/110 mg bd		110 mg bd >80 years and high-risk of bleeding; not recommended if creatinine clearance <30 mL/min	
Rivaroxaban	20 mg od		15 mg od if creatinine clearance 15–50 mL/min	
Edoxaban	60 mg od (creatinine clearance 50–95 mL/min)		30 mg od if: • Creatinine clearance 15–50 mL/min • Weight ≤60 kg • Concomitant treatment with strong P-glycoprotein inhibitor (e.g., verapamil, quinidine, dronedarone) Not recommended when creatinine clearance >95 mL/min or <15 mL/min	

*Dabigatran capsules should not be crushed or chewed or administered through Ryles tube since removal of intact capsule shell increases bioavailability of the drug by 75%.

**Edoxaban administration through Ryles tube is not recommended, pending trial results.⁹⁷

NOAC, newer oral anticoagulants.

now, the approved NOACs ensemble includes 4 drugs—dabigatran (direct thrombin inhibitor), apixaban, edoxaban, and rivaroxaban (factor Xa inhibitors). The major landmark trials for NOACs include RELY⁸⁸ for dabigatran, ARISTOTLE⁸⁹ and AVERROES⁹⁰ trials (Apixaban Versus ASA to Prevent Stroke In AF Patients Who Have Failed or Are Unsuitable for Vitamin K Antagonist Treatment) for apixaban, ROCKET-AF⁹¹ trial for rivaroxaban and ENGAGE-AF TIMI (Effective Anticoagulation with factor Xa Next Generation in Atrial Fibrillation-Thrombolysis In Myocardial Infarction 48)⁹² trial for edoxaban. The advantages of NOACs include a predictable pharmacokinetic profile, offsetting the need for frequent anticoagulation, better compliance, considerably less drug and food interactions, faster onset of action, and lower risk of systemic and intracranial hemorrhage. Potential limitations include high cost, absence of readily available antidote, difficulty in coagulation monitoring, and possible drug toxicity in the presence of renal failure.⁸⁸ Table 3 provides a concise summary of (1) pharmacokinetic profile and (2) the approved dose recommendations for NOACs for stroke prevention in nonvalvular AF.⁹³⁻⁹⁶

Choice of Specific Newer Oral Anticoagulants

Current evidence remains inadequate as regards the choice of individual NOACs. Once daily dosage NOACs such as rivaroxaban and edoxaban may be preferred in patients with compliance issues. Similarly, apixaban is a viable option in patients prone to gastrointestinal (GI) bleeding as it is the only NOAC associated with lower GI bleeding risk compared to warfarin. In patients with renal dysfunction and dyspepsia, rivaroxaban and apixaban are preferred over dabigatran in view of predominant nonrenal modes of drug clearance and absence of dyspepsia as an adverse effect. Dabigatran 150 mg bd is preferred in patients with high stroke risk (CHA₂DS₂VaSc) while reduced dosage (110 mg bd) or apixaban 5 mg bd is preferred in patients with bleeding risk or past history of life-threatening bleeds. In the very elderly patients, more than or equal to 80 years with impaired renal function and low weight, apixaban 2.5 mg bd is preferred.⁹⁶

Newer oral anticoagulant usage in presence of renal dysfunction is guided by the differences in renal clearance. As warfarin has the lowest renal clearance of <1%, it is undoubtedly, the safest OAC option in severe CKD, especially end stage renal disease (ESRD) (creatinine clearance \leq 15 mL/min). Among the NOACs, dabigatran has the highest renal clearance (80%) followed by edoxaban (50%), rivaroxaban (35%), and apixaban (27%). Meta-analysis of NOACs in CKD by Sardar et al. (10 RCTs) and Nielsen et al. (5 RCTs) has shown that when compared to warfarin, NOACs significantly reduce the risk of stroke or systemic embolism in mild-to-moderate CKD (creatinine clearance 30–79 mL/min) and risk of major bleeding is comparable to warfarin in moderate CKD (creatinine clearance 30–49 mL/min) but significantly reduced in mild CKD (creatinine clearance 50–79 mL/min).^{98,99} As per majority of recent guidelines, low-dose NOACs (except dabigatran) can be used in severe CKD (creatinine clearance 15–30 mL/min) with regular renal function monitoring.⁴⁶ Though dabigatran 75 mg bd has been

approved by United States Food and Drug Administration (US FDA) in patients with creatinine clearance 15–30 mL/min (not approved in Europe). All NOACs are contraindicated in ESRD. RCTs regarding OAC use in hemodialysis patients are lacking. There are conflicting data on efficacy of warfarin in ESRD with majority of studies indicating reduced stroke or systemic embolism risk but with increased risk of bleeding. The 2018 EHRA guidelines have suggested that NOACs are better avoided in patients with ESRD and those on dialysis in concordance with available evidence.¹⁰⁰

Available evidence indicates that all NOACs are contraindicated in the presence of Child-Turcotte-Pugh C cirrhosis and in liver disease with coagulopathy and resultant increased bleeding risk. Additionally, rivaroxaban is also contraindicated in Child-Pugh B cirrhosis.¹⁰⁰

Role of Left Atrial Appendage Occlusion Strategies in Primary Prevention of Stroke in Atrial Fibrillation

As stasis and thrombi formation within the LAA are harbingers of stroke and systemic thromboembolism in AF patients, it seems reasonable that occlusion or exclusion of LAA by interventional or surgical measures would aid thromboprophylaxis. Some of the devices available for LAA occlusion include WATCHMAN, PLAATO, Amulet, ACP, LAmbre, WaveCrest, Sideris patch, and ultrasept. The percutaneous left atrial cardioversion closure vs warfarin for atrial fibrillation (PROTECT-AF) and PREVAIL trials (Evaluation of the WATCHMAN LAA Closure Device in Patients With Atrial Fibrillation Versus Long Term Warfarin Therapy) compared long-term VKA treatment to LAA occlusion in AF patients. Both studies revealed that LAA occlusion using WATCHMAN device was noninferior to VKA treatment in moderate stroke risk patients of AF, with reduced risk of bleeding on prolonged follow-up.^{101,102} These findings were corroborated in a meta-analysis on LAA occlusion, as an alternative to VKA therapy, for stroke prevention in AF.¹⁰³

Surgical occlusion or exclusion of LAA is an alternative to interventional procedures for LAA closure; these can be done either as an isolated thoracoscopic procedure or with surgical AF foci ablation or open-heart surgery. A recent trial did not demonstrate definite benefit of surgical LAA occlusion in preventing strokes.¹⁰⁴ The LAAOS III (Left atrial appendage occlusion study), a large ongoing RCT on surgical LAA removal during concomitant open heart surgery in AF patients, estimates to enroll 4,700 patients from July 2012 to November 2020. The results of this trial would provide answers to the speculated beneficial role of LAA surgical removal.¹⁰⁵

Secondary Stroke Prevention in Atrial Fibrillation

Appropriate and timely initiation of optimum therapeutic strategies is core to the precept of secondary stroke prevention among patients with AF. It is imperative to initiate the patient on lifelong anticoagulation therapy after the occurrence of ischemic stroke in the presence of AF. While valvular AF is an

exclusive indication for VKA therapy, nonvalvular AF offers a broader therapeutic choice between NOACs and VKAs.

The core principles of drug choices, details, adverse effects, bleeding risk stratification are already outlined in the section above in detail.

Timing of Initiation of Anticoagulation after Ischemic Stroke/Transient Ischemic Attack

The optimum and safest time for initiating anticoagulation in AF-related stroke/TIA remains a matter of debate. Published data suggest 1–10% early stroke recurrence rate following a cardioembolic stroke within 2 weeks. Hence, it is prudent to initiate anticoagulation at an apt time without increasing the risk of ICH. Paciaroni et al. in their meta-analysis (Stroke, 2007) concluded that administration of parenteral anticoagulation within 48 hours of stroke onset, only resulted in more ICH without causing any reduction in recurrent stroke risk.¹⁰⁶ However, Abdul-Rahim et al. in their recent analysis of VISTA trial concluded that early initiation of OAC within 2–3 days of AIS, resulted in significant reduction in stroke recurrence, without causing increased risk of ICH.¹⁰⁷ Another study, observed that early NOAC initiation within 7 days did not prove beneficial in reducing stroke or ICH risk.¹⁰⁸

The Dierens rule (1-3-7-14) or the EHRA proposed 1-3-6-12 rule is an easy aid which is practically used for selecting the timing of anticoagulation initiation. According to this rule, anticoagulation may be started 1 day after a TIA, 3 days after a mild stroke (NIHSS <8), 6 days after a moderate stroke (NIHSS 8–16), and 12 days after a severe stroke (NIHSS >16); after excluding hemorrhagic transformation on noncontrast computed tomography (NCCT). Clinical points, which would favor early initiation of anticoagulation, include a low NIHSS (<8), presence of small infarct on imaging, spontaneous echo contrast, LA thrombi, younger age, and absence of hemorrhagic transformation.³³ Two large ongoing RCTs namely, TIMING study and START study, have been designed to specifically address the issue of optimum timing of NOAC initiation.¹⁰⁹

Atrial Fibrillation Patients on Oral Anticoagulants with Acute Ischemic Stroke Presenting within the Window Period

In general, as a standard of care, in all eligible AIS patients, current guidelines recommend intravenous thrombolysis in all patients with AIS presenting within 4.5 hours of onset and in the presence of large vessel occlusion (LVO), mechanical thrombectomy is recommended (standard thrombectomy window period of 6 hours or even within the delayed thrombectomy period of 6–24 hours, based on strict selection criteria).

However, patients who are already on OAC therapy and especially on NOAC's pose a special challenge in the management of AIS. Intravenous thrombolysis is NOT permissible until details of medication use, INR status, laboratory parameters like activated partial thromboplastin

time (aPTT), INR, platelet count, ecarin clotting time, thrombin time, or appropriate direct factor Xa activity assays, and dosing details are known. "Strict individualized risk benefit assessment will be required to make a decision on treating such patients in view of bleeding risk concerns".

In the presence of current OAC usage—either VKA or NOAC (with unknown or subtherapeutic coagulation parameters), direct endovascular mechanical thrombectomy is preferred over intravenous thrombolysis as the initial reperfusion strategy, in the presence of LVO.^{33,110,111} Bridging using thrombolysis and mechanical thrombectomy could be undertaken among patients with definite subtherapeutic coagulation parameters as discussed above, if available rapidly.

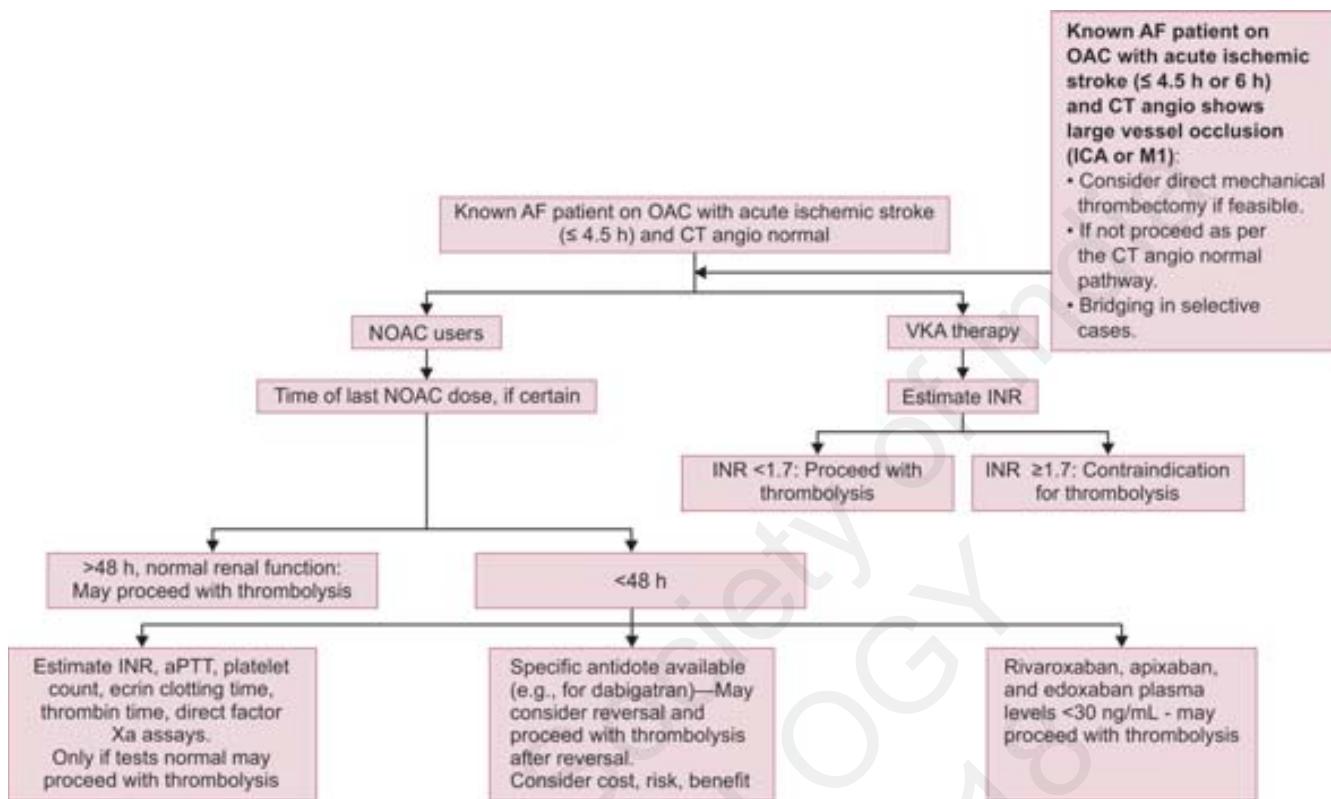

For patients without any proximal major vessel occlusion on computed tomographic angiography (CTA)/magnetic resonance angiography (MRA); severity of stroke, history of OAC intake details (dose, last dose timing), rapid availability of coagulation assays, and risk benefit assessment need to be done before proceeding for thrombolysis. Flowchart 2 provides an algorithmic representation of the practical management options of known AF patients on OACs presenting with AIS.

Resuming Anticoagulation after Intracerebral Hemorrhage—Timing?

Restarting OACs after an ICH is a difficult decision which merits serious risk benefit consideration. Current guidelines recommend OAC to be restarted 4–8 weeks after ICH in AF patients, provided the benefits of stroke risk reduction outweigh the harms of recurrent ICH. In a study on 2,619 ICH patients with AF, maximum benefit was obtained when OACs were restarted after 7–8 weeks.¹¹² In a meta-analysis of eight trials, authors observed that restarting of anticoagulation after ICH was associated with reduced risk of ischemic stroke, and there was no increase in recurrence of ICH.¹¹³ While the need for long-term anticoagulation after lobar bleed is controversial, published evidence indicate cerebral amyloid angiopathy as a contraindication to OAC.^{33,95}

CONCLUSION

The past few years have borne witness to tremendous advancements in the field of AF and stroke. The advent of NOACs is a major milestone and has revolutionized the thromboprophylactic arena of AF and stroke. The growing research in this field is anticipated to open up a plethora of high quality, patient-friendly treatment approaches. The development of antidotes to NOACs has further added to the armamentarium of management of AF-related strokes in the acute period. Ongoing research in the fields of occult AF detection, with better understanding of AF-related stroke pathophysiology and newer markers of stroke prediction also portend a brighter future with better pragmatic approaches in the thromboprophylactic and therapeutic realm.

AF, atrial fibrillation; aPTT, activated partial thromboplastin time; CT, computed tomography; ICA, internal carotid artery; INR, international normalized ratio; NOAC, newer oral anticoagulants; OAC, oral anticoagulant; VKA, vitamin K antagonists.

FLOWCHART 2: An outline for the practical management of AF patients on OAC who present within the stroke window period. Please see the text for detailed discussion and concerns.

Update 2018

Current Reperfusion Strategy in Acute Ischemic Stroke

MV Padma Srivastava, Vishnu VY

INTRODUCTION

The primary aim in management of acute ischemic stroke (AIS) is reestablishment of blood flow to save brain tissue which has not yet infarcted. In the last three decades, the management strategies have evolved from nihilism to thrombolytic therapy followed by endovascular therapy and recently to next generation endovascular devices and thrombolytic agents. The eligibility criteria and the drugs or devices for these two approved therapies have further evolved over the last two decades. In this review, we will discuss briefly the evolution of reperfusion therapy followed by the current best available evidence on reperfusion strategies in AIS.

THROMBOLYSIS IN ACUTE ISCHEMIC STROKE: “TIME CLOCK”

Thrombolysis in AIS arrived as a game changer but much later compared to cardiology practice. The main concept in the initial evolution of stroke thrombolysis was “time is brain” and the thrombolytic drug should be administered as early as possible.

The thrombolytic agent activates plasminogen to plasmin which cleaves the cross-linkages between fibrins in blood clots.¹ The efficacy of these agents depends on the age of clot, size and location, since higher density of cross linking of fibrin makes clot harder, more compact and difficult to dissolve.¹ Unlike the initial thrombolytic agents like streptokinase and urokinase, the only Food and Drug Administration (FDA)-approved tissue plasminogen activator (tPA) in stroke, alteplase (recombinant rtPA), is a fibrin selective analogue with short half-life. The dose of intravenous alteplase is 0.9 mg/kg up to 90 mg; 10% as a bolus followed by 1 hour infusion. Several trials like National Institute of Neurological Disorders and Stroke (NINDS) and European Collaborative Acute Stroke Study (ECAS) had proven the benefit for rtPA in AIS within 3 hours.^{2,3} Several prospective observational registries like Canadian Alteplase for Stroke Effectiveness Study (CASES) registry,⁴ and Safe Implementation of Thrombolysis

in Stroke-International Stroke Thrombolysis Register (SITS-ISTR) showed similar rates of mortality, symptomatic intracerebral hemorrhage (ICH) within 24 hours and functional independence.⁵ An individual patient data (IPD) meta-analysis of randomized controlled trials (RCTs) showed that thrombolysis using alteplase within 3 hours of stroke onset led to a good outcome {33% vs. 23%, or 1.75 [confidence interval (CI) 1.35–2.27]}.⁶

European Collaborative Acute Stroke Study III trial showed benefit of thrombolysis with alteplase in patients with clearly defined symptom onset between 3–4.5 hours of stroke onset [modified ranking scale, mRS 0–1 at 3 months, 52.4% vs. 45.2%, odds ratio (OR) 1.34, CI 1.02–1.76]. Third International Stroke (IST-3) trial had 1,177 patients in the 3–4.5 hours window period and the primary outcome was mRS 0–2 at 6 months (adjusted OR 0.73; 99% CI, 0.5–1.07). In the IPD meta-analysis, thrombolysis with alteplase showed benefit for patients with stroke onset within 3–4.5 hours (mRS 0–1, 35.3% vs. 30.1%, adjusted OR 1.26; 95% CI, 1.05–1.51).⁶ Thrombolysis with alteplase is approved from 3–4.5 hours in Europe, Australia, and many countries including all the leading guidelines. But US FDA has approved alteplase for thrombolysis only up to 3 hours. This may be due to the controversy in the evidence for thrombolysis using alteplase in 3–4.5 hours. In the ECAS III trial, there were baseline differences in the form of lower proportion of patients with previous stroke in alteplase group (7.7% vs. 14.1%, p = 0.003). When these patients were excluded and analyzed there was no significant difference in the primary outcome between alteplase and placebo (OR 1.19, 95% CI 0.89–1.59).⁷ In the IST-3 trial, even though the statistical analysis plan mentioned subgroup analysis using 95% CI, in the final analysis the authors used 99% CI. BS Alper et al. had done an unadjusted analysis of this data using 95% CI and uncovered a significant reduction in functional outcome (OR 0.76, 95% CI 0.60–0.97, number needed to harm, NNH = 16).⁸ Thrombolytic therapy beyond 4.5 hours was not found beneficial in three trials which used then existing conventional inclusion criteria

[Alteplase Thrombolysis for Acute Noninterventional Therapy in Ischemic Stroke-A (ATLANTIS-A), ATLANTIS-B and IST-3].⁹⁻¹¹

RECENT ADVANCES IN STROKE THROMBOLYSIS

Risk of major intracranial hemorrhage, low recanalization rates for large vessel occlusion (LVO), requirement for continuous infusion, and narrow window period are the major limitations of the currently approved thrombolytic agent, alteplase. Stroke research in the last decade had tried to surpass these limitations.

Low-dose versus Standard-dose Alteplase

The popular belief that there is higher risk of bleeding in Asians had led to approval of lower dose alteplase (0.6 mg/kg) in Japan based on a single group, open-label study with 103 patients.^{12,13} The Enhanced Control of Hypertension and Thrombolysis Stroke Study (ENCHANTED) trial assessed whether low-dose alteplase was as effective as usual dose in efficacy and risk for hemorrhage in a noninferiority hypothesis. It did not show noninferiority of low-dose alteplase in decreasing death or disability after AIS (mRS 2–6, 53.2% vs. 51.1%; OR 1.09; 95% CI, 0.95–1.25, $p = 0.51$ for noninferiority). But the rate of symptomatic ICH was significantly lower in low-dose alteplase (1.0% vs. 2.1%, OR 0.48; 95% CI, 0.27–0.86, $p = 0.01$). The secondary analysis of ENCHANTED trial found no clear differential benefit of low-dose alteplase in older, Asian, or severely affected patients with AIS compared to standard-dose alteplase.¹⁴ Hence, the clinical equipoise remains regarding low-dose alteplase even though we now know that risk of symptomatic ICH is lesser.

Thrombolysis in Minor Nondisabling Stroke

The role of thrombolysis with alteplase in minor non-disabling stroke is ambiguous. The American Heart Association (AHA) 2018 guidelines states “within 3 hours from symptom onset, treatment of patients with mild ischemic stroke symptoms that are judged as nondisabling may be considered. Treatment risks should be weighed against possible benefits, however, more study is needed to further define the risk-to-benefit ratio [Class IIb; level of evidence C (LoE C)]”. The first RCTs on thrombolysis in acute mild ischemic stroke with no disabling deficit (PRISMS: A Study of the Efficacy and Safety of Alteplase in Participants with Mild Stroke-NCT02072226) was stopped early recently due to slow recruitment (not published yet, abstract presented in International Stroke Conference, 2018). The trial had enrolled 313 patients (out of intended 948 patients) and hence was underpowered. An intention-to-treat (ITT) analysis was done for 156 patients in the alteplase group and 157 in the aspirin only group. The rate of symptomatic ICH (32% vs. 0) and any ICH (7.1% vs. 3.3%) was more in alteplase. Hence, among patients with low

National Institute of Health Stroke Scale (NIHSS) scores and with no disabling deficits, alteplase may not provide benefit and increases the risk of intracranial hemorrhage.¹⁵

Thrombolysis in Wake-up Stroke

Role of thrombolytic agents in wake-up stroke was controversial since time of onset of stroke was unknown. WAKE-UP trial [Magnetic Resonance Imaging (MRI)-Guided Thrombolysis for Stroke with Unknown Time of Onset] was designed to answer this highly clinically relevant research question.¹⁶ It was a multicenter, randomized double-blind placebo controlled trial which recruited stroke patients with unknown onset and coexisting diffusion-fluid-attenuated inversion recovery (FLAIR) mismatch in MRI. This mismatch (ischemic lesion visible in diffusion images but no lesion in FLAIR images) indicates that stroke might have occurred within 4.5 hours. They had excluded patients planned for thrombectomy. The trial was stopped early due to lack of funding after enrolling 500 patients of the estimated 800 patients. The primary outcome of mRS 0–1 was achieved significantly higher by alteplase group compared to placebo (53.3% vs. 41.8%; adjusted OR 1.61; 95% CI, 1.09–2.36, $p = 0.02$) with number needed to treat (NNT) of 8.7. There was no difference in rate of symptomatic hemorrhage (2% vs. 0.4%; OR 4.95; 95% CI, 0.57 to 42.87, $p = 0.15$). This gives hope to wake-up stroke patients without LVO and still have a salvageable ischemic penumbra.

NEXT GENERATION THROMBOLYTIC AGENT: TENECTEPLASE

An ideal thrombolytic agent should be efficacious, fast and long acting, with higher fibrin specificity, without pro-coagulant effect, lesser intracranial or systemic hemorrhages, active in platelet rich thrombi and finally also be cost-effective. Many “next generation” thrombolytic agents evolved over last decade and the most promising one is tenecteplase (TNK) which is a genetically modified tissue plasminogen activator with pharmacologic advantage over alteplase. TNK amino acid sequence differs from alteplase at three sites. TNK has similar mechanism of action but has 14-fold greater fibrin specificity, 80-fold greater resistance to inactivation by plasminogen activator inhibitor-1, no procoagulant action, longer half-life (18 min) and slower plasma clearance compared to alteplase (Table 1).^{17,18} Hence, the availability of a thrombolytic agent which can be given as a single intravenous bolus in AIS was exciting.

Evidence for Tenecteplase in Acute Ischemic Stroke

Haley et al. showed safety of TNK in AIS in an open-labeled dose escalation study involving 88 patients using four doses of TNK (0.1, 0.2, 0.4, and 0.5 mg/kg). Symptomatic ICH occurred only in 0.5 mg/kg (2/13, 13% patients).¹⁹ This was followed by four phase 2 trials which gave reasonable assurance regarding safety and efficacy of TNK. Parson et al. (2009) showed in a prospective non-randomized trial, greater

TABLE 1: Comparison of pharmacokinetic and pharmacodynamic properties of alteplase and tenecteplase

Properties	tPA	TNK
Fibrin specificity	++	+++
Thrombolytic potency	+	+++
PAI-1 resistance	-	++
Fibrinogen depletion	++	+
PRT activity	++	+++
Clearance (mL/kg/min)	16.1	1.9

PAI, plasminogen activator inhibitor; PRT, platelet-rich thrombus; tPA, tissue plasminogen activator; TNK, tenecteplase.

efficacy of intravenous TNK (0.1 mg/kg) in AIS patients with a defined ischemic-perfusion mismatch from a proximal vessel occlusion. Intravenous (IV) TNK arm had greater reperfusion, lesser infarct growth, and better early clinical improvement than patients who received IV tPA (0.9 mg/kg) in the 3 hours window. But the first randomized controlled trial comparing three doses of TNK with alteplase within the 3 hours window period was stopped early due to slow enrolment. But the 0.4 mg/kg TNK arm had an increased risk of hemorrhage. No definite conclusion on superiority or non-inferiority could be drawn from it. Parson et al. (2012) came up with their first phase 2 RCT on 75 AIS patients (perfusion mismatch with LVO, 0–6 h) with three arms (0.1 mg/kg TNK, 0.25 mg/kg TNK and 0.9 mg/kg tPA). Both the TNK arms had better reperfusion and clinical improvement at 24 hours compared to alteplase. The study had a selection bias for small cerebral infarctions affecting its generalizability.^{20–23} Another phase 2 trial (ATTEST: Alteplase versus TNK for Thrombolysis after Ischemic Stroke) failed to show any significant difference between alteplase and TNK in AIS patients within 4.5 hours.²⁴ They used conventional eligibility criteria for inclusion in trial and then used computed tomography (CT) perfusion and CT angiography to find out the percentage of “initial territory-at-risk” on CT perfusion that did not ultimately developed into infarct on the follow-up non-contrast CT scan (primary outcome). Around 35% of patients were excluded from primary analysis since they did not have adequate imaging and also there were significant baseline differences which might have affected the results ultimately.²⁵

The first phase 3 clinical trial with 1,100 patients was published in 2017 (NOR-TEST: Norwegian Tenecteplase Stroke Trial) which had a clinical primary outcome.²⁶ There was no difference in the primary outcome of mRS 0–1 at 3 months (64% vs. 63%, OR 1.08, CI 0.84–1.38, p = 0.52). In both the groups, the frequency of symptomatic ICH was similar. The major limitation of the trial was that more than 80% of patients had minor stroke or stroke mimic who were anyway more likely to have good prognosis.²⁷ EXTEND-TNK (Tenecteplase versus Alteplase before Endovascular Therapy for Ischemic Stroke) trial (2018) showed that in AIS patients (<4.5 h) with LVO eligible for thrombectomy, TNK caused better reperfusion (22% vs. 10%; OR 2.6; CI, 1.1–5.9) compared to alteplase. There was no difference in proportion of patients who had functionally independent outcome (mRS 0–2) or excellent outcome (mRS 0–1).

A meta-analysis of three phase 2 RCTs^{21,23,24} and one phase 3 RCT²⁶ involving 1,334 patients did not show any significant difference in mRS at 90 days, mortality at 90 days or any ICH/symptomatic ICH.²⁸ The authors claimed that “TNK group compared to the alteplase group had significantly better early major neurological improvement (relative risk; RR = 1.56, 95% CI 1.00, 2.43, p = 0.05)”. The authors have mentioned its grade evidence profile as critical outcome with moderate certainty. The meta-analysis did not include EXTEND-TNK trial. There is a compelling cost-effective argument favoring TNK over alteplase but we need cost-effective/benefit analysis studies to prove the advantage. Since, TNK can reperfuse 22% of LVO, it may be useful in settings where endovascular therapy is not available. We still need to await on-going clinical trials [Tenecteplase versus Alteplase for Stroke Thrombolysis Evaluation (TASTE), ATTEST-2, TNK-tPA for Minor Ischemic Stroke with Proven Acute Symptomatic Occlusion Trial 2 (TEMPO-2), Tenecteplase in Wake-up Ischemic Stroke (TWIST), Extending the Time for Thrombolysis in Emergency Neurological Deficits-Intra-arterial with Tenecteplase (EXTEND-IA TNK) Part 2] before having the final verdict on clinical superiority of TNK over alteplase.

ENDOVASCULAR THERAPY: “TISSUE CLOCK”

Early Window Endovascular Trials

Ever since the results of Multicenter Randomized Clinical Trial of Endovascular Treatment for Acute Ischemic Stroke in the Netherlands (MR CLEAN) trial and the following domino effect of multiple trials being stopped prematurely (Table 2), the standard of care for AIS (<6 h) with an anterior circulation LVO has been mechanical thrombectomy with stent retrievers.²⁹ The result of these six endovascular RCTs [MR CLEAN, Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE), REVASCAT, Solitaire with the Intention for Thrombectomy as Primary Endovascular Treatment (SWIFT PRIME), EXTEND-1A, THRACE] contradicted the results of the three previous RCTs [Intervention Management of Stroke (IMS) III, SYNTHESIS and Mechanical Retrieval and Recanalization of Stroke Clots Using Embolectomy (MR RESCUE)]. The reasons for the success of these trials are many including newer (better) technology, better work flow, and patient selection (smaller baseline infarct volume with confirmed LVO). The IPD meta-analysis of five trials [Highly Effective Reperfusion Evaluated in Multiple Endovascular Stroke trials (HERMES) collaboration] with 1,287 patients showed precise superiority of mechanical thrombectomy (mRS 0–1 at 90 days, 26.9% vs. 12.9%; OR 2.49; 95% CI, 1.84–3.35; p <0.0001; mRS 0–2 at 90 days, 46% vs. 26.5%; OR 2.35; CI, 1.85–2.98, p <0.0001).³⁰ NNT to reduce one point in mRS was 2.6.

Late Window Endovascular Trials

The year 2018 witnessed two landmark trials [DAWN and Diffusion and Perfusion Imaging Evaluation for Understanding Stroke Evolution (DEFUSE) 3] which brought high-quality evidence to extend the window period for

TABLE 2: Comparison of endovascular trials with second generation devices¹

RCT	MR CLEAN	ESCAPE	EXTEND-IA	SWIFT PRIME	REVASCAT	THERAPY	THRACE
No. of points	500 (267/233)	315 (150/165)	70 (35/35)	196 (98/98)	206 (103/103)	108 (54/54)	412 (208/204)

endovascular intervention up to 24 hours by careful selection of patients.^{31,32} DAWN (DWI or CTP Assessment with Clinical Mismatch in the Triage of Wake-Up and Late Presenting Strokes Undergoing Neurointervention with Trevo) trial was the first RCT to compare endovascular therapy with standard of care in AIS patients who were last known to be well 6–24 hours earlier.³¹ Similar to RCTs with second generation devices, DAWN trial carefully selected patients with small established infarct and a LVO in the anterior circulation. The trial used the concept of “clinical-core mismatch” which was significant clinical deficit disproportionately severe compared to the already established infarct. The infarct volume was measured by automated software on CT perfusion or MRI DWI imaging. The eligibility criteria were one of the following: “group A: age ≥80 years, NIHSS ≥10, core infarct <21 mL; group B: age <80 years, NIHSS ≥10, infarct <31 mL; group C: age <80 years, NIHSS ≥20, infarct 31–<51 mL”. DAWN trial enrolled 206 patients (EVT 107 vs. medical 99). The enrolment was stopped early after prespecified interim analysis which showed a high probability of success. Around 60% of patients had wake-up stroke (unknown stroke onset). Compared to medical arm, thrombectomy arm had significant benefit on the 90-day utility-weighted mRS (5.5 vs. 3.4) and rate of functional independence (mRS 0–2, 49% vs. 13%). This benefit was consistent across stroke severity, age, site of vessel involvement and stroke presentation (witnessed vs. unwitnessed vs. wake-up). The patients selected by “tissue window” in DAWN trial had similar rate of functional independence (mRS 0–2) when compared to “time window” in HERMES meta-analysis (DAWN, mRS 0–2 49% vs. HERMES mRS 0–2 46%).

Endovascular Therapy Following Imaging Evaluation for Ischemic Stroke (DEFUSE 3) trial reinforced the shift in paradigm created by DAWN trial. It enrolled 182 AIS patients (6–16 h after the time last known well) and also was stopped

early for efficacy.³² The inclusion criteria were presence of proximal LVO, initial infarct volume less than 70 mL and ratio of volume of ischemic tissue on perfusion imaging to infarct volume of 1.8 or more and an absolute volume of penumbra 15 mL or more assessed by CT perfusion or MR diffusion. Thrombectomy arm had a favorable shift in mRS at 90 days (OR, 2.77; p <0.001) and a higher percentage of patients who were functionally independent (mRS 0–2, 45% vs. 17%, p <0.001). There was lesser 90-day mortality in the endovascular arm and there were no difference in symptomatic ICH or serious adverse events. Thus, both DAWN and DEFUSE 3 have brought class I evidence for mechanical thrombectomy for selected patients satisfying their inclusion criteria.

Both these trials were stopped early which could have led to over estimation of effect of mechanical thrombectomy.^{33,34} Majority of patients in both the trials were wake-up strokes, which tend to occur close to awakening. Hence, many of these patients might be biologically within the established window period of 6 hours and the control group in these trials might have been at disadvantage. Even then these trials have shown the wake-up strokes with small core and large penumbra with LVO, mechanical thrombectomy can significantly change the outcome.

Late Window Paradox

Both DAWN and DEFUSE trials have shown us the concept of “late window paradox”.³⁵ Since “time is brain”, interventions done more than 6 hours of stroke onset should be less beneficial than those done within 6 hours. But results of DEFUSE and DAWN were better than those endovascular trials done within 6 hours. In fact, DAWN had the largest absolute increase (35.5%) in functional independence across any stroke therapy trial even after median time from stroke onset being 12.5 hours. DEFUSE 3 had 28% increase in functional independence and had the largest reduction

in mortality/severe morbidity (20%) ever achieved. Even HERMES (pooled analysis of five early window endovascular RCTs) had only 19.5% absolute increase in functional independence and 11% decrease in mortality. All these trials had similar patients, stroke severity, thrombectomy devices and reperfusion achievement. These better results in late window endovascular trials are called “late window paradox”. Various factors affect this phenomenon. A significant number of stroke patients with LVO have very protracted growth of the ischemic core for 12 hours or even longer. It is the good collateral circulation which keeps the ischemic core size small for this long period and eventually fails to increase the size of infarct. So, DAWN and DEFUSE had enrolled patients with very small ischemic core, very slow growth rate of infarct and large penumbra. The medical arm of these trials would have poor outcomes as most of them would not receive IV tPA as they are out of window period of 4.5 hours and their collateral circulation will eventually fail causing large infarct.

CONCLUSION

The recent advances in the reperfusion strategies have added “tissue window” to the existing “time window” and many patients with small ischemic core, large penumbra, good collaterals may benefit from mechanical thrombectomy if they have a proximal LVO even if they arrive within 6–24 hours of stroke onset. Wake-up stroke patients with unknown stroke onset may also benefit from thrombolysis with alteplase if they have diffusion-FLAIR mismatch. The next generation thrombolytic agent, TNK has shown huge promise and we eagerly wait for the on-going trials to provide definite evidence for its clinical superiority over alteplase.

Prevention of Stroke in Cardiac Patients

Harsh Wardhan, Nitin Aggarwal

INTRODUCTION

Stroke remains a major global health problem, and due to the ongoing demographic changes, including aging and health transitions observed in developing countries its impact is likely to increase in the future. The increasing global stroke burden strongly suggests that currently implemented primary stroke prevention strategies are not sufficiently effective, and new primary prevention strategies with larger effect sizes are needed. For the prevention of early recurrent ischemic stroke, the advantages of aspirin are greater than previously recognized. Direct oral anticoagulants (OACs) as an alternative to warfarin for atrial fibrillation (AF), and carotid stenting as an alternative to endarterectomy for symptomatic carotid stenosis are the other strategies used nowadays to prevent recurrent stroke. Despite stable incidence rates and declining mortality rates over the past two decades, the number of incident strokes, prevalent stroke survivors, disability-adjusted life years (DALYs) lost due to stroke, and stroke-related deaths are increasing. This review highlights recent developments in prevention of stroke in cardiac patients.

DEFINITION OF STROKE AND TRANSIENT ISCHEMIC ATTACK

Stroke is distinguished from transient ischemic attack (TIA), if the symptoms persist longer than 24 hours (or lead to earlier death). An updated definition of stroke is an acute episode of focal dysfunction of the brain, retina, or spinal cord lasting longer than 24 hours, or of any duration if imaging [computed tomography (CT) or magnetic resonance imaging (MRI)] or autopsy shows focal infarction or hemorrhage relevant to the symptoms.¹ This definition includes subarachnoid hemorrhage.¹ A TIA has been redefined as focal dysfunction of less than 24 hours duration and with no imaging evidence of infarction.¹

CARDIAC EMBOLISM AND STROKE

Cardioembolic stroke accounts for 25% of all ischemic strokes² and due to the advancement in cardiac imaging, its frequency has increased over time.² Various cardiac disorders may be the cause of cardioembolic stroke; however, it occurs most commonly as a result of AF in adults (50%) (Fig. 1).^{3,4} Other important causes include ventricular thrombus (20%), structural heart defects or tumors (15%), and valvular heart disease (15%) (Box 1).⁵ Although the aortic arch is not a cardiac structure, it is usually considered under sources of cardiac embolism.

Cardioembolic stroke is therefore a syndrome with diverse causes and not a single disease entity. A systematic approach, including a detailed history, physical examination, and review of neuroimaging, electrocardiogram, and echocardiographic

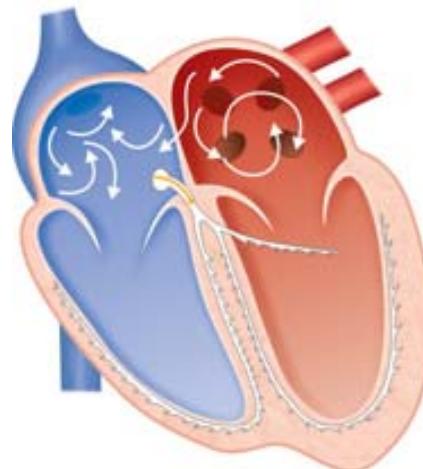

FIG. 1: Atrial fibrillation. Diagram depicts the abnormal electrical activity within the atria, which may lead to uncoordinated contraction of the atria, stagnant blood, and thrombus formation, and an irregular heart rhythm.

BOX 1 Major causes of cardioembolic stroke**Etiology of cardioembolism**

- Atrial fibrillation
- Valvular heart disease
- Ventricular thrombus
- Structural heart defects or tumors
- Myocardial infarction
- Congestive heart failure
- Patent foramen ovale
- Infective endocarditis
- Prosthetic valves

data, may be helpful to know the cause of cardioembolic stroke. Echocardiography, especially transesophageal echocardiography (TEE), remains the diagnostic standard to evaluate for cardioembolic sources of stroke.⁶ TEE is superior to transthoracic echocardiography (TTE) for the detection of cardioembolic sources.⁷ Overall, cardiac embolism as the cause of stroke is diagnosed in the absence of a large artery stenosis or occlusion, a clinical syndrome or radiographic appearance of a lacunar stroke, and unusual causes of stroke (e.g., vasculitis and drug abuse). However, approximately 15% of patients who have lacunar syndromes would also have risk factors for cardioembolism.⁸

STROKE PREVENTION IN ATRIAL FIBRILLATION

Atrial fibrillation is the most common cardiac arrhythmia and the incidence and prevalence of this disease are rising. It is estimated that by the year 2050 there will be over 7.5 million patients with AF in the USA alone.⁹ This disease carries a significant risk of morbidity and mortality driven in large part by the development of heart failure and thromboembolism.¹⁰ Oral anticoagulation therapy is effective in reducing risk of stroke and systemic embolism and is the standard of care for patients undergoing either a rhythm or rate control strategy.

Systemic embolization is a potential complication of any form of AF, and it can occur in patients with acute AF lasting as little as 72 hours. The forms of AF proposed by the American College of Cardiology or American Heart Association (AHA) or European Society of Cardiology are as follows:^{11,12}

- *Paroxysmal*: Self-terminating AF, in which episodes generally last less than 7 days and usually less than 24 hours; it may be recurrent
- *Persistent*: Fails to self-terminate and lasts longer than 7 days
- *Permanent*: Lasts for more than 1 year
- *Lone*: Paroxysmal, persistent, or permanent AF in the absence of structural heart disease
- *Nonvalvular*: Cases without rheumatic mitral valve disease, prosthetic heart valve, or valve repair.

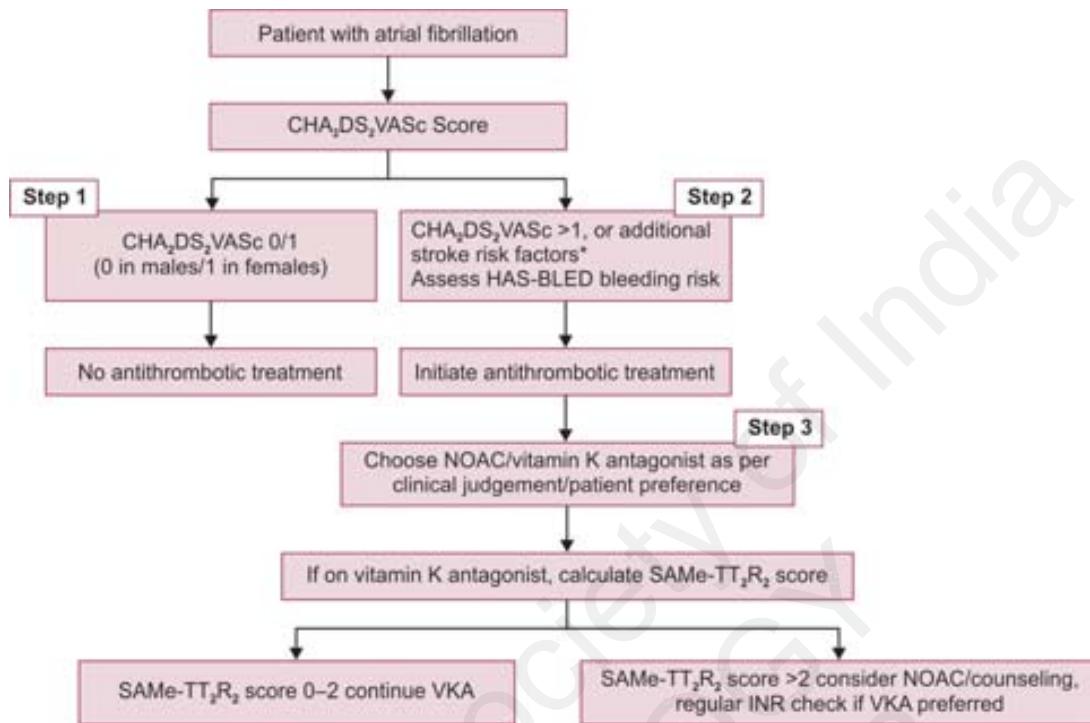

However, the stroke risk is increased fivefold in AF; it is not homogeneous and is associated with the presence of various stroke risk factors.¹³ The more commonly encountered risk factors have been used to formulate stroke risk stratification scores, such as the CHA₂DS₂-VASc score.¹⁴ The latter was designed to be simple, extending the older CHADS2 score by recognizing that age is an important driver of stroke risk (with the risk increasing above 65 years of age, although in Asians,

this risk may rise from age 50 upwards, hence requiring a recalibration of the CHA₂DS₂-VASc score),^{15,16} and that other commonly encountered risk factors such as “complicated” vascular disease (e.g., myocardial infarction and peripheral artery disease) would also increase risks. CHA₂DS₂-VASc is consistently good at identifying “low risk” patients and if an AF patient is defined as low risk using CHA₂DS₂-VASc (i.e., 0 in males and 1 in females), event rates (whether stroke or death) are usually less than 1% per year.

Treatment thresholds for stroke prevention with a stroke event rate of 1% per year is generally regarded as the threshold for thromboprophylaxis, given that AF-related strokes are more likely to be fatal or severely disabling.¹⁷ Even a single stroke risk factor confers an excess risk of stroke or mortality,¹⁸ and the net clinical benefit is positive for OAC compared to aspirin or leaving such patients untreated.¹⁹

The “Birmingham 3-step” management pathway to streamline decision-making for stroke prevention in patients with AF is shown in the flowchart 1.²⁰ The first step is to identify and offer stroke prevention to AF patients with low or even more than 1 stroke risk factors. At second step, a practical stroke score is meant to be reductionist, so that it does not matter whether the CHA₂DS₂-VASc score is 2 or 9 points, or whether biomarkers are positive or negative—that AF patient needs stroke prevention, which is OAC. For the latter or the third step, decision making between a vitamin K antagonist (VKA) or new oral anticoagulant (NOAC) can be helped by using the SAMe-TT₂R₂ score,²¹ [sex, age (<60 years); medical history (at least two of the following—hypertension, diabetes, coronary artery disease or myocardial infarction, peripheral arterial disease, congestive heart failure, previous stroke, pulmonary disease, and hepatic or renal disease); treatment (interacting drugs, e.g., amiodarone for rhythm control) (all 1 point); and the current tobacco use (2 points) and race (non-Caucasian; 2 points)] where patients with a score 0–2 are likely to do well on VKA with a good time in therapeutic range (TTR), whilst those with a score more than 2 are less likely to achieve a good TTR and additional measures such as regular follow-up [with international normalized ratio (INR) checks] and counseling, or a NOAC could be considered.²¹ Persistence and adherence with OAC are additional considerations, with some evidence for better compliance with NOACs compared to VKA.

Bleeding risk assessment has also been subjected to much misinformation and bleeding risk scores have been misused by the ill-informed.²² Many of the potentially reversible bleeding risk factors are contained within the HAS-BLED (Hypertension, Abnormal renal or liver function, Stroke, Bleeding, Labile INR, Elderly, Drugs or alcohol) score,²² which is a simple and well-validated score that has been tested in AF and non-AF patients, and is also predictive of bleeding risks in a patient not on antithrombotic therapy, aspirin, and on anticoagulation (whether with a VKA or a non-VKA anticoagulant); thus, the HAS-BLED score is applicable throughout the patient pathway. A high HAS-BLED score more than or equal to 3 is not an excuse to withhold OAC, and has been shown to be predictive of intracranial hemorrhage, the most feared complication of OAC.

HAS-BLED, Hypertension, Abnormal renal or liver function, Stroke, Bleeding, Labile international normalized ratio, Elderly, Drugs or alcohol; NOAC, new oral anticoagulant; VKA, vitamin K antagonist; INR, international normalized ratio.

FLOWCHART 1: The Birmingham 3 step management pathway to streamline decision making for stroke prevention in patients with atrial fibrillation.

ORAL ANTICOAGULANTS

Vitamin K antagonists have been the main drugs for the antithrombotic prevention in AF for 60 years. Despite its unquestionable impact to prevent strokes, medical community has to deal with significant limitations, such as common drug or food interactions, and the necessity of regular monitoring to adjust doses and *inter alia*. In the last 10 years, OAC therapy is now witnessing a revolution after the completion of large phase III clinical trials on the commonly termed NOACs. Advantage of the new agents is the use of fixed-dosing with no need for monitoring, few interactions, and a wider therapeutic window counteract their current disadvantages. The lack of an effective antidote, cost, or reservations in patients with kidney disease may explain their slow rate of expansion.

Two classes of NOACs are currently available, (1) the oral direct thrombin inhibitors (DTIs; e.g., dabigatran) and (2) oral direct factor Xa inhibitors (e.g., rivaroxaban, apixaban, and edoxaban). These drugs block only a single step in coagulation, unlike VKAs, which block the formation of multiple active vitamin K-dependent coagulation factors (factors II, VII, IX, and X). Recent data from seven European countries show a much better adherence to evidence and recommendations for oral anticoagulation.²³

Dabigatran

Dabigatran etexilate was the first NOACs studied and Food and Drug Administration (FDA) approved, is a highly

specific and competitive DTI, based on the results of the RE-LY (Randomized Evaluation of Long-term anticoagulant therapy with dabigatran etexilate) trial.²⁴ The RE-LY trial comparing two blinded doses of dabigatran etexilate (110 or 150 mg BID) with warfarin in 18,113 patients with AF and at least one additional risk factor (a mean CHADS score of 2.1). Dabigatran 150 mg BID was superior to warfarin with no significant differences in major bleedings. Gastrointestinal (GI) bleeding was more frequent with dabigatran 150 mg BD. Dabigatran 110 mg BD was noninferior to warfarin for the primary efficacy endpoint of stroke and systemic embolism, with a reduction of 20% in major bleedings. RELY-ABLE (The subsequent Long-term Multicenter Extension of Dabigatran Treatment in Patients with Atrial Fibrillation) study threw light on the long-term effects of two doses of dabigatran in patients completing RE-LY by extending the follow-up of patients on dabigatran from a mean of 2 years at the end of RE-LY by an additional 2.3 years.²⁵ Patients on warfarin were not enrolled in this study. RELY-ABLE confirmed the results reported in RE-LY.

Rivaroxaban

Rivaroxaban, a competitive and dose-dependent direct inhibitor of factor Xa and the second NOAC approved by the FDA and European Medicines Agency (EMA) based on the ROCKET AF (Rivaroxaban-Once Daily Oral Direct Factor Xa Inhibition Compared with Vitamin K Antagonism for Prevention of Stroke and Embolism Trial in Atrial

Fibrillation).²⁶ The ROCKET AF was a double-blinded study, which included 14,264 patients with nonvalvular AF and CHADS2 scores more than or equal to 2 (mean 3.5). The subjects were randomly assigned to rivaroxaban 20 mg once daily or dose adjusted warfarin. Patients with creatinine clearance (CrCl) of 30–49 mL/min received 15 mg of rivaroxaban. After a median follow-up of 1.93 years, Rivaroxaban was noninferior to warfarin for the prevention of stroke or systemic embolism; however, rivaroxaban failed to show superiority over warfarin in the intention-to-treat analysis ($p < 0.12$). There were no differences in the risk of major bleeding, although intracranial and fatal bleeding occurred less frequently in the rivaroxaban group.

Apixaban

Apixaban, a direct, reversible, competitive, and selective inhibitor of factor Xa and the last NOAC approved by the FDA and EMA for the prevention of stroke and embolism in nonvalvular AF. The ARISTOTLE²⁷ (Apixaban for Reduction In STroke and Other Thromboembolic Events in AF) was a randomized, double-blinded, double-dummy, and phase III trial comparing apixaban (5 mg BID) with dose-adjusted warfarin in 18,201 patients with nonvalvular AF (a mean CHADS2 score of 2.1). After a mean follow-up of 1.8 years, apixaban was found to be superior than warfarin, with fewer primary outcomes (overall strokes—both ischemic and hemorrhagic—and systemic emboli); however, there was no significant difference in the rate of ischemic strokes. Patients treated with apixaban had significantly fewer intracranial bleeds, but GI bleedings were similar between both groups. All-cause mortality was found to be significantly lower in the apixaban group. Similar results were found in the AVERROES study²⁸ when compared with aspirin alone.

Edoxaban

Edoxaban is another reversible factor Xa inhibitor, recently approved by the FDA but not yet by the EMA. The ENGAGE AF-TIMI 48 (Effective Anticoagulation with Factor Xa Next Generation in Atrial Fibrillation–Thrombolysis in Myocardial Infarction 48)²⁹ was a three-group, randomized, double-blinded, and double-dummy phase III trial, which compared the two dose regimens of edoxaban (30 mg once daily and 60 mg once daily) with warfarin in a total of 21,026 patients with nonvalvular AF. After a follow-up of 2.8 years, Both the regimens of edoxaban were noninferior to warfarin with respect to the prevention of stroke or systemic embolism, after a follow-up of 2.8 years; however, the lower dose trended toward inferiority, with a hazard ratio of 1.13 versus warfarin, and was inferior to specifically prevent ischemic stroke. Edoxaban was associated with lower, dose-related rates of bleeding, including major bleeding, intracranial bleeding, and life-threatening bleeding. An exception was GI bleeding, which occurred more frequently with high-dose edoxaban, but less frequently with low-dose edoxaban compared with warfarin.

Comparison between New Oral Anticoagulants

For the time being, no direct head-to-head comparisons between NOACs have been made in randomized controlled trials. The choice of one or another NOAC for a given patient is influenced by individual patient characteristics, including risk of stroke or venous thromboembolism (VTE), risk of bleeding, and comorbidity such as the presence of impaired renal function. Figure 2 show the comparative efficacy of high-dose of NOACs and warfarin.³⁰ Comparative analysis of the four NOACs confirmed that NOACs significantly reduced the composite of stroke or systemic embolic events by 19% compared with warfarin, which very much depended on large reduction in hemorrhagic strokes. Table 1 summarizes general recommendations based on patient characteristics, drug compliance, and tolerability. All NOACs except apixaban were associated with more GI bleeding than warfarin. However, it is important to highlight that at present all NOACs are clinically indicated in nonvalvular AF regardless of the estimated risk of stroke or bleeding. Finally, VKAs remain the first-line anticoagulant for patients with mechanical heart valves or rheumatic heart disease and for those with severe renal insufficiency, in whom NOACs are contraindicated.

PATENT FORAMEN OVALE

Patent foramen ovale (PFO) is a flap-like defect in the interatrial septum (Fig. 2) and a common finding (25%) in the general population, but in 40% of adults with cryptogenic stroke. The relationship of PFO and ischemic stroke remains an area of considerable debate. The mechanism through which PFO causes ischemic stroke remains speculative. The

TABLE 1: Suggested use of new oral anticoagulants according to patient characteristics

Patients characteristics	NOAC	Dose regimen
High risk of stroke	Dabigatran	150 mg BID (high CHADS-VASC score)
Previous stroke	Rivaroxaban	20 mg QD
High risk of bleeding or	Dabigatran	110 mg BID
Previous life-threatening bleedings	Apixaban	5 mg BID
Dyspepsia	Rivaroxaban	20 mg QD
	Apixaban	5 mg BID
GI bleeding	Apixaban	5 mg BID
Medication compliance problems	Rivaroxaban	20 mg QD
Elderly (≥80 years) and impaired renal function	Apixaban	2.5 mg BID

BID, twice daily; GI, gastrointestinal; NOAC, new oral anticoagulants; QD, once daily.

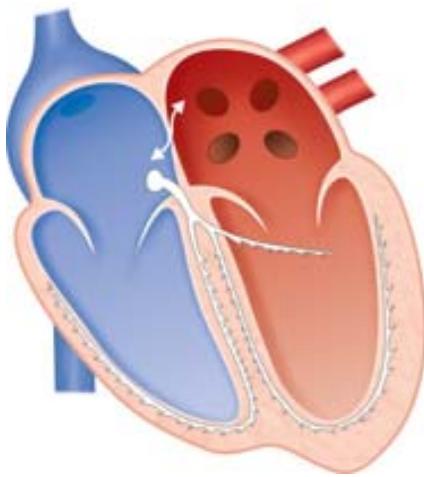

FIG. 2: Right to left shunting through patent foramen ovale.

prevailing hypothesis is that PFO-mediated stroke results from “paradoxical” (right to left) embolism caused by clots originating in the right side of the venous circulation proximal to the PFO that then traveling to the left atrium and the systemic circulation. Clinical examination of patients with PFO, documented deep vein thrombosis (DVT) and simultaneous pulmonary embolism (PE), and ischemic stroke support a right-sided to left-sided, or “paradoxical,” circulatory mechanism for stroke. Another hypothesis regarding PFO-mediated stroke is that vasoactive substances (e.g., serotonin) usually deactivated in the pulmonary circulation cross into the systemic circulation and lead to ischemic stroke. The latter hypothesis is weakly supported by the finding of patients with PFO and experience migraines who improve after PFO closure. Some studies suggest that the size of the PFO defect is important, with a large PFO (≥ 2 mm) more likely to be associated with an embolic stroke than a small PFO (<2 mm).³¹

Medical Therapy versus Closure for Patent Foramen Ovale

Despite the association between PFO and cryptogenic stroke, three early randomized clinical trials [CLOSURE I (Evaluation of the STARFlex Septal Closure System in Patients with a Stroke and/or Transient Ischemic Attack due to Presumed Paradoxical Embolism through a Patent Foramen Ovale),³² PC (Percutaneous Closure of Patent Foramen Ovale in Cryptogenic Embolism) trial,³³ and RESPECT (Randomized Evaluation of Recurrent Stroke Comparing PFO Closure to Established Current Standard of Care Treatment)³⁴ short-term] did not show a clear benefit of PFO closure for secondary stroke prevention. However, after FDA approval of the Amplatzer PFO occluder device and the results of two new randomized controlled trials,^{35,36} PFO closure seems to be have better results in comparison to medical therapy, in CLOSE (Patent Foramen Ovale Closure or Anticoagulants Versus Antiplatelet Therapy to Prevent Stroke Recurrence),³⁵ after a mean follow-up of 5.3 years, subjects who underwent

PFO closure had a lower risk of recurrent stroke than those maintained on antiplatelet therapy (0% vs. 6%). In REDUCE (Patent Foramen Ovale Closure or Antiplatelet Therapy for Cryptogenic Stroke),³⁶ after a median follow-up of 3.2 years, subjects who underwent PFO closure had a lower risk of recurrent stroke than those maintained on antiplatelet therapy (1.4% vs. 5.4%). In both these trials, PFO closure was associated with a higher risk of AF, which was believed to be primarily due to the closure procedure itself (i.e., self-limited). Therefore, PFO closure is of moderate benefit compared to antiplatelet therapy alone in the prevention of recurrent ischemic stroke in adults up to 60 years of age. It remains unknown how PFO closure compares to systemic anticoagulation (e.g., with novel OACs) for the prevention of recurrent ischemic stroke.

AORTIC ARCH DISEASE

An overlooked but a potentially serious source of embolic stroke is the aortic arch, especially when proximal aortic atheromatous disease is present. Large (>4 mm) and mobile plaques have a definite embolic potential. The stroke mechanism in patients with large or complex aortic plaques is believed to be predominantly thromboembolic. Aortic embolic disease manifests in different forms, including mobile and ulcerated plaques, aortic dissection, and aneurysms. Patients who have ascending aorta or proximal arch plaques of 4 mm thickness are up to seven times more likely to have cerebral infarction than controls (14.4% vs. 2%; $p <0.001$).³⁷ For nonmobile aortic plaque, statin therapy may be protective in preventing stroke,³⁸ whereas uncertainty remains about whether aspirin or warfarin is the optimal antithrombotic therapy for mobile plaques. Recently published ARCH trial³⁹ results suggest that in general, patients with stroke or TIA with aortic arch atherosclerosis should be treated with antiplatelet therapy rather than warfarin.

MYOCARDIAL INFARCTION, LEFT VENTRICULAR DYSFUNCTION, AND HEART FAILURE

Myocardial infarction and associated ventricular wall immobility lead to cardiomyopathy resulting in left ventricular thrombus formation and subsequent cardioembolic stroke. Cardioembolic strokes may occur within 1 day of myocardial infarction, and approximately half occur within the first week, although stroke risk remains high up to 3 months and then decreases gradually.^{40,41} Anterior wall myocardial infarction bears a higher risk for stroke than inferior wall myocardial infarction (25% vs. 5%). Management of patients who have experienced myocardial infarction with heparin for coronary disease helps decrease the risk for ventricular wall thrombus formation. TEE is the preferred test for detecting left ventricular wall and apical thrombi. Patients who experience anterior wall myocardial infarction and are found to have ventricular wall thrombus should be prescribed warfarin, with the goal of attaining an INR of 2.0–3.0 for up to 6 months, thereafter,

aspirin therapy may be given. Prolonged anticoagulation decreased stroke risk up to 40% over 3 years in the ASPECT (Anticoagulants in the Secondary Prevention of Events in Coronary Thrombosis) trial,⁴¹ although major bleeding complications were increased. If AF develops after myocardial infarction, anticoagulation may be considered indefinitely depending on other ischemic stroke risk factors, such as age more than 70 years, hypertension, heart failure, diabetes, and stroke, as per the CHADS-VASc Score.^{10-12,17}

DILATED CARDIOMYOPATHY

Dilated cardiomyopathy is associated with different causes (ischemic and nonischemic, infectious, and infiltrative). The Study of Left Ventricular Dysfunction (SOLVD)⁴² elucidated the relation between risk of embolic stroke and worsening ventricular function. In this study, warfarin and aspirin were associated with a lower rate of death or hospitalization due to heart failure than aspirin; however, only warfarin reduced death from worsening heart failure. Although, embolic stroke risk doubles when left ventricular ejection fraction (LVEF) declines below 28% compared with 35%, patients also benefit from aspirin alone (56% relative risk reduction in Survival and Ventricular Enlargement (SAVE),⁴³ without the bleeding complications. The Warfarin and Aspirin Therapy in Chronic Heart Failure trial (WATCH)⁴⁴ compares aspirin 160 mg/day, clopidogrel 75 mg/day, and warfarin (INR, 2.5–3.0) in 4,500 patients who had poor left ventricular function. Results showed that warfarin reduced nonfatal stroke compared with aspirin and clopidogrel ($p < 0.05$), but the combined end point of nonfatal myocardial infarction or stroke and death did not reach statistical significance ($p < 0.21$). The WARCEF trial (Warfarin Versus Aspirin in Patients With Reduced Cardiac Ejection Fraction)⁴⁵ compares the efficacy of warfarin (INR, 2.5–3.0; target, 2.75) versus aspirin (325 mg/day) on all-cause mortality and stroke (both ischemic and hemorrhagic) in patients who have LVEF of 35% or less. However, there was no significant overall difference in the primary outcome between treatment with warfarin and treatment with aspirin. A reduced risk of ischemic stroke with warfarin was offset by an increased risk of major hemorrhage. Therefore, as per the available data, warfarin did not provide an overall benefit and was associated with an increased risk of bleeding, there is no compelling reason to use warfarin rather than aspirin in patients with a reduced LVEF who are in sinus rhythm.

VALVULAR HEART DISEASE^{46,47}

Aortic Stenosis

In calcific aortic valve disease, clinically symptomatic cerebral embolic events are less common, unless concomitant AF, reduced LVEF, or mitral valve disease is present. Calcific emboli to the retina (i.e., asymptomatic emboli) or after valvuloplasty are reported. Antiplatelet therapy may be initiated in patients with TIA and bicuspid calcific aortic stenosis, but anticoagulation is generally not recommended.

Mitral Valve Stenosis

Mitral valve stenosis due to rheumatic heart disease with or without AF is an indication for warfarin anticoagulation, with INR ranging between 2.0 and 3.0, to prevent thromboembolic events (cerebral and systemic). Anticoagulation is recommended in some patients with mitral valve stenosis without AF and evidence of spontaneous echo contrast (SEC) ("smoke") within a large left atrium (>5.5 cm). In these patients, valvuloplasty may be attempted after a sufficient duration of anticoagulation.

Mitral Annular Calcification

Mitral annular calcification (MAC) not only denotes simply calcification of the mitral annulus, but also a syndrome characterized in elderly patients by a calcified mitral annulus, mitral stenosis or regurgitation, aortic stenosis, conduction disturbances, embolic phenomenon, and even endocarditis. Antiplatelet agents are reasonable first-line therapy, but if recurrent embolic events occur or AF develops, anticoagulation or valvular repair should be considered.

Mitral Valve Prolapse

Mitral valve prolapse (MVP) is the most common echocardiographic finding in normal individuals (4–6%). Palpitations or chest pain may be observed in symptomatic individuals. MVP is typically a benign echocardiographic finding and not associated with increased stroke risk unless it occurs in combination with MAC, mitral regurgitation, or AF. Antiplatelet agents remain first-line therapy, but anticoagulation is considered for recurrent cerebral ischemic events or MVP associated with AF or another embolic risk factor.

Prosthetic Cardiac Valves

Antithrombotic therapy depends on the type and location of the prosthetic valve and the presence of AF. For metallic valves, warfarin anticoagulation is typically recommended to attain a target INR ranging from 2.5 to 3.5. Prosthetic valves in the mitral position are associated with a higher thrombotic risk than those in the aortic position. Patients who have a bileaflet aortic valve without AF or left ventricular dysfunction should be prescribed warfarin to achieve a target INR ranging from 2.0 to 3.0. In patients with higher risk, aortic bileaflet valves, mitral bileaflet, or caged disc location in association with AF, warfarin with INR intensity of 2.5–3.5 and aspirin, 81–100 mg/day, may be given. Bioprosthetic valves complicated by thrombus formation, AF, or thromboembolism failing antiplatelet therapy may require warfarin anticoagulation with an INR ranging from 2.0–3.0.

Nonbacterial Thrombotic Endocarditis

Nonbacterial thrombotic endocarditis (NBTE), or marantic endocarditis, is a noninfectious process affecting normal or degenerative cardiac valves caused by fibrin thrombi deposits in patients with hypercoagulable states associated

with adenocarcinomas of the lung, colon, or pancreas that produce mucin.⁴⁸ Patients with NBTE may present with arterial and VTE and disseminated intravascular coagulation. Heparin, but not warfarin, has provided benefit⁴⁸ and helped treat the underlying neoplastic disorder. Libman-Sacks endocarditis is a noninfectious valvular abnormality associated with autoimmune disorders, such as systemic lupus erythematosus and the antiphospholipid antibody syndrome. No large-scale randomized trials exist to provide evidence-based data; however, some experts recommend anticoagulation with warfarin as primary treatment to prevent stroke.⁴⁹

Infectious Endocarditis

Before the advent of antibiotics, infectious seeding of heart valves or endocarditis was associated with a very high rate of cerebral embolism (70–90%), which decreased (12–40%) with the advent of antibiotics.^{7,50} Based on the blood culture results, specific antibiotic therapy for endocarditis remains the first-line treatment, whereas anticoagulation remains controversial or contraindicated⁴⁸ given the early rates of cerebral hemorrhage and the fact that anticoagulation does not decrease the incidence of embolism in native valve endocarditis. However, patients who have mechanical prosthetic valves may be at higher risk if anticoagulation is discontinued. Prosthetic valve endocarditis may be considered an anticoagulation dilemma, because patients have equal risks for ischemic stroke and cerebral hemorrhage, considering the patient's valve type, location, and presence of AF in weighing the ischemic and hemorrhagic risks.

Infective endocarditis of a prosthetic heart valve warrants early surgical consultation. Surgical replacement of an infected prosthetic valve presents a high risk for morbidity and mortality, especially for mitral position valves. Surgical removal or repair is considered for patients who have congestive heart failure, cardiac abscess, or persistently positive blood cultures despite antibiotic treatment. Early surgery is also warranted in fungal endocarditis.

Cardiac Tumors⁵¹⁻⁵³

Primary cardiac tumors are rare (<0.2% in unselected autopsy series), and most are benign (50% myxomas and papillary fibroelastoma) but associated with a high frequency of embolic events. Myxomas commonly occur in the left atrium and arise from the interatrial septum. They may embolize to the systemic circulation, particularly to the brain when tumor pieces break off or secondary thrombus formation occurs. TEE is invaluable in defining tumor location, size, and morphology. To prevent embolization, surgical resection of the tumor is recommended in all cases of myxomas. Papillary fibroelastomas are benign tumors that tend to originate on cardiac valves as single or multiple masses. Embolic events are typically the first clinical manifestation, because they are present on highly mobile valve leaflets. The embolic mechanism is the same as myxomas, caused by tumor fragmentation or secondary thrombus generation. Surgical resection is also indicated for fibroelastomas. Metastatic

tumors to the heart are 20–40 times more frequent than primary cardiac tumors, which are rare (e.g., angiosarcoma and rhabdomyosarcoma). Cerebral embolization can also occur from these tumors. Surgical treatment can be offered but depends on the underlying tumor type and prognosis.

Left Atrial Thrombus and Spontaneous Echo Contrast (“Smoke”)^{46,47,54,55}

Risk factors for left atrial appendage thrombus formation include AF, mitral stenosis, severe left ventricular dysfunction, left atrial dilatation, or presence of a prosthetic mitral valve. Demonstration of a left atrial appendage thrombus on TEE is associated with a threefold increase in the risk for stroke. SEC is defined as a smoke-like echo density moving within the cardiac chamber, typically the left atrium or left ventricle in LV dysfunction, indicating stagnant blood flow. TEE best visualizes SEC in the left atrium. The presence of SEC is a predisposing factor to thrombus formation and risk for ischemic stroke by three-to-fourfold. Oral anticoagulation decreases the stroke risk associated with SEC. Therefore, prophylactic anticoagulation is recommended for at least 3 weeks before electrical cardioversion for AF.

CONCLUSION

The past decade has seen extraordinary advances in the treatment and prevention of stroke. The magnitude and nature of the early benefits of immediate aspirin for TIA and ischemic stroke are recognized. AF is so common, and the default should be to offer stroke prevention to all AF patients unless deemed to be at low risk. Risk stratification is also not a “one off” assessment but a dynamic process, reflecting the elderly AF population with a high rate of hospitalizations, comorbidities, and polypharmacy. The advent of direct OACs has increased the uptake of effective anticoagulant thromboprophylaxis among patients with AF at high risk of recurrent cardioembolic stroke. The key to preventing recurrent stroke is to identify the cause of the initial event so that therapy can be individualized to the patient. While the vascular risk factors should be treated in all patients, anticoagulation and PFO closure would be appropriate in only some patients. Modification of risk factors is the main resource for effective prevention of stroke. Many therapeutic options are available at present, and continued research efforts are expanding the available options. A multidisciplinary approach with organized continued education will likely improve the efficacy of these measures. In the near future, studies embarking on the evaluation of the genetic determinants of cerebrovascular risk factors and outcomes will increase our understanding of cerebrovascular disease and will likely result in new therapies, with individualized programs for stroke prevention.

Stroke in Cath Lab

Neeraj Parakh, Kewal C Goswami

INTRODUCTION

Stroke is an uncommon complication in modern cardiac catheterization laboratories (Cath lab). To a large extent this is an avoidable complication, if basic diktats of catheterization are strictly followed. However, it is one of the most debilitating complication resulting in high incidence of mortality and morbidity.

INCIDENCE

Incidence of stroke in cath lab within 36 hours is <0.01% for diagnostic procedures and 0.1–0.4% for therapeutic procedures. As per Euro Heart Survey, incidence of stroke in cath lab for elective percutaneous coronary intervention (PCI) is 0.3% and the same is 0.6% for PCI in acute coronary syndrome. Higher incidence of stroke has been reported for valve interventions and for atrial fibrillation ablation. Asymptomatic embolism has been reported in 2–22% of cases in various studies. Thirty-day mortality for stroke in cath lab is up to 19% for ischemic stroke and up to 50% for hemorrhagic stroke.¹

MECHANISM AND RISK FACTORS

Embolization of clot/thrombus is the commonest cause for ischemic stroke in cath lab. Thrombus may form over wires, catheters, etc., especially if anticoagulation is not appropriate. Plaque or atherosclerotic material may get dislodged from aorta or arch vessels during catheter or wire manipulation.² Embolization of valve tissue or other material may rarely cause stroke.³ Various reasons for ischemic stroke in catheterization laboratory are as follows:

- Thrombus
- Calcific material
- Plaque/cholesterol particles
- Clot dislodgement from left ventricle (LV)/left atrium (LA)
- Air embolism
- Broken hardware

TABLE 1: Risk factor for ischemic stroke

Patient-related factors	Procedure-related factors
Older age >75 years	Emergent procedure
Diabetes	Prolonged procedure
Hypertension	Greater contrast use
Previous stroke	Retrograde catheterization of left ventricle in aortic stenosis
Renal failure	Bypass graft intervention
Heart failure	Intra-aortic balloon pump
Atherosclerotic burden such as triple-vessel disease	Coronary artery thrombus

BOX 1 Risk factor for hemorrhagic stroke

Risk factors

- Thrombolytics, Gp IIb/IIIa, anticoagulants, antiplatelets
- Age >75 years
- Female gender
- Low-body weight
- Systolic blood pressure (BP) >160 mm Hg
- Black race
- Acute coronary syndrome

- Periprocedural hypotension
- Arterial dissection
- Valve tissue

Hemorrhagic stroke is usually attributed to the use of thrombolytics, anticoagulation, Gp IIb/IIIa inhibitors, and antiplatelets. Risk factors for stroke are mentioned in table 1 and box 1.

PRESENTATION

Clinically, most of the strokes present either during the procedure or within 24 hours of the procedure. Common presenting complaints are visual disturbance, aphasia, dysarthria, hemiparesis, and altered mental status. Ischemic strokes present with maximal deficit at the onset and a fluctuating course thereafter, while hemorrhagic stroke

presents with gradual worsening and raised intracranial pressure. Clinical features and focal deficit corresponds to the affected vascular territory. Nonfocal encephalopathy as presenting feature indicates diffuse bilateral infarcts.

EVALUATION

An immediate evaluation by a neurologist or stroke team for a focused history and examination should be the first step. Basic ABC (airway, breathing, circulation) for the management of critically ill patients should be followed. Hypoglycemia remains an important differential diagnosis, especially in diabetic patients. Determination of symptom onset is very important in planning for thrombolysis or mechanical intervention in case of ischemic stroke. Noncontrast computed tomography (CT)/magnetic resonance (MR) and concurrent neurovascular imaging should be performed immediately after the basic neurological examination for determining the type and localization of the lesion. CT or MR perfusion imaging is required only for uncertain diagnosis.

Differential Diagnosis

The differential diagnosis of stroke in cath lab includes transient ischemic attack, seizure disorder, migraine, encephalopathy, and hypoglycemia. Use of sedatives during the procedure or comorbid medical or neurologic conditions may confound the accurate diagnosis of stroke. Contrast-induced transient cortical blindness is another rare occurrence with use of contrast media.⁴ Blurring of vision starts within minutes of the procedure and rapidly progresses to complete blindness, usually associated with headache. Vomiting, confusion, aphasia, memory impairment, and limb weakness may also be present. A CT scan done immediately after the symptom onset shows extravasation of the dye into the subarachnoid space and brain tissue in the posterior third of the brain. This at times is mistaken for subarachnoid hemorrhage. In nearly all cases, the neurologic impairments and neuroimaging abnormalities gradually resolve over days. Postulated mechanisms include direct neurotoxic effect, idiosyncratic reaction, microembolization, hypoxia, edema, and endothelin release (large volumes of radiocontrast is associated with elevated endothelin levels and endothelins have been implicated in posterior leukoencephalopathy).

TREATMENT

Hemorrhagic Stroke

Basic principle of treatment of hemorrhagic stroke is the reversal of anticoagulation, blood pressure control, treatment of raised intracranial pressure, and supportive treatment.

Ischemic Stroke

Given the rarity of stroke in cath lab, there are no randomized studies regarding revascularization in these patients. Usually, the guidelines for stroke in general population are also followed in case of stroke in cath lab (Boxes 2 and 3). Specific therapy for ischemic stroke includes the following:

BOX 2 rtPA in stroke—NINDS inclusion criteria

Inclusion criteria

- Clinical diagnosis of ischemic stroke causing measurable neurologic deficit
- Onset of symptoms <4.5 hours before beginning treatment; if the exact time of stroke onset is not known, it is defined as the last time the patient was known to be normal
- Age ≥18 years

rTPA, recombinant tissue plasminogen activator; NINDS, National Institute of Neurological Disorders and Stroke.

BOX 3 rTPA in stroke—NINDS exclusion criteria

Exclusion criteria

- Historical
 - Stroke or head trauma in the previous 3 months
 - History of intracranial hemorrhage
 - Intracranial tumor, arteriovenous malformation, or aneurysm
 - Recent neurosurgery
 - Noncompressible arterial puncture in the previous week
- Clinical
 - Symptoms suggestive of subarachnoid hemorrhage
 - Persistent blood pressure elevation (systolic ≥185 mm Hg or diastolic ≥110 mm Hg)
 - Hypoglycemia (serum glucose <50 mg/dL)
 - Active internal bleeding
 - Acute bleeding diathesis
- Hematologic
 - Platelet count <100,000 mm⁻³
 - Current anticoagulant use with an international normalized ratio (INR) >1.7 or prothrombin time (PT) >15 seconds
 - Heparin use within 48 hours and an abnormally elevated activated partial thromboplastin time (aPTT)
 - Current use of a direct thrombin inhibitor or direct factor Xa inhibitor
- Head CT scan
 - Evidence of hemorrhage
 - Irreversible injury
- Relative exclusion criteria
 - Only minor and isolated neurologic signs
 - Rapidly improving stroke symptoms
 - Major surgery or serious trauma in the previous 14 days
 - Gastrointestinal or urinary tract bleeding in the previous 21 days
 - Myocardial infarction in the previous 3 months
 - Seizure at the onset of stroke with postictal neurologic impairments
 - Pregnancy
- Additional relative exclusion criteria for treatment from 3 hours to 4.5 hours from onset
 - Age >80 years
 - Oral anticoagulant use regardless of INR
 - Severe stroke (NIHSS score >25)
 - Combination of both previous ischemic stroke and diabetes mellitus

CT, computed tomography; NIHSS, National Institutes of Health Stroke Scale; rTPA, recombinant tissue plasminogen activator; NINDS, National Institute of Neurological Disorders and Stroke.

- Intravenous thrombolysis—within 4.5 hours
 - Intra-arterial thrombolysis
 - Intra-arterial mechanical thrombectomy—within 6 hours
- Treatment of acute stroke after cardiac catheterization (TASCC) registry included 66 cases of ischemic strokes from seven major North American academic centers. Twelve (18%) of these patients were treated with thrombolysis by recombinant tissue plasminogen activator (rTPA) (seven intravenous and five intra-arterial).

Thrombolysed patients had better National Institutes of Health Stroke Scale (NIHSS) score from baseline to 24 hours as compared to nontreated cases ($p < 0.001$). There was no significant difference in bleeding events and mortality rates were also similar. This data suggests that emergent cerebral revascularization should be a routine consideration.⁵

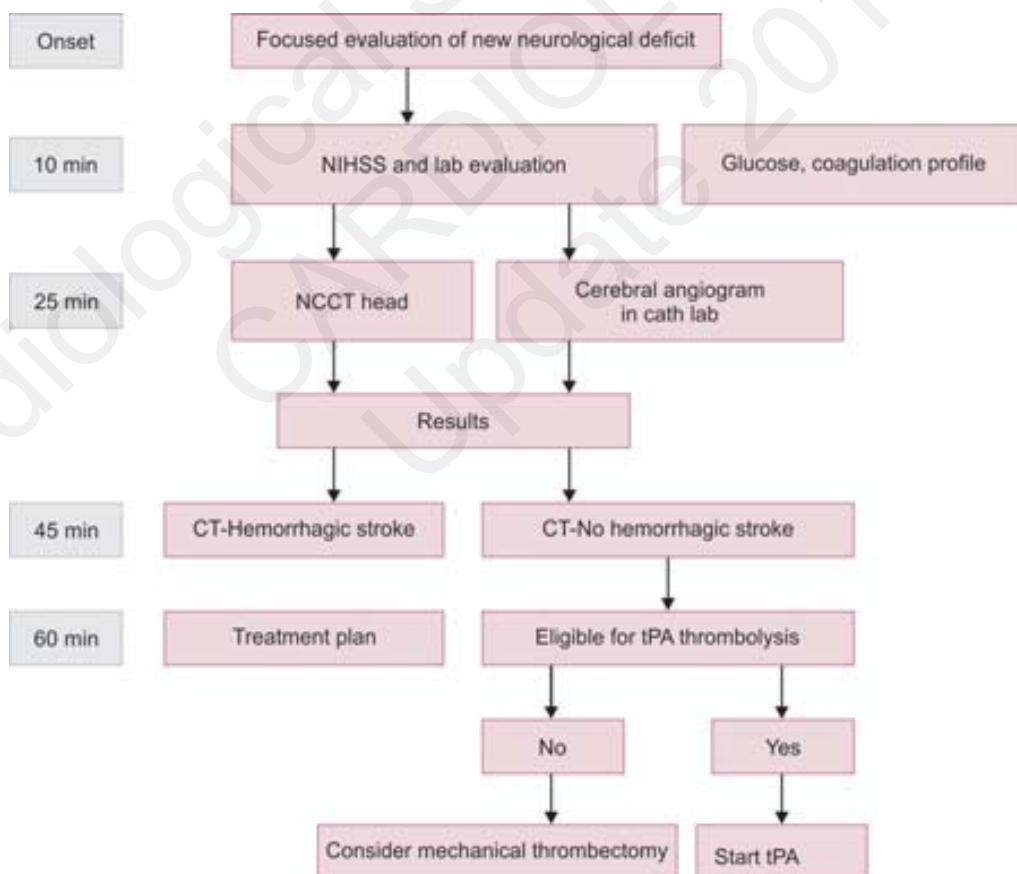

Thrombolysis in Stroke (Flowchart 1)

Intravenous tissue plasminogen activator (tPA) is initiated within 4.5 hours of clearly defined symptom onset (at a dose of 0.9 mg/kg, not exceeding 90 mg, given as a 10% bolus followed by continuous infusion of the remaining 90% over 60 minutes), followed by adjunctive endovascular therapy in patients with large vessel occlusions. In case of ischemic stroke due to large artery occlusion in the proximal anterior

circulation, intra-arterial mechanical thrombectomy using a second-generation stent retriever device should be initiated within 6 hours of symptom onset. Intra-arterial tPA (20–40 mg) should be initiated in the 4.5- to 6-hour time window in patients otherwise eligible for tPA (but not eligible for mechanical thrombectomy). Intra-arterial tPA requires infrastructure and expertise. Doses of tPA required in intra-arterial thrombolysis are much lower than intravenous tPA. Before starting thrombolysis, normal activated partial thromboplastin time (aPTT) should be documented if heparin was administered within 48 hours. Protamine can be used to reverse the effect of heparin. For patients with a prolonged aPTT, endovascular therapies with intra-arterial tPA and/or mechanical embolectomy are treatment options. Gp IIb/IIIa inhibitor therapy may increase the risk of hemorrhagic complications with intravenous tPA. In such cases, endovascular interventions are treatment options. Antiplatelet therapy is not a contraindication to intravenous tPA.⁶

Stroke during Transcatheter Aortic Valve Replacement

Transcatheter aortic valve replacement (TAVR) has become the latest treatment option for high-risk patients with aortic stenosis (AS). Incidence of stroke has been one of the main

NIHSS, National Institutes of Health Stroke Scale; tPA, tissue plasminogen activator; CT, computed tomography; NCCT, Non Contrast Computed Tomography

FLOWCHART 1: Stroke algorithm.

concerns associated with TAVR. In the PARTNER I trial comparing TAVR and surgical valve replacement, stroke rates were higher after TAVR.⁷ Periprocedural stroke leads to a five times higher incidence of death after TAVR.⁸ Transcatheter aortic valve registry reported overall stroke rate of 2% during hospital stay. Up to 50% of all strokes during TAVR happen during first 24 hours after the procedure.⁹ Embolic protection devices (EPDs) are emerging as a promising approach to decrease the incidence of stroke during TAVR. A reduction in the frequency of ischemic lesions has been seen; however, more research and trial data are required before their routine clinical use is established. At least three EPDs (Sentinel, Embrella, TriGuard) are under evaluation and preliminary results are encouraging.¹⁰

CONCLUSION

Each cath lab should set up a stroke protocol. Time is brain, so this inevitable complication should be handled expeditiously in cath lab.¹¹ Prevention strategy, such as adequate flushing of lumened catheters and balloons is a must, to keep the system air-free. Adequate heparinization and frequent neuro-checks should reduce the stroke incidence to a minimum. Routine intra-arterial thrombolysis is not recommended over intravenous therapy, but the judgment should be left to the consulting stroke team depending upon the need, infrastructure, and expertise. Stroke in cath lab remains the most treatable neurological conditions, and expeditious use of the stroke protocol is the fastest, safest, and most effective way to manage such patients.

SECTION **20**

Peripheral Vascular Disease

Varicose Veins: Interventional Approach

Sanjeev Kumar, Vineeta Ojha

INTRODUCTION

Chronic venous insufficiency (CVI) is characterized by insufficient venous return to the heart, is related primarily to retrograde flow in lower extremity veins (venous reflux). Chronic venous insufficiency and reflux are usually caused by valvular incompetence, which may or may not be associated with venous obstruction. Patients may present with symptoms ranging from spider veins or telangiectasias to varicose veins, lipodermatosclerosis or venous ulcers. Fifteen percent of the men and 25% of the women suffer from varicose veins and in most of them, it appears by 30 years of age.^{1,2} The current challenge in front of us is to provide the patients an effective treatment strategy for symptoms related to venous reflux that is associated with low recurrence rates, lesser recovery time, less morbidity, and visibly better outcomes. The past two decades have witnessed the development of some minimally invasive strategies that achieve these goals.

ANATOMY AND PATHOPHYSIOLOGY

The major superficial veins of the legs are the short saphenous vein (SSV), which runs in the posterior compartment and the great saphenous vein (GSV), which runs from ankle to groin in medial compartment. Superficial veins communicate with deep veins of the leg via multiple perforating veins which pass through openings in the deep fascia. The main deep vein of the leg is the popliteal vein until it courses upward into the thigh and becomes the femoral vein (FV) (Fig. 1). The veins have valves which are one way and prevent retrograde flow. When these valves start malfunctioning, there is backward flow of blood into these veins. Major valves whose dysfunctions cause varicose veins are saphenofemoral junction (SFJ) and saphenopopliteal junction (SPJ). The major risk factors for causation of varicose veins are: female hormones, family history, gravitational forces (more in pregnant patients), and hydrostatic forces in the muscular compartments of the legs.¹

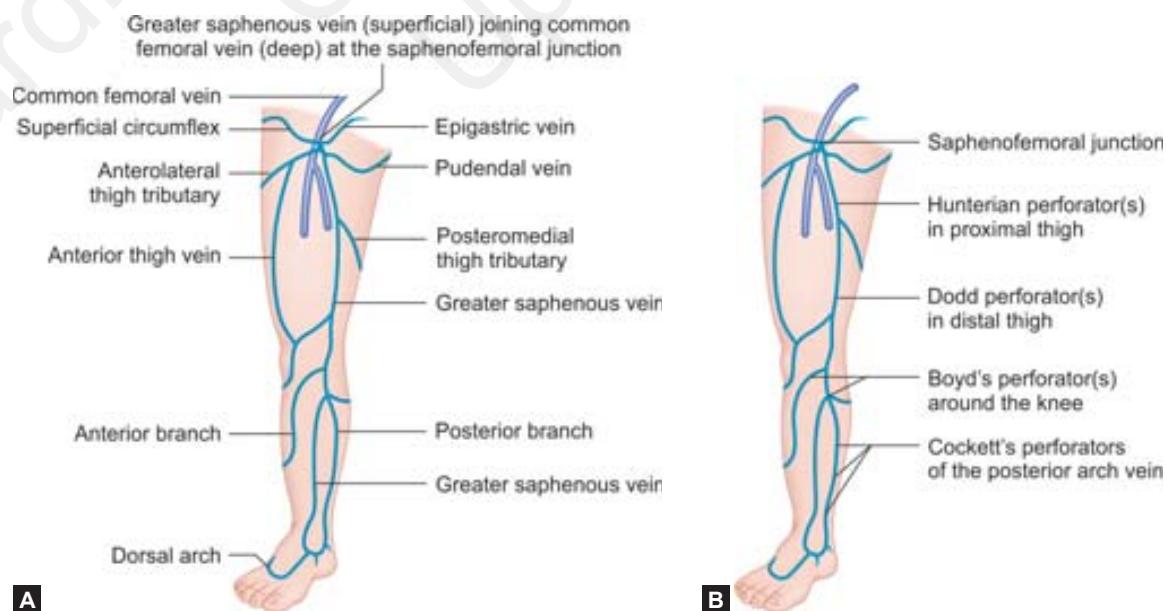

FIG. 1: Anatomy of superficial venous system. A, Superficial veins of the leg; B, Perforators.

NATURAL HISTORY

Literature on the natural history of lower extremity varicosities show that, at a mean follow-up of 19 months, 73% of limbs remain stable, 11% develop worsening clinical stage, and a few percent more develop worsening reflux on duplex ultrasound without associated symptomatic progression.³ In normal individuals, the progression of chronic venous disease (CVD) is slow. Poor prognostic factors for progressive CVD include the combination of both reflux and obstruction, recurrent deep venous thrombosis (DVT), and multisegmental disease.⁴

CLASSIFICATION

To standardize the treatment and reporting of the chronic venous disorders, a dedicated classification (CEAP) has been proposed to help in diagnosis and comparison of varied manifestations of CVD. It was developed by a committee of the American Venous Forum in 1994 and it was subsequently accepted as a standard for classifying CVD. The basic CEAP classification gives a brief description of the clinical class of the CVD (C) based upon the symptoms, the etiology (E), the anatomical (A) distribution, and the underlying pathophysiology (P), whether reflux or obstruction. Clinical classification is shown in table 1.

TABLE 1: Clinical classification of chronic venous disorders

CEAP classification	
C—Clinical	Description
C0	No visible or palpable signs of venous disease
C1	<ul style="list-style-type: none"> • Spider veins ("telangiectasias") (<1 mm in diameter) • Reticular veins ("venulectasias") (1 to <3 mm in diameter)
C2	Varicose veins (3 mm or larger in standing position)
C3	Venous edema; corona phlebectatica ("ankle flare")
C4	<ul style="list-style-type: none"> • Skin changes ascribed to venous disease • C4a: Eczema ("stasis dermatitis") or brownish hyperpigmentation • C4b: Lipodermatosclerosis or atrophie blanche
C5	Healed ulcer (and skin changes as described above)
C6	Active ulcer (and skin changes as described above)
E—Etiological	
Ec	Congenital
Ep	Primary
Es	Secondary (post-thrombotic)
En	No venous cause identified
A—Anatomical

Ap	Perforator veins
Ad	Deep veins
An	No venous location identified
P—Pathophysiological	
Pr	Reflux
Po	Obstruction
Pr, o	Reflux and obstruction
Pn	No venous pathophysiology identifiable

INDICATIONS FOR TREATMENT

Indications for treatment include symptoms from uncomplicated varicose veins and complications from varicose vein disease. Uncomplicated varicose veins are associated with a variety of symptoms: pain/aching, fatigue/heaviness, itching/burning sensation, leg cramps, calf/ankle swelling, restless legs, and leg warmth.⁵ Complications include blood stasis in the varicosities with subsequent superficial phlebitis, progression of disease, and rarely, variceal bleeding. The CEAP class C3 to C6 are actively treated and sometimes C2 class is also treated because of esthetic reasons. Decision to treat is based on four major concerns: symptoms, reflux, concerns for future worsening and complications, and lastly, unesthetic appearance of varices.

TREATMENT OPTIONS FOR VARICOSE VEINS

The approach is determined by anatomy and the clinical status of the patient. Therapy needs to be targeted to the veins that are actually the source of the problem whether it is the GSV, SSV, perforators, or accessory veins. The therapeutic approach will also be determined in large part by the size and morphology of the specific veins to be treated. The traditional

gold standard is a flush ligation of GSV at SFJ, followed by stripping of the GSV. Surgery of varicose veins is usually performed under anesthesia and might cause neurological damage (7–40%), scars, hematoma, and postoperative pain.^{6–8} Though surgery is very effective in short term, 5-year recurrence rates are approximately 30% for GSV and 50% for SSV.⁹ There are multiple minimally invasive therapies that can be applied to venous reflux disease as discussed subsequently.

Evaluation before Treatment

- **Clinical:** A thorough history should include duration and types of symptoms and history of DVT, any prothrombotic condition and prior treatments. Treatment should not be done in the setting of acute DVT. Physical examination should include the evaluation of the arterial system, signs of CVD, and size and location of patient's varicosities. The CEAP score is determined for each patient
- **USG Doppler:** Doppler evaluation of venous system should be done in details. Points to be evaluated are SFJ, SPJ incompetence or reflux or transient reflux (criteria to intervene), diameter of SFJ or SPJ [more than 3 mm are usually amenable to endovenous laser ablation (EVLA) or radiofrequency ablation (RFA)], superficial dilated varicosities in the legs, sites of incompetent perforators, presence of DVT (contraindication to thermal-based therapy), etc. In addition to the superficial, deep and perforator veins, attention should be paid to accessory veins too, like anterior accessory vein, vein of Giacomini, etc. which also serve as a source of venous reflux
- **Preprocedure steps:** After medical history and clinical as well as Doppler evaluation, informed consent needs to be taken. Patients must be told about the likely complications and the likely need for more than one session. Adequate hydration needs to be ensured. Intravenous (IV) cannula should be in place for all the patients, if need arises, premedication in the form of injection Emeset and IV Tramadol can be administered to the apprehensive patients.

INTERVENTIONAL APPROACH TO MANAGEMENT OF VARICOSE VEINS

Minimally Invasive Options

To increase the effectiveness and patients' health-related quality of life (HRQOL) and to reduce postoperative time, therapy-related complications and costs, newer minimally invasive methods such as ultrasound-guided foam sclerotherapy (UGFS), EVLA, and RFA are now widely used in the treatment of lower extremity varicosities. Venous ablation using n-butyl cyanoacrylate (NBCA) is a newer technique that does not require tumescent anesthesia (TA) or compression.

USG-guided Foam Sclerotherapy

Sclerotherapy is the method using the biological, physical, and chemical properties of an agent used to damage the

target vessel. First described in 1939, foam sclerotherapy has recently increased in popularity.¹⁰

Mechanism of Action

Sclerotherapy causes endothelial damage by selective intravascular delivery of a sclerosant into an intravascular space that exerts its injury by direct contact with endothelium in a dose-dependent way. Other than fibrosis, agents might produce other effects like denaturation of proteins, thrombosis, cell dehydration, osmosis, and physical obstruction due to polymerization. Therapeutic effect of sclerotherapy is dependent on the choice of agent, the sclerosant concentration *in vivo*, and the duration for which the sclerosant is in contact with endothelium, also called "dwell-time".

Sclerosing Agents

The salient features of various sclerosing agents are summarized in table 2.¹¹ Sodium tetradecyl sulfate (STS) and polidocanol are the most widely used sclerosants. Allergy to the sclerosant, infection, DVT, and severe arterial disease are the major contraindications to sclerotherapy.

Procedure

It is performed in an angiography suite with USG facility. No sedation is required in most cases, however, if patient is apprehensive, conscious sedation or local nerve block is recommended. A tourniquet may be tied proximally for proper distension. Percutaneous introduction of butterfly needle into the varicosity is done under ultrasound guidance till free backflow of blood is observed. Further, venography is performed during gentle contrast injection and stopped as soon as deep vein is seen to fill and contrast amount is noted. Same amount of sclerosant foam is injected slowly into the vein. There are two main techniques of foam preparation: Tessari, and Monfreux. The Tessari method has become the more popular technique (Fig. 2). The foam, thus formed, displaces blood from the vein to be treated and persists in the vein to maximize its sclerosant effect (Fig. 3). Some authors also advocate aspirating the contrast before introducing the sclerosant to prevent more dilution. If there are signs of extravasation, in the form of induration or skin blanching, injection of sclerosant is stopped immediately. Compression at the SFJ during the procedure can be done to prevent passage of sclerosant into deep venous system. Local compression for 5–10 minutes is applied after injection. Staged sclerotherapy can be done 6–8 weeks apart.^{11–13} Parsi et al. recommended a novel approach for saphenous vein ablation, i.e., catheter-directed sclerotherapy, in which access to GSV can be gained at knee or ankle, and catheter is advanced till 5 cm proximal to SFJ. Tumescent anesthesia is applied in perivenous plane. Foam is injected while catheter is withdrawn.¹⁴

Complications

Minor local complications are pain, swelling, reddish discoloration, hyperpigmentation, and telangiectatic matting (~16%). Other complications are juxtalesional skin necrosis, thrombophlebitis, neuropathy, DVT (0–0.2%), compartment

TABLE 2: Sclerosing agents and their salient features

Agent	Salient features
Ethanol	<ul style="list-style-type: none"> • Most efficacious, lowest recurrence • Denudation and destruction of intima • Inexpensive • Highest complication rate (7.5–27.9%) very toxic, procedure always under general anesthesia • Skin necrosis—major complication • Other complications—adjacent nerve palsy, hemoglobinuria, acute pulmonary hypertension • Maximum dose—1 mL/kg (however, limited to 10 mL/session)
Sodium tetradecyl sulfate	<ul style="list-style-type: none"> • Thrombosis and obliteration of the vessel • Safer than ethanol—lower rates of skin and nerve damage • Maximum dose—3 mL of 3% solution
Polidocanol	<ul style="list-style-type: none"> • Anesthetic properties—painless procedure • Less degree of endothelial damage • Hemolysis and elevation of D-dimers—at high dose • Maximum dose—10 mL of 3% solution
Ethanolamine oleate	<ul style="list-style-type: none"> • Causes fibrosis and sclerosis in delayed manner • Less penetrative effect—less adjacent nerve injury • Maximum dose—1 mL of 5% ethanolamine solution
Bleomycin	<ul style="list-style-type: none"> • Indications—painful bleeding, ulcerated lesions • Maximum 15 mg per session
Doxycycline	<ul style="list-style-type: none"> • Cellular reaction with deposition of fibrin • Dose range 100–1,000 mg per session

FIG. 2: Tessari technique: A syringe containing 1–2 mL of sclerosant is connected to a syringe containing 2 mL air via three-way stopcock. Twenty rapid passages are made.

syndrome, hemoglobinuria, pulmonary embolism, cardio-pulmonary collapse, etc. A complication specific to intra-vascular administration of ethanol is precapillary pulmonary arterial spasm with increase in the pulmonary arterial pressure and right heart failure rarely. Sustained pulmonary hypertension has been described in 30% of patients per ethanol administration, but does not have a long-lasting effect, and it does not correlate with the total dose given.¹⁵

Success Rates or Efficacy of Sclerotherapy

Success rates for sclerotherapy alone as in literature vary from 31 to 100%. O'Hare et al. published the results of UGFS for varicose veins. After 2 weeks, 93% of the major veins were

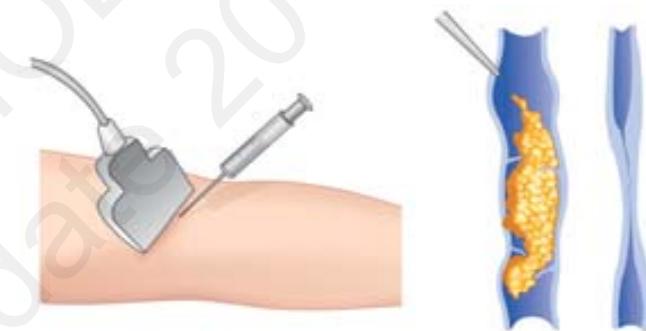

FIG. 3: Sclerotherapy technique.

totally occluded on Doppler examination. After 6 months, in 74% of the patients, the major veins remained occluded. No patient had DVT.¹⁶ In another study which included 453 patients with a follow up period of 3 years, sclerotherapy was done using the Monfreux and Tessari methods, immediate success rates were 88.1% and 93.3%, respectively.¹⁷

Thermal or Heat-based Therapies—RFA and EVLA

Radiofrequency Ablation

Radiofrequency ablation was approved by the United States Food and Drug Administration (US FDA) in 1999 (VNUS

FIG. 4: VNUS Medical Technologies, Inc. device components for radiofrequency ablation. The ClosurePlus catheter possesses a micro-thermocouple that continuously measures vein wall temperature and provides feedback to the VNUS radiofrequency generator. Delivery of radiofrequency energy via the Closure electrodes (inset) causes resistive heating of the vein wall resulting in vein shrinkage and occlusion.

Closure; VNUS Medical Technologies, CA), as a minimally invasive method to obliterate superficial veins with reflux. Later, ClosurePlus and ClosureFast devices have also been developed.

Mechanism of Action

With RFA, high-frequency alternating current is applied to the vein wall by direct contact of the prongs of the RFA catheter with the venous endothelial layer. This causes disruption of vessel wall architecture and carbonization of the vessel. Very little thrombus is formed and precise tissue destruction is achieved.¹² Since there is a need for the direct contact of the catheter prongs with the endothelium, the application of RFA may be limited to veins smaller than 12 mm (Fig. 4).

Technique

The target vein is accessed using USG guidance, generally at the knee for GSV, and above the ankle for SSV. Further, the RFA catheter advanced to approximately 2–3 cm below the SFJ under USG guidance, immediately below the superficial epigastric vein. Tumescent anesthesia (a combination of 30 mL 0.1% lidocaine, 2 ampoules of epinephrine, and 10 mL bicarbonate with 200 mL cold saline) is injected perivenously along the vein. Tumescent anesthesia serves multiple purposes: analgesia, prevention of heat injuries to skin and also, compression of the vein to improve contact between the catheter prongs and the endothelium. Electrodes are available in two sizes—6Fr and 8Fr. The 6Fr probe treats vessels up to 8 mm and the 8Fr probe can be used for vessels measuring 8–12 mm in diameter. Larger vessels can be treated using additional strategies like extreme Trendelenburg position, increased TA volume, applying Esmarch bandage, etc. Radiofrequency ablation is performed with an intraluminally introduced ClosureFast catheter with a heating element measuring 7 cm. Segmental energy is delivered in 20-second

cycles at a temperature of 120°C. In older RFA systems like VNUS, the temperature of probe was 85°C, and pullback rate was low (2.5–3 cm/min). During catheter withdrawal, impedance, temperature, and generator output should be monitored, to adjust the rate of withdrawal accordingly.¹⁸ After completing catheter withdrawal, ultrasonography is performed to assess the patency of deep veins and for success of closure. It is recommended that after the procedure, patients should use compression stockings for 2 weeks, and resume normal daily activities immediately. Follow-up USG at 24–48 hours postprocedure is performed to confirm the occlusion of treated vein and absence of DVT.

Complication

Endovenous heat-induced thrombosis (extension of thrombus in common FV) is considered a major complication of thermal treatment of varicose veins and its incidence varies from 0 to 5.7% in literature. Minor side effects are pain, bruising, ecchymoses, paresthesias, etc.¹⁹

Outcomes

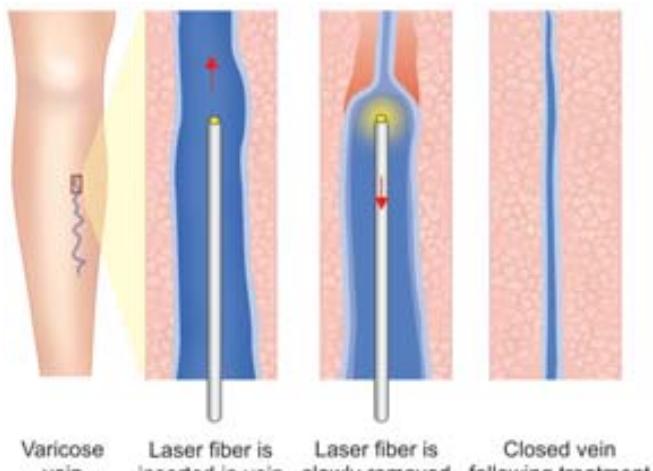

In a prospective multicenter study, review of 1,078 limbs in 890 patients was done at 1 week, 6 months, and 1, 2, 3, and 4 years. The vein closure rates were 91%, 88.8%, 86.2%, 84.2%, and 88.8%, respectively.²⁰ In a prospective, randomized controlled trial (RCT) comparing RFA and ligation with stripping (EVOLVeS Study), 2-year results showed RFA to be at least equivalent to surgery for GSV occlusion and that QOL scores were higher in RFA group at 2 years.²¹ The RECOVERY Study (RFA vs. Laser) established that RFA was superior to EVLA by a significant margin as measured by multiple parameters like postprocedure recovery duration and QOL parameters. All scores like that of pain, tenderness, and ecchymosis were statistically lower in the ClosureFast (RFA) group.²²

Endovenous Laser Ablation

Application of laser energy intraluminally to treat superficial venous reflux disease started to rise in popularity in the 1990s. It was approved by FDA in 2002 (Fig. 5).

FIG. 5: Endovenous laser ablation machine.

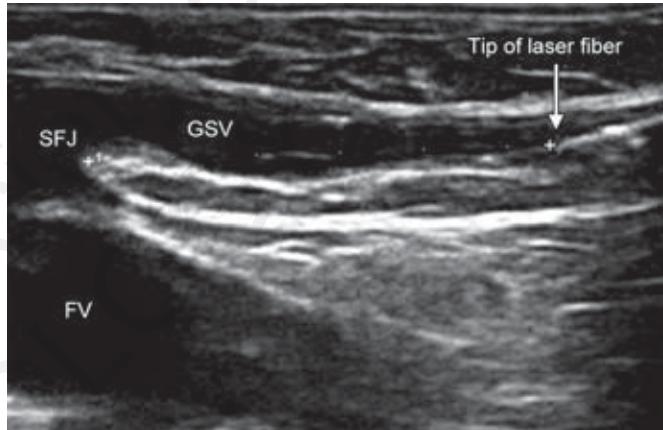

**FIG. 6:** Mechanism of action of endovenous laser ablation.

Mechanism of Action

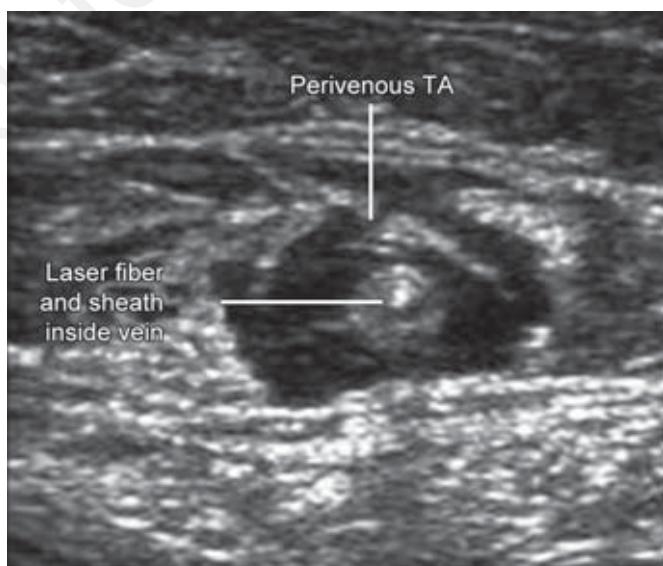

Endovenous laser ablation applies laser energy directly inside the vein which causes boiling of the blood inside the vein, and there is spread of these steam bubbles up to the vein wall which disrupts the vessel wall architecture.²³ Some authors argue that the heat produced by the steam is not sufficient to destroy the wall of the vein, and that it needs direct contact of the venous wall with the laser energy itself. Whichever theory is accepted, the final mechanism is that heating the vein wall leads to contraction of the collagen and endothelial destruction. The final result is the fibrosis of the vein (Fig. 6).²⁴

Technique

The patient is asked to lie down and is placed in reverse Trendelenburg position and GSV is accessed at the knee under USG guidance. A 5Fr sheath is introduced inside the vein over a guidewire. A laser fiber is then introduced through the sheath so that the tip lies approximately 2 cm below the SFJ. The location of the tip is confirmed on USG and the visible red beam through the skin. Laser fibers emitting energies at variety of wavelengths are available for, e.g., 810/940/980/1,320/1,470/1,560 nm. The one most commonly used at our institution is 1,470 nm fiber. After applying the TA in perivenous sheath, the GSV is treated in the pulsed mode or continuous mode at 6–12 watts of power. Pulsed mode has been shown to have a higher risk of adverse events than continuous mode Doppler. Hence, continuous mode is more commonly used. Radial endovenous energy density of 60–80 J/cm² is applied with simultaneous and gradual withdrawal of the catheter (Figs. 7 to 9). Higher wavelengths are associated with less postoperative pain and ecchymosis. Postprocedure patients wear compression stocking for 2 weeks, undergo follow-up USG at 48 hours, and resume normal daily activities almost immediately.^{12,23} A covered tip design of the laser fiber, which has been recently developed, prevents the bare tip to directly come in contact with the venous wall, which prevents perforation of the vein wall and subsequently reduces pain and bruising, but failure rate of this design is quite high. Deep venous thrombosis, an inability to move, target vein thrombus, severe arterial disease, and pregnancy are contraindications to EVLA.

**FIG. 7:** Endovenous laser ablation catheter and laser fiber.

FV, femoral vein; GSV, great saphenous vein; SFJ, saphenofemoral junction.

FIG. 8: The tip of the laser is visualized by ultrasonography imaging and is kept at least 2 cm away from saphenofemoral junction.**FIG. 9:** Perivenous tumescent anesthesia (TA).

Outcomes

Endovenous laser treatment (EVLT) has shown excellent results in early obliteration of GSV. A retrospective review of 130 limbs in 92 patients at Mayo Clinic demonstrated an immediate occlusion rate in GSV to be 100% and reinter-

vention rate of 0% in EVLT (vs. 17% in RFA).²⁵ A bigger trial evaluating 499 limbs demonstrated immediate obliteration rates of 98.2% in GSV and a 2-year success rate to be about 93.4%.²³ A meta-analysis also showed that results of EVLA are more effective than surgery, UGFS, and RFA.²⁶

Complications

Similar to RFA. Pain, bruising, and induration of the thigh are common adverse effects of EVLA as compared to RFA which may be due to laser-induced perforation of the venous wall and extravasation of blood into adjacent tissue.

Comparative outcomes of different modalities are summarized in table 3.

Glue

Endovenous cyanoacrylate closure (CAC) is a newer technique approved by the US FDA (2015). It is a nontumescent, nonthermal, nonsclerosant procedure which is used endovenously to permanently close the vein [VenaSeal; Sapheon, VariClose Vein Sealing System (VVSS); Biolas]. The glue used is NBCA.

Trials and Outcomes

Early evidence from two studies does support the efficacy and safety of CAC for treatment of refluxing GSV.^{22,29} Koramaz et al. published a retrospective study comparing CAC (VariClose) with EVLA for incompetent GSVs. The average procedure time and 1 year closure rates in the CAC and EVLA groups were 7 and 18 minutes and 98.6% and 97.3%, respectively. There was lesser incidence of adverse events after CAC (pigmentation and phlebitis).³⁰ First major randomized control trial evaluating CAC for varicose veins is VenaSeal Sapheon Closure System Study (VeClose Trial), a comparison of CAC versus RFA. Radiofrequency ablation was done with ClosureFast catheter. Out of 222 subjects, a 12-monthly follow-up was done for 192 subjects. At month 1, there was complete occlusion of vein in 100% of CAC patients and 87% of RFA patients. At month 12, both the groups showed nearly similar complete occlusion rates (97.2% in the CAC, 97 % in the RFA). Hence, occlusion is fast with CAC compared with RFA. Likelihood to recanalize was more in RFA group than the CAC group.³¹

TABLE 3: Intermediate and long-term success rates of endovenous therapies^{20,21,23,27,28}

Reference, year	Sample size	Therapy	Follow-up in years	Occlusion (%)
Cabrera et al., 2000	500	Foam	3	95
Min et al., 2003	499	EVLA	2	93
Merchant et al., 2005	1,078	RFA	4	88
Lurie et al., 2005	65	RFA	2	96
Christenson et al., 2010	100	EVLA	2	93
Zuniga et al., 2012	355	RFA	1	98

EVLA, endovenous laser ablation; RFA, radiofrequency ablation.

Technique

After taking venous access using a 7Fr introducer sheath, a 5Fr delivery catheter is taken 5 cm inferior to the SFJ. Compressing the proximal GSV with the USG probe, two 0.1 mL drops of glue are administered 1 cm apart and additionally the treated segment is compressed with hand for 3 minutes. Subsequently serial 0.1 mL aliquots are administered at 3 cm distances along the target vein, and each treated segment is compressed for 30 seconds. Perivenous TA is not needed.

Complications

Complications are usually mild, with phlebitis being the most common as glue is an irritant. Mean intraprocedural pain ratings, paresthesias, and incidence ecchymoses are low. Burn marks and pigmentation which are common with thermal therapies are not observed.

Cryosclerosis

It was introduced by Milleret et al. in 1981. A cryoprobe which is quite flexible, is introduced inside the vessel with its tip refrigerated to -89°C after local anesthesia. The process causes thrombosis with very little inflammatory reaction and almost no pain. Then there is progressive fibrosis of the vein and recanalization almost never happens.³²

There have been very few RCTs to support this therapy; however, Balint et al. published the results of a prospective trial in the year 2016. Out of 96 patients, 48 patients were administered cryosclerosis and the others were treated with conventional stripping. The occlusion rate was 81%. Recurrent varicosities were observed in 35% and 42% of the patients who received cryosclerosis and surgery, respectively. There was no significant difference between the groups ($p = 0.391$). Yet, cryosclerosis seems to be effective in the occlusion of the GSV.³³

Mechanochemical Ablation

The ClariVein mechanochemical ablation (MOCA) system is the first ablation technique which employs a hybrid method in a single system. The tip of the catheters rotating wire causes endomechanical abrasion; and there is simultaneous injection of sclerosing agent over the rotating wire which causes chemical destruction.³⁴

The device is composed of a catheter and a motor handle (to rotate the bent tip of abrasion wire). Catheter lumen is also connected to sclerosant syringe via side port. It is recommended to let the wire rotate for 3 seconds and withdraw simultaneously for about 0.5 cm to cause a venospasm at the proximal site, which is then followed by continuous rotation and withdrawal along with sclerosant delivery.³⁴ Occlusion rates are high (~97%) in the limited number of trials that have demonstrated its use.³⁵

Endovenous Steam Ablation

All access steps are similar to EVLA. After TA and placement of catheter, pulses of steam at 120°C are released via generator. Catheter is withdrawn stepwise. About 3 cm below the SFJ or SPJ, four steam puffs are delivered with gentle manual

TABLE 4: Advantages and disadvantages of endovenous therapies for varicose veins

Therapy	Advantages	Disadvantages
Foam sclerotherapy	<ul style="list-style-type: none"> • Technical ease • Low cost • Less complications 	<ul style="list-style-type: none"> • Microemboli • Skin necrosis
RFA	<ul style="list-style-type: none"> • Short- and long-term safety and efficacy is high • Superior to EVLA for postoperative ecchymosis and pain³⁸ 	<ul style="list-style-type: none"> • Slow pull back time • Frequent need for a second catheter pass • High rate of additional treatments needed • Relative difficulty in treating larger veins
EVLA	<ul style="list-style-type: none"> • Very-high immediate success rate • Fast pull-back rate 	<ul style="list-style-type: none"> • More minor complications, such as pain, edema, and bruising • Vein perforation with high energy
Glue	<ul style="list-style-type: none"> • TA is not required, fast • Early closure • Lower recanalization • Less ecchymosis • Compression stockings not required postprocedurally • Nonthermal—absence of paresthesias, burn, pigmentation, nerve injury • Due to viscosity and rapid polymerization, less incidence of deep venous thrombosis or pulmonary embolism³⁹ 	<ul style="list-style-type: none"> • Phlebitis more common
ClariVein MOCA	<ul style="list-style-type: none"> • TA not required • Mechanical + chemical ablation • No risk of thermal injury to skin, nerves, and muscle 	<ul style="list-style-type: none"> • Not Food and Drug Administration approved for varicose veins • Noise or vibration from catheter

EVLA, endovenous laser ablation; MOCA, mechanochemical ablation; RFA, radiofrequency ablation; TA: tumescent anesthesia.

pressure on the SFJ or SPJ. Subsequently, two to three puffs are delivered at 1 cm intervals depending on vein diameter. For the proximal segment during treatment, junction is compressed manually since the steam can reach some distance beyond the catheter tip. Postprocedure, patients should be advised to wear compression stockings for 2 weeks and to mobilize immediately after the treatment. The reported occlusion rates vary between 65 and 96%.³⁶ However, more RCTs are required to establish the use of this technique (Table 4).³⁷

CONCLUSION

Chronic venous disease or varicose veins are important health issues with large loss in quality of life to the patient. Early recognition and management is important. With the introduction of endovenous strategies for superficial venous reflux, conventional surgical therapies are now rarely performed because endovenous therapies are minimally invasive, less morbid, done in outpatient basis with equal long-term efficacy as surgery. Ideally, treatment selection is according to individual patients' needs. The thermal-based techniques have widely been used in last decade. The newer nonthermal methods like glue and MOCA have multiple advantages and hold promise in future.

Deep Vein Thrombosis: Controversies and Consensus

Surender Deora, Kewal C Goswami

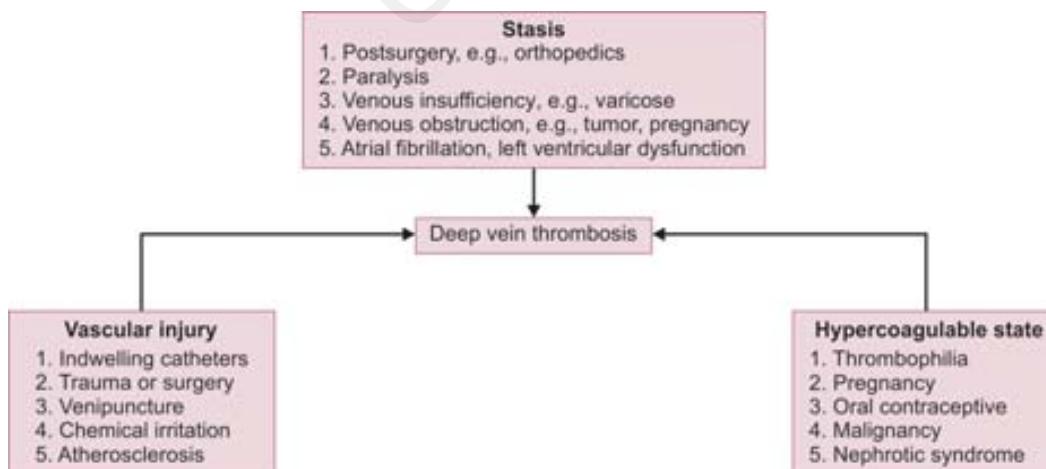

INTRODUCTION

Venous thromboembolism (VTE) is a thrombotic disorder manifesting as deep vein thrombosis (DVT) and pulmonary embolism (PE). Almost two-third cases of VTE are of DVT with involvement of proximal veins of legs but may also affect upper limb, splanchnic veins, and cerebral veins.¹ It is the third leading cause of vascular disease after myocardial infarction and stroke.² The incidence of DVT is 1:1000 per year and it increases with age with females more commonly affected in younger age group and males in elderly age group.³⁻⁵ It is more common in African Americans as compared to Native Americans and Asians. The lifetime risk of VTE increases by 8% after the age of 45 years.⁶ There are mainly three contributing factors as suggested by Virchow (Virchow's triad) for the formation of thrombus: stasis, vascular injury, and hypercoagulability (Flowchart 1). In 30–50% of the clinical cases, the cause of DVT is unknown and is unprovoked but it may also be secondary to provoking factors such as prolonged immobilization, cancer, oral

contraceptives, trauma, and thrombophilia.⁷ Proximal DVT is mainly due to chronic conditions whereas distal DVT in calf veins is mostly transient. It is high after orthopedic surgery with approximately 1% of patients developing DVT even after prophylactic anticoagulation.⁸ Overall, the most common provoking factor is cancer in 19% of the patients followed by surgery and immobilization contributing to 15%.^{9,10}

EVALUATION AND MANAGEMENT OF DEEP VEIN THROMBOSIS

There is significant morbidity and mortality in patients of VTE with mortality reaching up to 20% with PE and 2–5% with DVT mainly in those with proximal vein involvement.¹¹ The DVT itself can also impair the quality of life (QoL) with 20–50% of patients developing post-thrombotic syndrome (PTS) within 2 years after proximal DVT.¹² There is high recurrence risk in initial 3–6 months and therefore anticoagulation is needed in this period.¹³ Therefore, the diagnosis of DVT should be made at the earliest and managed to prevent PE.

FLOWCHART 1: Clinical conditions associated with Virchow's triad leading to deep vein thrombosis.

TABLE 1: Therapeutic options available for the treatment of deep vein thrombosis

Duration treatment	Acute (5–10 days)	Short-term (3–6 months)	Long-term (>6 months)
IV heparin	Yes	No	No
SQ LMWH	Yes	Yes (cancer)	Yes (cancer)
SQ FONADAPARINUX	Yes	No	No
WARF	No	Yes	Yes
NOACs	Yes	Yes	Yes
		Rivaroxaban, apixaban—start day 1, no overlap heparin	
		Dabigatran, edoxaban—heparin overlap 5–10 days	
Aspirin	No	No	Yes

LMWH, low-molecular-weight heparin; NOACs, non-VKA oral anticoagulants; IV, intravenous.

Various practice guidelines have been published for the diagnosis and management of DVT patients. Many recommendations are based on strong clinical evidence and there is no controversy in applying those in clinical practice (Table 1). However, many recommendations are still based only on expert opinion and thus lead to significant practice variations across the regions and therefore need a consensus. This review will concentrate on these gray zones in the evaluation and management of DVT.

Imaging of Contralateral Asymptomatic Leg

The diagnosis of DVT is mainly based on clinical symptoms and imaging. Although venography is the gold standard, venous ultrasound (VUS) is most commonly practiced in clinical setting. VUS includes direct imaging of thrombus, compression ultrasonography, and abnormal spectral and color-Doppler flow. The sensitivity and specificity of VUS in diagnosing proximal DVT is 94.2% and 93.8%, respectively. The sensitivity increases with color Doppler although with reduced specificity.¹⁴ After the diagnosis of DVT in the affected leg, it is debatable whether the contralateral leg should be scanned or not. The studies conducted for evaluation of prevalence of DVT in asymptomatic contralateral leg had inconsistent findings. Some studies have shown frequent association whereas some has shown no DVT in contralateral leg.^{15,16} Le Gal et al. reported in their retrospective cohort study that for the diagnosis of unilateral clinically suspected DVT, the whole limb VUS is sufficient.¹⁷ The study included 2,804 patients with clinically suspected DVT in which 21.8% had positive VUS. Out of these only 0.8% of patients had thrombus in both affected leg and contralateral leg and 0.2% had thrombus in only contralateral leg. The authors concluded that VUS of contralateral leg in clinically suspected DVT has very low yield and needs large number of scanning to diagnose one case of contralateral DVT. On the other hand, data from the OPTIMEV study had different results. This was a large multicenter, prospective, observational French study

in patients with suspected DVT. Galanaud et al. performed the data analysis in the subgroup of patients who underwent bilateral VUS for unilateral DVT.¹⁸ The study included 5,206 patients with clinical DVT, with 27% having positive VUS. In 5% of these patients contralateral DVT was diagnosed along with affected limb and 4.2% had positive VUS in only contralateral leg. The study finally concluded that bilateral VUS is necessary in certain groups of patients presenting with unilateral clinical DVT. However, the consensus is that the patients with active cancer, those with PE and normal ipsilateral VUS, and admitted elderly patients of >75 years of age are mostly benefitted with bilateral VUS. In conclusion, the VUS for contralateral leg is needed only in specific subgroup of patients at high risk of recurrent DVT.

Management of Isolated Distal Deep Vein Thrombosis

There is uncertainty regarding benefits of anticoagulation in patients with isolated distal DVT. The CACTUS study evaluated acute calf DVT in low-risk patients from 23 centers in Canada, France, and Switzerland.¹⁹ In this randomized, double-blind placebo-controlled trial, patients were randomized to either low-molecular-weight heparin (LMWH) nadroparin (171 UI/kg, subcutaneously, once a day) or placebo (saline 0.9%, subcutaneously, once a day) for 6 weeks. There was no difference in rate of proximal extension or VTE between LMWH and placebo but there was an increased risk of clinically relevant nonmajor bleeding. At least 15% of untreated patients with isolated distal DVT may have either extension of thrombus to popliteal vein or may cause PE.²⁰ Therefore, these patients either need anticoagulation or VUS surveillance. These patients are to be risk stratified so that the anticoagulation can be started in high-risk distal DVT only (Table 2). After risk stratification, high-risk patients should be managed with full-dose anticoagulation for at least 3 months and low-risk patients may be either given anticoagulation for short time (4–6 weeks) or may have a VUS surveillance. The role non-VKA oral anticoagulants (NOACs) are not well

TABLE 2: Risk factors associated with increased risk of progression to proximal veins or venous thromboembolism in patients with isolated distal deep vein thrombosis

Risk factors for increased complication after distal DVT	
High-risk conditions	Low-risk conditions
<ul style="list-style-type: none"> • Male • Age >50 years • Unprovoked DVT • History of VTE • Extensive thrombosis (>5 cm length, >7 mm maximum diameter, multiple veins) • Cancer • Positive D-dimer • Isolated DVT involving popliteal trifurcation 	<ul style="list-style-type: none"> • Transient risk factors e.g., OCP, hormone replacement therapy • Transient clinical conditions which are completely resolved e.g., fracture, long travel

DVT, deep vein thrombosis; VTE, venous thromboembolism; OCP, oral contraceptive.

established in isolated distal DVT but all patients are advised for compression stockings.

Thrombolysis versus Anticoagulation in Acute Proximal Deep Vein Thrombosis

Current standard treatment of DVT is anticoagulation and compression stockings. The main aim of anticoagulation is to prevent thrombus extension, reduce the incidence of VTE and recurrent DVT. Anticoagulation with heparin and oral therapy has reduced the thrombosis-related complications and mortality in DVT patients and is in the range of 2.5–5% with comparable risk of bleeding.²¹ Despite the use of adequate anticoagulation, almost half of the patients with DVT develop PTS.^{12,22} It is mainly caused by valvular and vascular injuries due to chronic DVT leading to raised venous pressure. This results in chronic tissue edema, subcutaneous fibrosis, and sometimes venous ulcers. The patients with PTS complain of heaviness in legs especially after prolonged standing and in evening hours, chronic mild pain in legs, and in severe cases venous ulcers. The QoL in these patients with PTS is significantly hampered and therefore the need was felt for revascularization of the affected veins as early as possible leading to the concept of “open vein hypothesis.” The updated Cochrane review of 17 randomized controlled trials assessed the effects of thrombolytic therapy and anticoagulation versus anticoagulation in the management of patients with acute DVT of the lower limb.²³ Results of early and intermediate follow-up of 1,103 patients showed complete clot lysis and improved venous patency in the treatment group. Also the PTS and leg ulcerations were significantly less in patients that received thrombolysis but with complications. Patients receiving thrombolysis had more stroke and data on recurrent DVT and PE were inconclusive. There was also no significant effect on mortality and the incidence of severe PTS was not reduced. Thus, the authors concluded that the thrombolysis increases venous patency and reduces the risk of PTS by one-third but at the cost of increased risk of bleeding. Therefore, the usefulness of this strategy is limited to select patients only.

The use of catheter-directed thrombolysis (CDT) by directly infusing the drug into the clot is safer probably due to lower drug dose and was equally effective as systemic

thrombolysis. The 5-year result of CAVENT trial studying 209 patients of acute proximal DVT treated with alteplase and anticoagulation versus anticoagulation alone found no significant difference in the QoL.²⁴ Similar results were also shown in ATTRACT trial where pharmacomechanical CDT did not reduce the risk of PTS but caused increased bleeding.²⁵ Therefore, in conclusion, any thrombolysis, either systemic or catheter-directed, in patients presenting with acute DVT, has not proven any long-term clinical benefits in terms of recurrent DVT, severe PTS, or mortality and hence is not recommended in patients with high proximal DVT.

Role of Compression Stockings for Post-thrombotic Syndrome

Post-thrombotic syndrome may occur in half of the patients with DVT with latency period extending up to 10 years. The cumulative frequency has been estimated to be 23% at 2 years and 28% at 5 years.²⁶ Treatment of PTS is difficult once it is established and only limited modalities are available. The cornerstone of PTS prevention was use of elastic compression stockings. This was based on two small randomized trials which have shown benefits in prevention of PTS by half after 2 years in DVT patients.^{27,28} The effectiveness of compression stocking was recently challenged by findings from the SOX trial.²⁹ This was multicenter, randomized, placebo-controlled trial that enrolled patients from 24 centers in USA and Canada. A total of 806 patients having first proximal DVT diagnosed by VUS were randomized to either compression stocking (ankle pressure 30–40 mm Hg) or placebo (ankle pressure <5 mm Hg). There was no significant difference observed in the PTS with the incidence of 14.2% in the active stocking group and 12.7% in the placebo group using the Ginsberg criteria and was 52.3% in the active group and 52.3% in the placebo group using Villalta criteria. However, the major limitation of SOX trial was insufficient adherence to compression therapy and compliance definition (stockings wearing for ≥3 days/week) was significantly lower than in previous studies (56% vs. 90%).²⁷ The main reason cited for poor adherence was local irritation and cosmetic look. This result had affected the practice of routine use

TABLE 3: Indication of inferior vena cava filter according to various societies

Status of various guidelines for the indications for inferior vena cava filter insertion		
Indications	Supporting societies	Opposing societies
Acute VTE and contraindication for anticoagulation	ACCP, AHA, SIR, ACR	—
Anticoagulation failure	AHA, SIR, ACR	—
Hemodynamically unstable patients with VTE	ACCP, AHA, SIR, ACR	—
Massive PE treated with thrombolysis or mechanical thrombectomy	ACCP, SIR, ACR	AHA
Prophylaxis in high-risk population (polytrauma, spinal cord injury)	SIR, ACR	ACCP
Iliocaval DVT, mobile thrombus	SIR, ACR	—

ACCP, American College of Chest Physicians; AHA, American Heart Association; ACR, American College of Radiology; DVT, deep vein thrombosis; PE, pulmonary embolism; SIR, Society for Interventional Radiology; VTE, venous thromboembolism.

of compression stocking in DVT patients and also gave rise to changes in some guidelines. The incidence of PTS and adherence to compression stocking decreases with time, and therefore the exact duration of the compression needed to be defined. Till the publication of the SOX trial the usual duration for compression stocking was 24 months, but because of the adherence issue, shorter durations of compression stocking were studied. The OCTAVIA trial evaluated the duration of compression stocking 24 months versus 12 months on the occurrence of PTS and QoL.³⁰ The study concluded that strict adherence to the compression stocking decreases the incidence of PTS but is not noninferior to 24 months of therapy. The IDEAL DVT was multicenter, randomized, single-blind, noninferiority trial at 14 centers in the Netherlands and Italy, and compared the effectiveness of individualized duration of elastic compression therapy, with standard duration of therapy of 24 months for the prevention of PTS.³¹ The participants were given the compression stockings for first 6 months and then individualized according to the Villalta scores to extended duration. The study concluded individualized tailored approach to be highly efficient as treatment could be stopped in 55% of patients at 6 months, and in an additional 11% of patients at 12 months, and is cost effective. Therefore, based on the available evidence the consensus is that the compression stocking is helpful in reducing the incidence of PTS but each patient needs individualized approach for the duration of the compression stocking.

Role of Inferior Vena Cava Filter

Acute PE is a dreaded complication of DVT and the 1-month mortality is twice that of DVT, although DVT is diagnosed twice as often as PE.¹ Anticoagulation is the cornerstone in the management of acute VTE patients. Current recommendation for inferior vena cava (IVC) filter is in patients with acute VTE and contraindications for anticoagulation or with any complication related to anticoagulation. There is a paucity of high-quality data for the use of IVC filter in patients with acute VTE. In spite of that the use of IVC filter is increasing in clinical practice especially with the introduction of retrievable filter. The PREPIC (Prevention du Risque d'Embolie Pulmonaire par Interruption Cave) trial randomized 400 patients with proximal DVT to receive anticoagulation

with a permanent IVC filter versus anticoagulation alone.³² After 2 years of follow-up, the patients in IVC filter had twice as common nonsignificant symptomatic PE but significantly more symptomatic DVT. At 8 years follow-up, there were significantly fewer symptomatic PEs in the filter group, but more symptomatic DVTs in the filter group with no difference in mortality.³³ The PREPIC 2 was open-label, randomized trial with 6 months of follow-up to evaluate the efficacy and safety of retrievable vena cava filters plus anticoagulation versus anticoagulation alone for preventing PE recurrence in patients presenting with acute PE and a high-risk of recurrence.³⁴ The study results at 3 months did not reduce the risk of recurrent PE and hence concluded no role of IVC filter in patients who can be anticoagulated. The meta-analysis by Bikdeli et al. in patients with DVT and at risk of PE has shown insignificant decrease in risk of PE, increased risk of DVT, and no change in all-cause mortality.³⁵ This meta-analysis included 11 studies of which six were randomized-controlled trials, but all of these randomized trials were considered low-to-moderate quality and none of them included the patients with contraindications to anticoagulation. Therefore, the routine use of IVC filter in patients with proximal DVT is not indicated and even its use in patients with contraindication to anticoagulation is purely based on expert consensus (Table 3).

Management in Cancer Patients with Deep Vein Thrombosis

Venous thromboembolism is a frequent complication in cancer patients and is the second leading cause of death after cancer progression. The annual incidence is as high as 20% depending on the type and site of tumor and associated risk factors.³⁶ It is associated with 2–6-fold increased risk of mortality and significantly affects the management of these patients.³⁷ Various practice guidelines have been published for the management of cancer-associated thrombosis but still many challenging clinical scenario persists where controversy prevails.

Type and Duration of Anticoagulation

All international practice guidelines recommend the use of LMWH for initial 3–6 months of diagnosis of DVT in cancer

patients. It has many added advantages as compared to oral vitamin K antagonist (VKA). LMWH does not need frequent monitoring and is absorbed even if the patient is having nausea and vomiting. It has less drug-to-drug interactions. It also appears to have antiinflammatory properties and may have effect on cancer progression.^{38,39} The role of VKA is restricted only as an alternative to LMWH. The safety and efficacy of NOACs in cancer patients is still unclear. There are systematic reviews and meta-analysis comparing the NOACs and VKA in cancer patients and has shown nonsignificant lower risk of recurrent VTE and major bleeding episodes as compared to VKA.⁴⁰ However, the quality of evidence is low as the trials were underpowered to show noninferiority or superiority of NOACs to VKA in cancer patients and included lower risk patients. Therefore, the use of NOACs is not recommended in the acute and long-term management of cancer-related VTE until large, well-conducted, high-quality randomized control trials are ensured.

There is limited data available for anticoagulation beyond 6 months of treatment, which is still debatable. These patients need risk stratification based on type of tumor, disease stage, and comorbid conditions of the patients.⁴¹ Any randomized clinical trial in this subset of cancer patients is not feasible. Also the type and dose of anticoagulation beyond 6 months is uncertain. LMWH is preferable because of its strong data in acute management and in recurrent VTE. The use of VKA or NOACs is still unclear because of lack of clinical data. These cases are to be managed according to individual, case-by-case approach and tailored according to patient's clinical status.

Recurrent Venous Thromboembolism Despite Anticoagulation

Patients with cancer and VTE have high risk of recurrent VTE despite adequate anticoagulation. The incidence of recurrent VTE at 6 month is 7–9% and 10–17% in patients receiving VKA and LMWH, respectively.^{42,43} There is lack of randomized clinical trials to guide management in such patients and potential therapeutic options available either change the anticoagulant or dose escalation of the given anticoagulant. These patients may also be offered IVC filter to prevent PE. Based on retrospective cohort studies and International

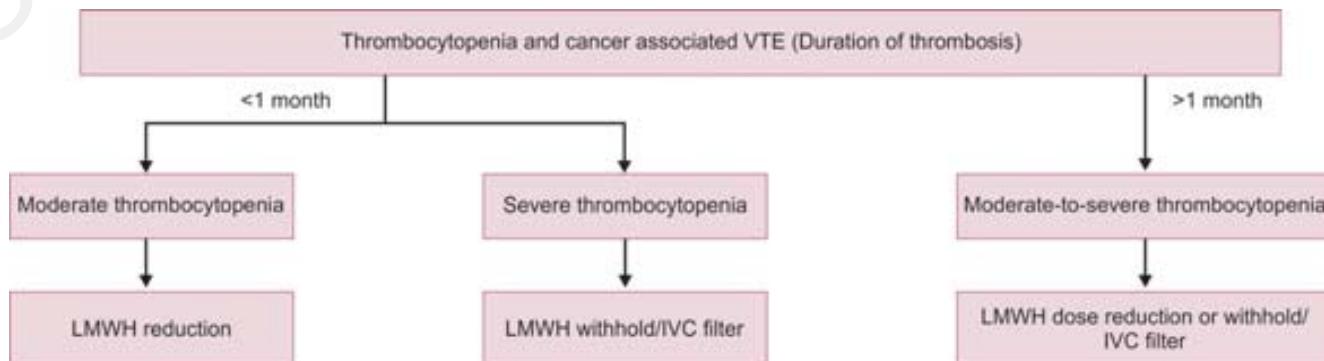

Society on Thrombosis and Haemostasis (ISTH) registry, many professional societies recommend full therapeutic doses of LMWH in patients with recurrent VTE despite anticoagulation with VKA or NOACs.⁴⁴ Similarly, based on two cohort studies, it is recommended to escalate the dose of LMWH by 20–33% in patients with recurrent VTE despite treatment with LMWH.⁴⁵ Patients developing recurrent VTE despite dose escalation are very challenging and need to be managed on a case-by-case basis. IVC filters are used only in those patients who have absolute contraindications to anticoagulation and have been shown to have no net benefit in preventing recurrent VTE and no impact on survival. Therefore, the American College of Chest Physicians panel recommends IVC filter as last resort in such patients.⁴⁴

Anticoagulation in Thrombocytopenia

Management of cancer patients on anticoagulation and thrombocytopenia is very challenging. The approach to these patients is on a case-to-case basis and depends upon the cause of thrombocytopenia, its severity, and expected duration. Thrombocytopenia may be due to chemotherapy-induced or by direct bone-marrow infiltration of cancer. There is general consensus that platelet count of $50 \times 10^9/L$ is safe for initiation of therapeutic doses of anticoagulation. Those patients with moderate ($30–50 \times 10^9/L$) and severe ($<30 \times 10^9/L$) thrombocytopenia need special risk stratification in terms of bleeding risk and chances of recurrent VTE. The first month after VTE is the highest risk period for recurring events and therefore the management also differs depending upon the time since diagnosis of VTE (Flowchart 2).

Treatment of Incidental Cancer-related Pulmonary Embolism

There is an increase in the rate of diagnosis of cancer-related PE with use of multiple-detector computed tomography (MDCT) and up to 50% are incidentally detected.⁴⁶ There is limited available literature on the management of incidental PE in cancer patients. The prognosis of cancer patients with incidental detection of PE is similar to patients with symptomatic PE and therefore needs the same management. For the first 6 months, LMWH is the recommended

VTE, venous thromboembolism; LMWH, low-molecular-weight heparin; IVC, inferior vena cava.

FLOWCHART 2: Management strategy in cancer patients with venous thromboembolism and thrombocytopenia.

therapy and after that individual case-based approach is needed after risk stratification. For patients detected with isolated subsegmental PE (SSPE) and without DVT can be managed conservatively without anticoagulation. In patients with multiple SSPE, consensus suggests of anticoagulation therapy.⁴⁷

Screening for Cancer in Unprovoked Deep Vein Thrombosis

Cancer is one of the important risk factor for VTE and the risk increases by 4.1-fold as compared to noncancer patients.⁴⁸ There is a complex interaction between tumor cells releasing cytokines, the hemostatic system causing platelet activation, and characteristics of the individual patient.⁴⁹ VTE may be the presenting manifestation of cancer in some patients, especially if DVT is unprovoked. The SOMIT trial randomized 201 patients with unprovoked VTE to extensive screening for cancer or no screening within 4 weeks of diagnosis.⁵⁰ The extensive screening strategy identified malignancies at an earlier stage and almost 93% of the malignancies were detected. However, there was no difference in mortality between the two groups. Similarly, the study was performed between 2002 and 2008 of 630 patients having objectively confirmed unprovoked VTE, who underwent extensive screening versus standard screening.⁵¹ The extensive screening led to a diagnosis of cancer in 5.5% of patients at baseline and 3.7% during a median 2.5-year follow-up period as compared to 2.5% at baseline and 5.0% during a median 2.6-year follow-up period in standard screening group. Again there was no benefit in overall or cancer-related mortality in extensive screening group. Therefore, both these trials have concluded that extensive screening for cancer in patients with unprovoked VTE leads to more diagnosis of cancer with less time delay without having any effect on mortality. Also extensive screening is not cost-effective and may have procedure-related complications. The sensitivity of detecting cancer is also 50–70% and 30–50% of patients still remain undetected. Therefore, in conclusion, extensive screening for detection of cancer in patients with unprovoked VTE is not indicated.

CONCLUSION

Deep vein thrombosis is a commonly encountered clinical problem in community and hospitals. Despite advances in the diagnosis and management of DVT there are controversies in many clinical settings because of the insufficient available data. Mostly the consensus on these controversies is based on expert reviews and needs a case-by-case approach.

Renal Artery Stenosis: When and How to Intervene?

George Joseph

INTRODUCTION

Renal artery stenosis (RAS) is a common cause of secondary hypertension. The etiology in more than 90% of cases of RAS is atherosclerotic renal artery stenosis (ARAS), with fibromuscular dysplasia (FMD) coming a distant second.¹ In India and other tropical/subtropical countries, RAS with secondary hypertension is not uncommonly caused by Takayasu arteritis (TA). This chapter will focus on these three etiologies of RAS, though several others such as aortorenal dissection, trauma, extrinsic compression, and posttransplant RAS may be occasionally encountered.

ATHEROSCLEROTIC RENAL ARTERY STENOSIS

Atherosclerotic renal artery stenosis produces a spectrum of clinical syndromes ranging from asymptomatic incidentally detected lesions to renovascular hypertension, ischemic nephropathy, and accelerated cardiovascular disease.² The underlying pathophysiology begins with RAS-induced reduction in renal blood flow resulting in activation of the renin–angiotensin–aldosterone axis, which in turn causes vasoconstriction, sodium retention, aldosterone secretion, vascular remodeling, sympathetic activation, and myocardial effects including left ventricular hypertrophy.² Later these processes, transition to alternate vascular mechanisms mediated by signals such as oxidative stress, endothelin, and vasoconstrictor prostaglandins that are not entirely dependent on the renin–angiotensin system.² Kidney injury in ARAS is produced by complex interactions between factors such as vascular rarefaction, oxidative stress injury, and recruitment of inflammatory cellular elements that ultimately produce fibrosis.³ ARAS has profoundly adverse effects on the cardiovascular system and the kidney, i.e., in excess of what can be explained simply on the basis of hypertension or degree of renal impairment.⁴ Patients with ARAS have more cardiovascular comorbidity and a greater prevalence of left

ventricular hypertrophy and diastolic dysfunction than those without ARAS with the same level of blood pressure and degree of renal dysfunction.⁵ Another important consideration is that ARAS is a progressive disorder; in one study,⁶ progression of ARAS occurred in 53% of affected arteries, and total occlusion developed in 9%, all of which had a high-grade stenosis at baseline. In another study,⁷ renal atrophy occurred in 21% of ARAS cases with high-grade stenosis and in nearly 6% of those with less than 60% stenosis.

Detection of Renal Artery Stenosis

Apart from the occasional abdominal bruit radiating to the flank, physical examination provides no specific clues to the presence of hemodynamically significant RAS.¹ Clinical suspicion of its presence may arise in certain situations (Box 1) and should initiate appropriate diagnostic evaluation.^{1,8}

Noninvasive Diagnostic Evaluation

The 2017 European Society of Cardiology (ESC) guidelines⁸ and the 2013 American College of Cardiology Foundation/American Heart Association (ACCF/AHA) guidelines⁹ recommend duplex ultrasonography (DUS) as the first-line imaging modality to screen for significant RAS [class I, level of evidence (LOE) B]. Peak systolic velocity (PSV) in the main renal artery has 85% sensitivity and 92% specificity to identify angiographically significant RAS.⁸ PSV and end-diastolic velocity (EDV) obtained using DUS can be used to determine the renal resistive index, calculated as (PSV-EDV)/PSV. Renal resistive index correlates closely with pressure gradient across the stenosis in patients with unilateral RAS¹⁰ and may help to identify more severe RAS.⁸ DUS has advantages such as being inexpensive, noninvasive, and easily repeatable to assess disease progression; however, it requires experience, may be difficult in overweight subjects, may fail to visualize portions of the renal artery, and may miss the highest PSV tracing and accessory renal arteries.⁸ Computed tomography angiography (CTA) and magnetic resonance angiography (MRA) show

BOX 1**Clinical situations suggesting presence of renal artery stenosis***

- Onset of hypertension before age of 30 years
- Onset of severe hypertension after the age of 55 years, when associated with chronic kidney disease or heart failure
- Hypertension and abdominal bruit
- Rapid and persistent worsening of previously controlled hypertension
- Resistant hypertension (other secondary cause unlikely and target not achieved despite four drug classes including a diuretic and a mineralocorticoid-receptor antagonist in appropriate doses)
- Hypertensive crisis (acute renal failure, acute heart failure, hypertensive encephalopathy, or grades 3–4 retinopathy)
- New azotemia or worsening of renal function after treatment with renin–angiotensin–aldosterone system blockers
- Unexplained atrophic kidney or discrepancy in kidney size, or unexplained renal failure
- Flash pulmonary edema
- Multivessel coronary artery disease or peripheral artery disease
- Unexplained congestive heart failure or refractory angina

SCAI expert consensus statement for renal artery stenting appropriate use. *Catheter Cardiovasc Interv.* 2014;84:1163–71; Aboyans V, Ricco JB, Bartelink ME, et al. 2017 ESC Guidelines on the Diagnosis and Treatment of Peripheral Arterial Diseases, in collaboration with the European Society for Vascular Surgery (ESVS): Document covering atherosclerotic disease of extracranial carotid and vertebral, mesenteric, renal, upper and lower extremity arteries. Endorsed by: The European Stroke Organization (ESO), The Task Force for the Diagnosis and Treatment of Peripheral Arterial Diseases of the European Society of Cardiology (ESC) and of the European Society for Vascular Surgery (ESVS). *Eur Heart J.* 2018;39:763–816.

equally high sensitivities and specificities for the detection of RAS, but are more costly than DUS.^{1,8} CTA has higher spatial resolution, but involves exposure to radiation and iodinated contrast.^{8,9} Gadolinium-enhanced MRA provides excellent characterization of the renal arteries and kidney, but tends to overestimate stenosis severity and produces artifacts in patients with renal artery stents.⁸ CTA and MRA are recommended as screening tests to establish the diagnosis of RAS in both the ACCF/AHA and the ESC guidelines (class I, LOE B).^{8,9}

Invasive Diagnostic Evaluation

Invasive diagnostic angiography remains the gold standard for the diagnosis of RAS and should be considered for patients with inconclusive noninvasive testing and a high clinical suspicion of RAS and for patients at high risk for RAS and who require invasive angiography for other indications (ACCF/AHA and ESC class IIb, LOE B/C).^{1,8,9} The 2014 Society for Cardiovascular Angiography and Interventions (SCAI) expert consensus statement classifies visually estimated angiographic RAS severity of less than 50%, 50–70%, and more than 70% as being mild, indeterminate, and significant, respectively. However, the correlation between degree of stenosis and hemodynamic impact is poor and so a variety of physiological parameters have been studied to guide treatment.⁴ Pressures proximal (Pa) and distal (Pd) to the

TABLE 1: Invasive physiologic parameters used in renal artery stenosis evaluation*

Parameters	Acronym	Condition	Calculation
Mean resting pressure gradient	MPG	Rest	Pa – Pd (mean)
Mean hyperemic pressure gradient	MHG	Hyperemia	Pa – Pd (mean)
Peak resting systolic pressure gradient	RSG	Rest	Pa – Pd (peak)
Peak hyperemic systolic pressure gradient	HSG	Hyperemia	Pa – Pd (peak)
Resting pressure ratio	RPR	Rest	Pd/Pa (mean)
Renal fractional flow reserve	rFFR	Hyperemia	Pd/Pa (mean)
Renal flow reserve	RFR	Both	APVh – APVr

APVh, average peak intrarenal flow velocity during hyperemia; APVr, average peak intrarenal flow velocity at rest; *Pa, pressure proximal to renal artery stenosis; Pd, pressure distal to renal artery stenosis.

Source: Adapted from van Brussel PM, van de Hoef TP, de Winter RJ, et al. Hemodynamic measurements for the selection of patients with renal artery stenosis: a systematic review. *JACC Cardiovasc Interv.* 2017;10:973–85.

RAS using a 014-inch pressure wire or peak flow velocities using a Doppler wire are studied under resting and hyperemic conditions and various parameters are calculated (Table 1).

Using these parameters, the SCAI guidelines reclassify 50–70% RAS as significant if physiologic testing reveals mean resting pressure gradient (MPG) >10 mm Hg, or peak hyperemic systolic pressure gradient (HSG) >20 mm Hg (induced with intra-renal bolus of papaverine 30 mg or dopamine 50 µg/kg), or renal fractional flow reserve (rFFR) ≤0.8.¹ The ESC guidelines classify ≥60% stenosis by DUS as significant; however, an invasively determined peak resting systolic pressure gradient (RSG) >20mmHg or a resting pressure ratio (RPR) <0.90 is considered necessary to confirm significant stenosis in symptomatic patients.⁸ Van Brussel et al. recently reviewed 15 studies concerning basal and hyperemic hemodynamic measurements in patients with RAS as a guide to treatment and concluded that the correlation between angiographic stenosis severity and hemodynamic data was relatively poor, and the predictive value of intrarenal functional data for outcome is still insufficient; this may be at least partly related to the heterogeneity in methodology and subjects' characteristics.¹¹ Myocardial and renal physiologies have distinct differences, because of which physiological indexes successful in coronary artery interventions may not be fully transferable to the setting of RAS.¹¹ Currently, adequate tools to reliably establish the hemodynamic significance of any degree of ARAS in humans do not as yet exist.⁴

Medical Management of Atherosclerotic Renal Artery Stenosis

The ESC and ACCF/AHA guidelines recommend medical therapy as the first-line treatment for ARAS.^{8,9} Both recommend angiotensin-converting enzyme inhibitors (ACEIs),

angiotensin receptor blockers (ARBs), calcium channel blockers, and beta-blockers (class I), but the ESC guidelines recommend diuretics as well (class I), and caution that ACEI/ARB therapy in patients with bilateral severe RAS or RAS in a single functional kidney must be done only if well-tolerated and under close monitoring (class IIb). The ESC also considers statins and antiplatelet therapy as part of best medical therapy.⁸

Revascularization in Atherosclerotic Renal Artery Stenosis

The potential benefit of renal revascularization in ARAS seems intuitive. Indeed, several nonrandomized studies of percutaneous transluminal renal angioplasty (PTRA) and renal artery stenting (RAS) in ARAS showed clinical benefit.¹²⁻¹⁷ Early randomized trials comparing PTRA with medical therapy in patients with moderate to severe ARAS showed modest but significant effect on blood pressure.¹⁸ However, three recent major randomized controlled trials (Table 2) showed no difference between endovascular therapy and best medical therapy.¹⁹⁻²¹ Apart from having design flaws, these trials have been criticized for excluding categories of patient who might have benefited from revascularization and for not defining the length of kidney disease in their patient population making it impossible to determine if the duration of renal dysfunction had any impact

on outcome after intervention.²² Another criticism is that data was not provided on different subgroups of patients, some of whom might have benefited from renal revascularization.²² However, a later subgroup analysis on the Cardiovascular Outcomes with Renal Atherosclerotic Lesion (CORAL) trial data did not support a benefit of stenting based on the degree of stenosis, hemodynamic significance of the lesion, or higher pretreatment blood pressure.²³ In 2016, an expert panel systematically reviewed all data from randomized and nonrandomized studies concerning the comparative effectiveness and safety of RAS, surgical revascularization, and medical therapy to treat ARAS with regard to clinically important outcomes; they concluded that the strength of the evidence, that there is no or only a minimal clinically relevant difference between these treatments with regard to outcome or blood pressure control, is low.²⁴ In other words, it remains uncertain whether mechanical treatment of ARAS is beneficial or not.⁴

Current Indications for Percutaneous Revascularization in Atherosclerotic Renal Artery Stenosis

Given the prevailing uncertainty whether mechanical treatment of ARAS is beneficial or not and the negative results of recent randomized trials, it is unsurprising that the 2017 ESC guidelines state that routine revascularization is not

recommended in ARAS (class III, LOE A) and make a class IIb LOE C recommendation for RAS with unexplained recurrent congestive heart failure or sudden pulmonary edema (cardiac destabilization syndromes).⁸

The pre-CORAL²¹ 2013 ACCF/AHA guidelines accord class IIb, LOE C recommendation to percutaneous revascularization in asymptomatic ARAS, whether unilateral, bilateral, or in a solitary kidney.⁹ In three specific situations class IIA, LOE B recommendation is made by the ACCF/AHA: (1) one is hemodynamically significant RAS and accelerated hypertension, resistant hypertension, malignant hypertension, hypertension with an unexplained unilateral small kidney, and hypertension with intolerance to medication; (2) the second is RAS and progressive chronic kidney disease (CKD) with bilateral RAS or a RAS to a solitary functioning kidney; and (3) the third is significant RAS with unstable angina.⁹ A class I, LOE B recommendation is made for hemodynamically significant RAS and cardiac destabilization syndromes.⁹

Based on an expert panel review of available data,¹ the SCAI concluded that revascularization of significant (>70%) RAS may be considered appropriate care in the following situations:

- Cardiac destabilization syndromes (flash pulmonary edema or acute coronary syndrome with severe hypertension)
- Resistant hypertension (uncontrolled hypertension with failure of maximally tolerated doses of at least three antihypertensive agents, one of which is a diuretic, or intolerance to medications)
- Ischemic nephropathy with CKD with estimated glomerular filtration rate (eGFR) less than 45 mL/min/1.73 m² and global renal ischemia (unilateral significant RAS with a solitary kidney or bilateral significant RAS) without other explanation.

Current Indications for Surgical Revascularization in Atherosclerotic Renal Artery Stenosis

The ESC guidelines state that in case an indication for revascularization of ARAS exists, then surgical revascularization should be considered for patients with complex anatomy of the renal arteries, after a failed endovascular procedure or during open aortic surgery (class IIa, LOE B).⁸ The ACCF/AHA gives class I, LOE B/C recommendations to surgical revascularization in ARAS with multiple small renal arteries or early primary branching of the main renal artery, and in combination with pararenal aortic reconstruction.⁹

Revascularization Modality

With the exception of a few situations discussed earlier, open surgical renal revascularization has been largely replaced by percutaneous intervention (PI) for ARAS because of the increased morbidity and mortality associated with surgery.²⁵ Of the two percutaneous renal revascularization techniques available, RAST is significantly better than PTRA. Van de Ven et al.²⁶ performed a randomized trial comparing PTRA with

RASt for ARAS. About 42 patients in each arm were followed up for 6 months. Complications were similar. However, primary success rate (<50% residual stenosis) was worse with PTRA compared to RASt (57% vs. 88%), as were primary patency rate at 6 months (29% vs. 75%) and restenosis after a successful primary procedure (48% vs. 14%). Secondary RASt (performed in 12 patients) for primary or late failure of PTRA was as successful as primary RASt. Intention to treat analysis showed no difference in clinical results at 6 months between PTRA and RASt. The authors concluded that RASt was a better technique than BA to achieve vessel patency in ostial ARAS. Primary RASt and primary PTRA plus rescue RASt have similar outcomes, but the burden of reintervention after PTRA outweighs the potential saving in stents. The ACCF/AHA guidelines recommend renal stent placement for ostial ARAS lesions that meet the clinical criteria for intervention (class I, LOE B).⁹

Vascular Access

Conventionally, femoral arterial access has been used for renal interventions and offers several advantages such as the large caliber of the access vessel and proximity to the renals. However, radial artery access is being increasingly used to reduce access site complications and improve patient comfort. However, the operator needs specific technical skills as well as knowledge of device compatibility. Both radial arteries are suitable for renal intervention. Generally, the left radial access allows a shorter distance to renal arteries, but the right radial approach is ergonomically more comfortable with lower radiation exposure for the operator. Extra-long guiding catheters and balloons may be required in taller patients or with excessive aortic arch tortuosity.²⁷ The brachial artery may also be used, but is associated with a higher local complication rate.

Embolectic Protection Device and “No-touch” Technique

Atheroembolization during stenting for ARAS occurs in virtually every patient²⁸ and could be responsible for deterioration of renal function postprocedure. Embolic protection devices (EPDs) have, therefore, been used during RASt for ARAS. Khosla et al.²⁹ retrospectively studied 18 patients who underwent RASt for ARAS using EPDs and compared them with matched controls. At 12-month follow-up, stage-4 CKD patients treated with EPD had significantly higher eGFR than controls. Use of EPDs adds to the procedure cost and is technically challenging in renal arteries that bifurcate early. Generally, use of EPDs is confined to RASt procedures in patients with impaired renal function.²⁵ Another technique used to limit atheroembolization and prevent potential ostial renal artery injury during RASt for ARAS is the “no-touch” technique (Fig. 1).³⁰ In this technique, two guidewires are used, the first is placed in the aorta to prevent contact between the guiding catheter and the renal artery ostium, and the second is placed in the renal artery and serves as a rail over which the balloon and stent are passed.

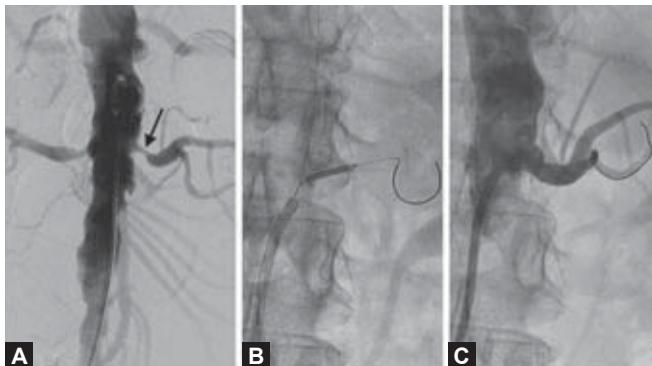

FIG. 1: “No touch” technique of renal artery stenting. **A**, Severe atherosclerotic ostioproximal stenosis of the left renal artery with extensive atheromatous aortic plaques in the vicinity; **B**, Two 014-inch guidewires are introduced through a 7-F guiding catheter, one is passed up the abdominal aorta and the other enters the left renal artery. A balloon-expandable stent is ready for deployment in the left renal artery; **C**, Poststenting selective left renal angiogram showing a good angiographic result.

Hardware

Renal interventions are performed using either a guiding catheter (such as a 7-F Renal Double Curve) and 014 or 018-inch guidewires, or long sheaths (such as the 6-F Ansel 55 cm) and 035-inch guidewires. Predilatation is usually reserved for severe lesions. Stents used in ARAS should be balloon expandable for accurate positioning and better radial strength. Bare-metal stents (BMSs) are almost always used, though drug-eluting stents have been tried in an effort to reduce restenosis. Zahringer et al.³¹ in a prospective multicenter nonrandomized trial (GREAT Trial), compared 52 patients undergoing RAST for ARAS using BMSs with 53 using sirolimus-eluting stents (SESSs). Both stents significantly improved blood pressure, but angiographic outcome at 6 months did not show any significant difference (binary restenosis rate 6.7% for SES vs. 14.6% for BMS, $p = 0.30$).

Renal Artery Occlusions

The SCAI consensus document¹ considers revascularization of unilateral, solitary, or bilateral renal artery chronic total occlusion as rarely appropriate care probably because such kidneys are atrophic and revascularization is unlikely to restore any significant function. However, atrophic kidneys can be hormonally active and, therefore, contribute to significant hypertension and pulmonary edema;³² also, not all kidneys with occluded arteries are atrophic, as the occlusion may be recent (Fig. 2) and viability may be preserved by collateral blood flow. Torsello et al.³³ surgically revascularized 52 kidneys with occluded arteries; they found that postoperatively blood pressure normalized or became easier to control in 89% of patients and mean plasma creatinine levels reduced significantly, enabling two severely uremic patients to discontinue hemodialysis; these benefits have to be weighed against an operative mortality of 5.7%. Percutaneous recanalization techniques in general have improved significantly of late and carry much lower risks. Very recently, Petrov et al.³⁴ reported successful

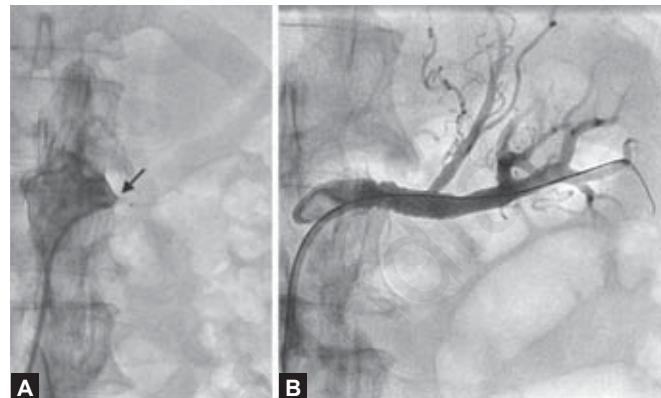

FIG. 2: Recanalization and stenting of a recently occluded renal artery in a patient presenting with pulmonary edema. **A**, Atherosclerotic ostial occlusion of the left renal artery; **B**, Postintervention selective left renal angiogram showing a good angiographic result.

recanalization of occluded renal arteries in six of seven hypertensive patients with elevated plasma renin levels; in the six patients with successful recanalization, blood pressure reduced significantly and plasma renin levels normalized at 6 months and 12 months follow-up.

Restenosis

The incidence of restenosis after RAST with BMS was 17% in a meta-analysis of 14 studies involving 678 patients.³⁵ The optimal treatment of in-stent restenosis is unclear. Zeller et al.³⁶ used four different treatment modalities in 31 patients with 33 second-time (reoccurring) in-stent restenotic lesions. Primary success rate was 100% with all modalities. During follow-up, repeat in-stent restenosis was seen in 71% with balloon angioplasty, 43% with drug-eluting stents, 17% with covered stents, and 100% with cutting balloon angioplasty.

Follow-up

Atherosclerotic renal artery stenosis patients undergoing RAST should be followed at 1 month, 6 months, 1 year, and annually thereafter.²⁵ Parameters to be assessed are blood pressure control, renal functions, and DUS imaging. DUS is the recommended imaging technique to screen for in-stent restenosis. DUS should take into account that a stented artery is less compliant than a native artery and that PSV and renal/aortic velocity ratio obtained by DUS are higher for any given degree of arterial narrowing within the stent, and hence obtaining a postprocedure DUS is reasonable to establish a new baseline PSV.³⁷

FIBROMUSCULAR DYSPLASIA

Fibromuscular dysplasia is a nonatherosclerotic, noninflammatory vascular disease that most commonly affects the renal and internal carotid arteries, but can involve other arterial territories as well.³⁸

Pathology

The pathological classification scheme of renal artery FMD is based on the arterial layer in which the lesion predominates.³⁸ Medial fibroplasia is the most common type, involves the middle to distal portion of the artery and is characterized by the classic “string of beads” appearance with the beading being larger than the normal caliber of the artery; only the arterial media is involved, the intima and adventitia being spared. Perimedial fibroplasia is another type of FMD that spares the intima and adventitia, characterized by a homogeneous collar of elastic tissue at the junction of the media and the adventitia; it is diagnosed when focal stenoses or multiple constrictions are observed, often with a robust collateral network; the “beads” are usually less numerous than in medial fibroplasia and are typically smaller in diameter than the normal caliber of the artery. Intimal fibroplasia occurs in less than 10% of FMD cases and appears angiographically as: (1) focal concentric stenosis, (2) long smooth narrowing, or (3) redundancy of the artery. Adventitial hyperplasia is the rarest type of FMD featuring sharply localized, tubular areas of stenosis.

Clinical Features and Imaging

Women, 15–50 years of age, are most commonly affected by renovascular FMD.³⁸ In most cases, it is detected incidentally, though evaluation for systemic hypertension may also reveal this condition. Angiographic progression of disease occurs in up to 37% of cases of renovascular FMD. DUS is an important diagnostic modality; elevated flow velocities in the distal portion of the renal arteries are suggestive of renovascular FMD; a renal resistive index less than 0.8 in the cortical vessels suggests a favorable response to revascularization. CTA and MRA are useful in detecting renovascular FMD, though the spatial resolution of the latter may be inadequate. Conventional angiography remains the most accurate method for diagnosing FMD.

Therapy

Medical treatment for systemic hypertension in FMD should follow standard guidelines. According to the 2017 ESC guidelines,⁸ revascularization using balloon angioplasty with bail-out stenting is recommended (class IIa, LOE B) in cases of hypertension and/or signs of renal impairment related to renovascular FMD. The 2013 ACCF/AHA criteria also recommend balloon angioplasty with bail-out stenting (class I, LOE B) for FMD lesions that meet the clinical criteria for intervention; vascular surgical intervention is also recommended at the same level, especially for those exhibiting complex disease that extends into the segmental arteries and those having macroaneurysms. Although, there is a paucity of prospective data suggesting superiority of one treatment modality over the other, the percutaneous approach is increasingly favored in view of lower cost, invasiveness, and morbidity.³⁸ Successful angioplasty often results in substantial and rapid reduction in blood pressure (Fig. 3). Restenosis is seen in 7–27% of cases. Follow-up using periodic DUS imaging is important to detect progression of disease, restenosis, or loss of kidney volume.³⁸

TAKAYASU ARTERITIS

Takayasu arteritis is a rare large-vessel vasculitis affecting the aorta and its primary branches producing stenotic or aneurysmal lesions. The renal artery is frequently stenosed or occluded in TA, resulting in secondary systemic hypertension, kidney atrophy, and renal insufficiency. Over the last three decades, there have been numerous reports of surgical^{39–42} and endovascular^{43–49} treatment of RAS in TA. These have fuelled two debates: (1) one is whether surgical treatment is superior to PI, and (2) the second is that if PI is performed, whether balloon angioplasty is better than stenting.^{49,50} Surgical revascularization preceded PI historically, and is better established in the existing guidelines,^{51,52} which

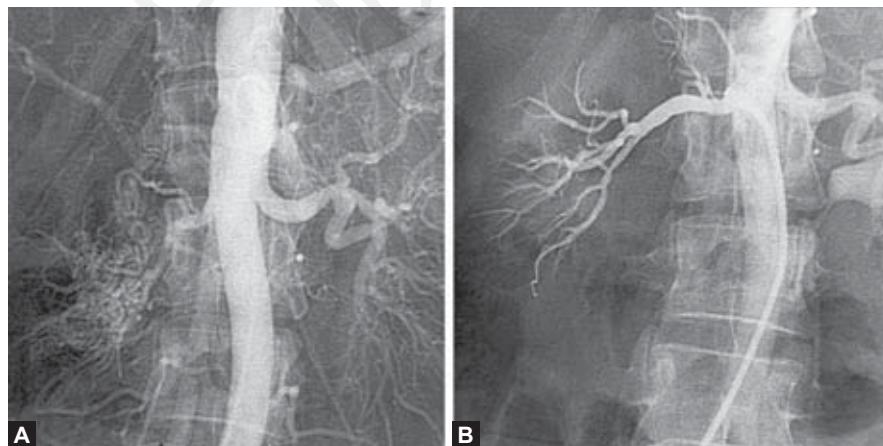

FIG. 3: Renal angioplasty in fibromuscular dysplasia. **A**, Abdominal aortogram in a young hypertensive woman showing perimedial fibroplasia type of fibromuscular dysplasia affecting the right renal artery; the involvement is nonostial, with multiple constrictions and a robust collateral network; “beading”, typical of medial fibroplasia, is not seen; **B**, Angiogram, performed after balloon angioplasty of the main and first-order branches of the right renal artery, showing a good result. The patient had a rapid and substantial reduction in blood pressure.

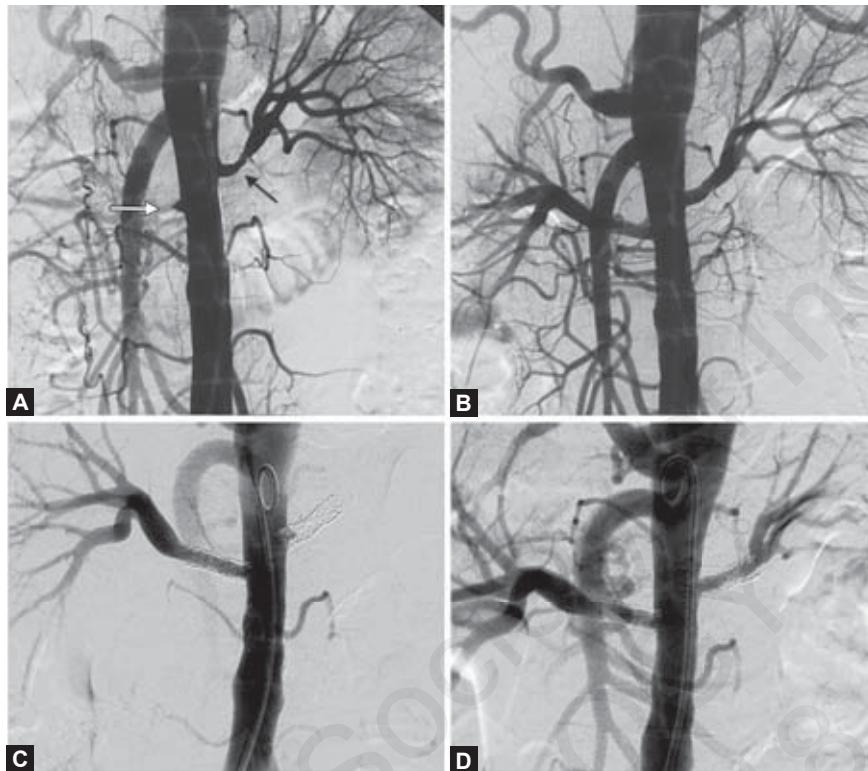

FIG. 4: Percutaneous renal interventions in a 17-year-old woman presenting with accelerated hypertension that remained uncontrolled despite six antihypertensive medications. **A**, Abdominal aortogram showing proximal occlusion of the right renal artery (white arrow) and stenosis of the left renal artery (black arrow) with minor visceral aortic narrowing, typical of Takayasu arteritis; **B**, Aortogram obtained after right renal artery recanalization and bilateral renal stenting, showing good immediate result; **C**, Follow-up aortogram obtained after 6 years showing patency of the right renal stent and restenotic occlusion of the left renal stent; **D**, Aortogram, obtained after recanalization and balloon dilatation of the left renal stent, showing restored patency.

do not consider PI in TA as standard therapy, and recommend restriction of its use to discrete lesions in high-risk patients during disease remission with the caveat that restenosis frequently occurs after PI in TA. However, these recommendations were based on small case series that used PI techniques developed largely for atherosclerotic vascular disease.⁵³ The relative rarity of TA, small numbers of patients in most TA case series, and wide variation in treatment strategies have retarded elucidation of the best way to treat vascular lesions in TA.⁵³ Arterial lesions in TA pose several distinctive impediments to obtaining successful PI outcomes and mandate development of disease-specific PI techniques to overcome these hurdles.

CHRISTIAN MEDICAL COLLEGE, VELLORE INTERVENTIONAL EXPERIENCE IN TAKAYASU ARTERITIS RENAL ARTERY STENOSIS

A total of 717 TA patients (mean age 29.6 years, 74.9% female) underwent 2,932 PIs to treat 1,893 arterial lesions in all vascular territories over 23 years (1996–2018) at Christian Medical College (CMC), Vellore, India. Of these patients, 315 of these patients underwent 676 renal artery PI procedures to treat 436 RAS lesions (214 left-sided and 222 right-sided). In

105 patients 2 renal arteries were treated, while in 9 patients 3 renal arteries were treated. Baseline serum creatinine was above 1.4 mg/dL during the first PI (PI-1) in 45 (10%) lesions, and inflammatory markers were elevated in 48%. 96% of the lesions were in hypertensive TA patients. Of the 436 renal lesions, 56 (12.8%) were occlusions, of which 48 (86%) were successfully recanalized (Fig. 4) with eight failures to cross. PTRA alone was done in 56 lesions during PI-1, using a mean balloon diameter of 4.8 mm and mean pressure of 8.8 atm; early successful outcome (residual <50%) was obtained in 52 (92.8%). RASt was done in 372 lesions during PI-1, either electively or to overcome suboptimal PTRA results, using a mean balloon diameter of 5.7 mm and mean pressure of 17 atm; early successful outcome was obtained in 359 (96.5%). Follow-up was obtained in 336/436 (77%) of all lesions at a mean of 31.8 months after PI-1. Follow-up obtained in 41/56 (73%) of lesions treated with PTRA during PI-1 revealed successful outcome (stenosis <50%) in 19 (46%) and suboptimal outcome/failure (stenosis >50%) in 22 (54%); 20 lesions in the latter subgroup were subjected to PI-2 (stenting in 14, repeat PTRA in 6). Follow-up obtained in 294/372 (79%) of lesions treated with RASt during PI-1 revealed successful outcome in 170 (58%) and suboptimal outcome/failure in 124 (42%); 117 lesions in the latter subgroup were subjected to PI-2 (balloon dilatation in 93, second stent in 24). Further

PIs (mostly simple balloon dilatation only) were performed at subsequent follow-up visits if required (average number of PIs per lesion was 1.55, range 1–8), leading to progressive increase in the cumulative success rate. At the final follow-up obtained after a mean of 40.6 months after the last performed PI, successful outcome was obtained in 223/269 (87%) of lesions. In the 386 lesions that were stented, BMSs alone were used in 236 and covered stents with or without BMS in 150; use of covered stents was associated with reduction in the number of PIs required (1.39 vs. 1.55) and time required (10.1 months vs. 61.9 months) to achieve sustained success. There were no in-hospital deaths. Complications included arterial dissection 16, rupture three, perforation one, distal embolization two, stent thrombosis six, inadequate stent expansion nine, stent displacement/distortion nine, and groin complications five; given that these occurred in 676 renal PI procedures, their absolute rate is low. Thus, PI used to treat RAS in TA yields a high level of mid- to long-term success with acceptably low morbidity; the key factors to achieve this are aggressive immunosuppressive therapy to control disease activity, use of high-pressure noncompliant balloons and covered stents, and repeated PIs till sustained success is obtained.

Carotid Artery Stenting in 2018

Vivudh P Singh, Ranjan Modi, Atul Mathur

INTRODUCTION

Stroke is a major global health problem accounting for the second most common cause of death.¹ India being in midst of epidemiological and economical transition is particularly affected.² Besides being most populous we are also facing brunt of an increasing aging population. Approximately 20% of cases are due to extracranial carotid artery stenosis. Unlike coronary artery disease symptoms are due to embolization, rather than thrombosis. Symptomatic patient have much higher rate of embolism than asymptomatic patients although asymptomatic patients outweigh symptomatic patient by 4:1. Principally the source is internal carotid artery (ICA, 25%); however, intracranial small vessel disease (25%) cardiac embolism (20%), and idiopathic (25%) are other significant contributors.

In order to prevent stroke, carotid endarterectomy (CEA) has been used extensively as a primary option to eliminate both hemodynamic instability as well as the source of cerebral atheroembolism. Its efficacy was evaluated in four well-designed randomized controlled trials: North American Symptomatic Carotid Endarterectomy Trial (NASCET) the European Carotid Surgery Trial (ECST), Asymptomatic Carotid Atherosclerosis Study (ACAS), and Asymptomatic Carotid Surgery Trial (ACST). These studies have established a class Ia indication for CEA.

Carotid artery stenting (CAS) has been evaluated by multiple large randomized clinical trials (RCTs) that recognize CAS as an alternative to CEA for stroke prevention¹ in surgical-risk symptomatic patients when the anticipated risk of periprocedural stroke or mortality is less than 6% [(class I, level of evidence (LOE) B]. They also preferred CAS to CEA when carotid lesions were anatomically unfavorable (i.e., in cases of restenosis, high cervical or intrathoracic lesions, or following radiation therapy) (class IIa, LOE B). Finally, they have also recommended that CAS may be considered in highly selected asymptomatic patients with more than or equal to 60% angiographic stenosis (class IIb, LOE B).

Primary prevention is defined as aims to prevent carotid disease from ever developing. Secondary prevention is defined as aims at reducing the clinical impact of asymptomatic carotid stenosis [i.e., stenosis are present and the aim is to prevent them from causing a transient ischemic attack (TIA) or stroke]. The goal of tertiary prevention is to reduce the risk of recurrent TIA or stroke in patients who present with a TIA or stroke secondary to carotid stenosis. Decisions regarding carotid interventions should involve a multidisciplinary team (MDT) including neurologists or stroke physicians, vascular surgeons, and interventional radiologists at every hospital.

MANAGEMENT OF CAROTID ARTERY DISEASE

Definition of Stroke and Transient Ischemic Attack

Stroke diagnosis has been based on the World Health Organization (WHO) definition of a focal, occasionally global, loss of neurological function lasting more than 24 hours (or leading to death) and which has a vascular etiology. A TIA was defined in a similar manner, but the duration was less than 24 hours.³ Imaging has shown that many TIA patients have evidence of acute infarction (particularly when symptoms lasted several hours) and this led to proposals that the classical definitions of stroke or TIA should be revised. One revised definition of TIA proposed by the American Heart Association (AHA) is "a brief episode of neurologic dysfunction resulting from focal temporary cerebral ischemia, which is not associated with acute cerebral infarction". Ischemic stroke is defined as "an episode of neurologic dysfunction caused by focal cerebral or retinal infarction, where infarction is defined as brain or retinal cell death, attributable to ischemia, based on neuropathology, neuroimaging, and/or clinical evidence of permanent injury".

Silent infarction is defined as “imaging or neuropathological evidence of cerebral/retinal infarction without a history of acute neurological dysfunction attributable to the lesion”.⁴

Methods for Measuring Carotid Artery Stenosis Severity

The ECST and the NASCET trials used different methods for measuring stenosis severity.

- A 50% NASCET stenosis is equivalent to a 75% ECST stenosis
- A 70% NASCET stenosis equates to an 85% ECST stenosis.⁵

The ECST measurement method has important advantages over NASCET. The NASCET method does not permit reliable measurement of stenosis severity in patients with large volume plaques within dilated carotid bulbs. Here, the residual luminal diameter may be only slightly less than that of the distal ICA. In this situation, the NASCET measurement method will record a less than 50% stenosis, whereas the ECST method will measure this as being more than 70%. In this rare situation, recently symptomatic patients with large volume plaques consistent with an ECST more than 70% stenosis should be considered for revascularization.

Imaging Strategies in Carotid Artery Disease

Angiography has now been abandoned because of angiography-related stroke. In the ACAS, the 30-day death or stroke rate was 2.3% after CEA, but about half of these strokes (1.2%) were angiographic related.⁶

Duplex ultrasound (DUS) is usually the first-line imaging modality because of its low cost and accessibility.

The advantage of computed tomographic angiography (CTA) and magnetic resonance angiography (MRA) is the ability to simultaneously image the aortic arch, supra-aortic trunks, carotid bifurcation, distal ICA, and the intracranial circulation, which is mandatory if a patient is being considered for CAS.

Contrast-enhanced MRA (CEMRA) has a higher accuracy than noncontrast MRA techniques but requires administration of a paramagnetic contrast agent such as gadolinium.⁷ Catheter angiography is now rarely required, unless there are discrepancies on noninvasive imaging.

SECONDARY PREVENTION IN ASYMPTOMATIC PATIENTS

Medical Therapy

Control of Risk Factors

In a pooled analysis smoking was associated with a significant increase in the prevalence of a more than 50% ICA stenosis.⁸ About 5% of males aged more than 65 years who are current smokers have a more than 50% ICA stenosis on DUS screening⁹ and smoking was shown to increase plaque progression.¹⁰ In a meta-analysis of 32 studies, smoking

was associated with a significant increase in late ischemic stroke.¹¹ In a meta-analysis, moderate physical activity was associated with a 25% relative risk reduction (RRR) in ischemic stroke.¹²

Antiplatelet Therapy

There is conflicting opinion regarding antiplatelet therapy in asymptomatic patients because of concerns of increase in bleeding events. In the Asymptomatic Cervical Bruit study, patients with more than 50% asymptomatic ICA stenoses were randomized to 325 mg aspirin versus placebo, at follow-up, there was no difference in ischemic events or death.¹³ By contrast, the Asymptomatic Carotid Emboli Study (ACES) reported that antiplatelet therapy was an independent predictor of lower rates of ipsilateral stroke or TIA in patients with asymptomatic 70–99% stenoses.¹⁴

In the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization Management and Avoidance (CHARISMA) study, where 7% had asymptomatic 50–99% ICA stenosis, there was no evidence that dual antiplatelet therapy (DAPT) conferred any benefit over single antiplatelet therapy.¹⁵ The net effect on stroke was not significant.¹⁶

Presently monotherapy with aspirin remains the antiplatelet agent in asymptomatic carotid artery stenosis patients, with clopidogrel reserved for patients who are aspirin intolerant.

Lipid-lowering Therapy

In ACST-1 patient who were on lipid-lowering therapy, the 10-year risk of stroke was 13.4% in medical therapy patients and 7.6% after CEA. However, in patients not on statins, the 10-year stroke risk was 24.1% in Optimal medical treatment (OMT) patients, versus 17.9% after CEA, suggesting that statins reduce long-term stroke in patients with asymptomatic stenoses.¹⁷ With regard to dosage of statin therapy in these asymptomatic patients there are insufficient data available.

Management of Hypertension

Hypertension is associated with an increased risk of carotid disease.¹⁸ Treatment of hypertension reduces stenosis progression (14% vs. 31%) and promotes regression (32% vs. 0%) compared with placebo.¹⁹ Regression of carotid intima-media thickness (IMT) has been shown with patients with reductions in carotid pulse pressure.²⁰ The European Lacidipine Study on Atherosclerosis, compared lacidipine with atenolol, and concluded that lacidipine was associated with greater reductions in carotid IMT progression and fewer atherosclerotic plaques, despite smaller falls in blood pressure (BP), suggesting an independent, antiatherosclerotic action.²¹ Similar results have been obtained for angiotensin-converting enzyme (ACE) inhibitors; however, calcium channel blockers (CCBs) reduce IMT progression more than diuretics, beta-blockers, or ACE inhibitors in many studies.²²

None of the studies or RCTs has evaluated the effect of antihypertensive therapy on stroke prevention in patients

TABLE 1: Recommendations for management of asymptomatic carotid artery disease (European Society of Cardiology Guidelines 2017)

Recommendations	Class	Level
In "average surgical risk" patients with an asymptomatic 60–99% stenosis, CEA should be considered in the presence of clinical and/or more imaging characteristics that may be associated with an increased risk of late ipsilateral stroke, provided documented perioperative stroke/death rates are <3% and the patient's life expectancy is >5 years	IIa	B
In asymptomatic patients who have been deemed "high-risk for CEA" and who have an asymptomatic 66–99% stenosis in the presence of clinical and/or imaging characteristics that may be associated with an increased risk of late ipsilateral stroke, CAS should be considered, provided documented perioperative stroke/death rates are <3% and the patient's life expectancy is >5 years	IIa	B
In "average surgical risk" patients with an asymptomatic 60–99% stenosis in the presence of clinical and/or imaging characteristics that may be associated with an increased risk of late ipsilateral stroke, CAS may be an alternative to CEA provided documented perioperative stroke/death rates are <3% and patient's life expectancy is >5 years	IIb	B

CAS, carotid artery stenting; CEA, carotid endarterectomy.

with asymptomatic carotid stenoses (ACS). In practice, BP should be maintained less than 140/90 mm Hg in patients with carotid artery stenosis and ACS.²³

Management of Diabetes

Diabetes is associated with a twofold increased risk of ACS,²⁴ as well as stroke.^{25,26} In various meta-analyses, it has been shown that there is no evidence that tight glycemic control reduces stroke risk,²⁷ the UK Prospective Diabetes Study observed that tight BP control, mean BP 144/82 mm Hg, in patients with diabetes was associated with a 44% relative RRR in stroke, compared with patients with mean BP 154/87 mm Hg (Table 1).^{28,29}

TERTIARY PREVENTION IN RECENTLY SYMPTOMATIC PATIENTS

The term "symptomatic" refers to any patient who has suffered a carotid territory symptom within the preceding 6 months. Carotid territory symptoms include (1) hemisensory impairment, (2) hemimotor deficits, and (3) higher cortical dysfunction.

"Crescendo TIAs" involve multiple TIAs within a short time period, with full recovery in between.

"Stroke-in evolution" refers to a fluctuating deficit (never fully back to normal) or a progressively worsening neurological deficit.³⁰

Medical Therapy

Control of Risk Factors

The control of modifiable risk factors including smoking, exercise, diet, and obesity is an important aspect of tertiary prevention in patients of carotid stenosis.

Antiplatelet Therapy

The importance of starting antiplatelet therapy at an earlier time was documented in various meta-analysis which compared aspirin started in the first few days after symptoms onset, compared to control. Early aspirin therapy reduced

the 6-week risk of recurrent stroke by 60% as well as disabling or fatal stroke by 70%.^{31,32}

Antiplatelet Therapy during Carotid Artery Stenting

All guidelines recommend that patients of CAS should receive DAPT. However, this is mainly based on the coronary literature, with no data from large RCTs in CAS patients.

Meta-analyses of the various RCTs suggested aspirin plus clopidogrel therapy after coronary artery stenting,³³ however, the only RCT in CAS patients, aspirin plus heparin was associated with significantly higher perioperative neurological events and a nonsignificantly higher risk of bleeding complications compared with aspirin plus clopidogrel.³⁴

Presently, most guidelines advise at least 4 weeks of treatment with aspirin and clopidogrel after CAS.³⁴ Literature shows long-term DAPT confers no additional benefit over single antiplatelet, unless indicated for cardiac reasons.^{35,36}

Statins during Carotid Artery Stenting

Various studies have reported that statin therapy started prior to CAS are associated with significant reductions in 30-day risk.³⁷⁻³⁹ Studies reported that 30-day death/stroke/myocardial infarction (MI) risk was significantly lower in CAS patients who were pretreated with statins (4%), versus 15% who were not.³⁷ A similar study reported that preoperative statin therapy was associated with significant reductions in perioperative death/stroke/MI (6.8%) versus 13.9% in those not taking statins pre-CAS.^{39,38} Statin usage has not been evaluated in RCTs, but the evidence from these various studies suggest that pretreatment with statins in patients undergoing CAS is advocated.

Treatment of Hypertension

No RCT has evaluated the role of antihypertensives in patients with symptomatic carotid stenoses. However, a meta-analysis of 13 BP treatment trials in patients with history of stroke reported a significant RRR in stroke on antihypertensive therapy.⁴⁰

TABLE 2: European Society of Cardiology recommendations: features associated with high risk of carotid endarterectomy

Recommendations	Class	Level
CEA is recommended in symptomatic patients with 70–99% carotid stenoses, provided the documented procedural death/stroke rate is <6%	I	A
CEA should be considered in symptomatic patients with 70–99% carotid stenoses, provided the documented procedural death/stroke rate is <6%	IIa	A
In recently symptomatic patients with a 50–99% stenosis who present with adverse anatomical features or medical comorbidities that are considered to make them "high-risk for CEA", CAS should be considered, provided the documented procedural death/stroke rate is <6%	IIa	B
When revascularization is indicated in "average surgical risk" patients with symptomatic carotid disease, CAS may be considered as an alternative to surgery, provided the documented procedural death/stroke rate is <5%	IIb	B
When decided, it is recommended to perform revascularization of symptomatic 50–99% carotid stenoses as soon as possible, preferably within 14 days of symptom onset	I	A
Revascularization is not recommended in patients with a <50% carotid stenosis	III	A

CAS, carotid artery stenting; CEA, carotid endarterectomy.

Though in symptomatic patients with severe bilateral ICA stenoses, aggressive BP lowering before revascularization may not be advisable.⁴¹

CAROTID ARTERY STENOSIS VERSUS CAROTID ENDARTERECTOMY

There has been a large section of literature published regarding choice of procedure for carotid artery stenosis (CAS vs. CEA).

Carotid artery stenting is the procedure of choice for high-risk patients compared to CEA. Features associated with high risk of CEA (Tables 2 and 3) (ESC recommendations) and predictors of high perioperative risk of CEA (Table 4) are independent variables for the choice of treatment. These factors can predict CAS as the choice of treatment for CAS (Table 5).

TABLE 3: Features associated with high risk of carotid endarterectomy

Medical comorbidity	Anatomic criteria
Elderly >75 years	Surgically inaccessible lesions
Congestive heart failure (NYHA class III/IV)	At or below C2
Unstable angina	Below the clavicle
CAD with >2 vessels >70%stenosis	Ipsilateral neck irradiation
Recent myocardial infarction <30 days	Spinal immobility of the neck
Planned open heart surgery (<30 days)	Contralateral carotid artery occlusion
Ejection fraction <30%	Laryngeal palsy
Severe pulmonary disease (COPD)	Tracheostoma
Severe renal disease	Previous ipsilateral CEA or neck surgery

CAD, coronary artery disease; CEA, carotid endarterectomy; COPD, chronic obstructive pulmonary disease; NYHA, New York Heart Association.

TABLE 4: Predictors of perioperative risk in carotid endarterectomy

Neurologic
• Deficit within past 24 h Stroke within past 7 days Crescendo TIA
• Global cerebral ischemia
• CT evidence of stroke
Angiographic
• Ulcerated plaque on stenosis
• >3 cm distal carotid stenosis
• >5 cm proximal carotid stenosis High bifurcation (at C2) Intraluminal thrombus
Medical
• Age >50 years
• Hypertension, COPD, severe obesity, DM

DM, diabetes mellitus; TIA, transient ischemic attack; COPD, chronic obstructive pulmonary disease.

TIMING OF INTERVENTIONS AFTER ONSET OF SYMPTOMS

The following are the definitions of "first event", "index event", and "most recent event".⁴²

- The "first event" is the first symptom to affect the patient
- The "index event" is the symptom that led the patient to seek medical advice
- The "most recent event" is the symptom that occurred most recently.⁴²

Timing of Carotid Artery Stenting

The time of performing CAS after symptom onset is controversial. A pooled series from four registries reported higher 30-day stroke rates (8.8%) when CAS was performed early less than 14 days, compared with 5.9% when CAS was performed later than 14 days.^{43,44}

Timing of Carotid Interventions after Intracranial Endovascular Therapies

A meta-analysis of randomized trials reported that emergency endovascular treatment of acute ischemic stroke

TABLE 5: Indication associated with carotid endarterectomy

Indication	Recommendation	LOE
<ul style="list-style-type: none"> • Symptomatic high surgical risk • Among patients with symptomatic severe stenosis (>70%) in whom the stenosis is difficult to access surgically, medical conditions are present that greatly increase the risk of surgery , or when other specific circumstances exist, such as radiation-induced stenosis or restenosis after CEA, CAS may be considered when performed by an experienced operator 	Class IIa	B
It is reasonable to choose CAS over CEA when revascularization is indicated in patients with neck anatomy unfavorable for arterial surgery	Class IIa	B
<ul style="list-style-type: none"> • Symptomatic average surgical risk • CAS is indicated as an alternative to CEA for symptomatic patients at average or low risk of complications associated with endovascular intervention when the diameter of the lumen of the internal carotid artery is reduced by >70% as documented by noninvasive imaging or >50% as documented by catheter angiography and the anticipated rate of periprocedural stroke or mortality is <6% 	Class I	B
CAS is indicated as an alternative to CEA for symptomatic patients at average or low risk of complications associated with endovascular intervention when the diameter of the lumen of the internal carotid artery is reduced by >70% by noninvasive imaging or >50% by catheter angiography	Class I	B
<ul style="list-style-type: none"> • Asymptomatic high surgical risk patients • Selection of asymptomatic patient for carotid revascularization should be guided by an assessment of comorbid conditions, life expectancy and other individual factors and should include a thorough discussion of the risks and benefits of the procedure with an understanding of patient preferences 	Class I	C
It is reasonable to choose CAS over CEA when revascularization is indicated in patients with neck anatomy unfavorable for arterial surgery	Class IIa	B
<ul style="list-style-type: none"> • Asymptomatic average surgical risk patients • Prophylactic CAS might be considered in highly selected patients with asymptomatic carotid stenosis (minimum 60% by angiography, 70% by validated Doppler ultrasound), but its effectiveness compared with medical therapy alone in this situation is not well established 	Class IIb	B

CAS, carotid artery stenting; CEA, carotid endarterectomy; LOE, level of evidence.

was associated with a twofold improvement in functional outcome, compared with patients on medical therapy. Presently, there is no data to whether adjuvant CEA or CAS should be performed as a synchronous or staged intervention in these patients, but ESCAPE (The Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness) trial advised not to routinely perform CAS at the time of endovascular therapy.⁴⁵

Benefit of Revascularization in Less than 50% Stenosis

In patients with less than 50% stenoses who report recurrent symptoms, it is important to ensure that optimal medical treatment should be initiated. If symptoms persist, despite optimal medical therapy, it may be reasonable to consider CEA or CAS.

CAROTID ARTERY STENTING OVER CAROTID ENDARTERECTOMY

Carotid artery stenting can be considered as an alternative to CEA in high-risk patients.

STAGED OR SYNCHRONOUS BILATERAL CAROTID INTERVENTIONS

Few patients can present with bilateral 70–99% stenoses. Either they will be totally asymptomatic, or have one stenosis symptomatic. It is extremely rare for bilateral severe ICA stenoses to be symptomatic simultaneously. The question is whether synchronous bilateral CEAs should be considered. While it is feasible to undertake bilateral synchronous CEAs,⁴⁶ the most dangerous complication is injury to both recurrent laryngeal and/or hypoglossal nerves. Accordingly, if bilateral (synchronous) revascularization is absolutely necessary, it may be better to consider bilateral CAS. However, in most patients, staged bilateral CEAs is appropriate, especially in the patient with a symptomatic 50–99% stenosis on one side and an asymptomatic 70–99% stenosis on the other.

CAROTID ARTERY STENTING TECHNIQUE

Adjuvant medical therapy has been a cornerstone of our intervention advances. It is now in guidance to start dual antiplatelet with aspirin and clopidogrel, if patient is not on any drug. Aspirin 300 mg loading should be done.

Postprocedure dual antiplatelet should be continued for at least 1 month followed by clopidogrel. It is now recommended to routinely administered 0.6–1.2 mg of atropine in view of anticipated hypotension and bradycardia (Table 6). Femoral is choice of access for most operators although radial may be preferred in aortoiliac tortuosity or occlusion or hostile aortic arch anatomy. The choice of sheath or guide catheter approach depends on the perceived technical difficulty of the procedure. Guide catheters have better torque control and are preferred for more challenging cases, such as steep aortic arch (types II or III), tortuous carotid artery, or extremely stenotic or calcified carotid lesions. Traditionally, Judkins Right and Amplatz 1, multipurpose have been used. In sheath approach a 6 Fr 90-cm Shuttle sheath is typically used. Either a 5 Fr diagnostic JR4 or VTK catheter can be used to engage the innominate or left common carotid artery. Following arterial access, intravenous (IV) heparin (50–100 U/kg) is given to achieve an optimal activated clotting time between 250 and 300 seconds (Table 7).

There has been lot of ongoing debate over stent cell design. Self-expanding tapered stents (nitinol or stainless steel) are preferred as they enable easy and accurate one-handed deployment. They are designed for low profile and rapid exchange. There are two types of cell designs. Open cell design enhances deliverability while remaining conformable and gentle on the vessel. Closed cell design secures the lesion and holds plaque in place. Hybrid cell design (See figure 1) ensure combination of better trackability and protection.

The International Carotid Stenting Study (ICSS)⁴⁷ reported 5.1 % risk of death or stroke at 30 days with closed cell

TABLE 6: Carotid artery stenting technique

Guiding catheter	Long sheath system
*Better torque control	Less torque control
*More rigid better support	Less rigid less support
*Better for tortuosity	–
7F/8F sheath size	*6F sheath size
Uneven transition with inner catheter	*Dilator provides smooth transition

*Comparison of choice of hardware, advantage of either technique marked as green.

TABLE 7: Recommendations for carotid artery stenting

Recommendation	Class	Level
The use to embolic protection devices should be considered in patient undergoing CAS	IIa	B
Proximal protection devices are not recommended in patients with advanced common carotid disease, or those with external carotid artery disease (where an occlusion balloon is to be positioned in the external carotid artery) or in patients with contralateral occlusion and insufficient collateralization	III	C

CAS, carotid artery stenting.

design versus 9.5% with open cell ($p = 0.024$) there is no guideline recommendation for dual stent reducing procedural risk. Routine predilatation which predisposes to higher stroke risk is only advisable when there is anticipated difficulty is passing stent or filter protection devices.

Cerebral protection device (CPD): They are has now been relegated to class IIa (level II) as there has been conflicting evidence supporting their use. A meta-analytics comprising of 11,655 patient favored CPD as it reduced perioperative stroke death. Proximal protection device which work without crossing the stenotic lesion are an attractive option in prevention of embolic drug all stage of CAS. In a systematic review there has been reduction in periprocedural stroke 0.62 [RRR 95% (1.054–0.72)].

COMPLICATIONS

Perioperative Stroke

Stroke because of aortic arch manipulation is the most common intraprocedural cause. Protection device filters are also not full proof as they may be malapposed or incompletely deployed. Even if they are completely deployed it is worthwhile to remember that smallest pore size is 80 μm even in latest filter, so small particle can escape through them (Table 8).

If stroke do occurs, dedicated neurological devices can be used for cleaning of embolic material from main branch of ICA that gives to M2 segment. Thrombosuction can also be tried. Thrombolysis is not beneficial as embolism comprises of plaque rather than fibrin clot. However, if needed the agent studied are urokinase (500,000 two unit) at half as bolus or rTPA can be given as a 5-mg bolus, followed by slow infusion (maximum dose 20 mg). Selective glycoprotein (Gp) IIb/IIIa inhibitor (abciximab) has been tried in treatment of stroke.⁴⁸ Delphi et al. have enumerated predictor of periprocedural stroke (1) Type II aortic arch, (1) Bovine arch, (3) arch atheroma, (4) external carotid artery disease, (5) markedly angulated distal ICA, (6) long stenosis, and (7), pinhole stenosis (Table 9).⁴⁹

Poststenting hypotension is generally a self-limiting event. To prevent it is important to hold antihypertensive

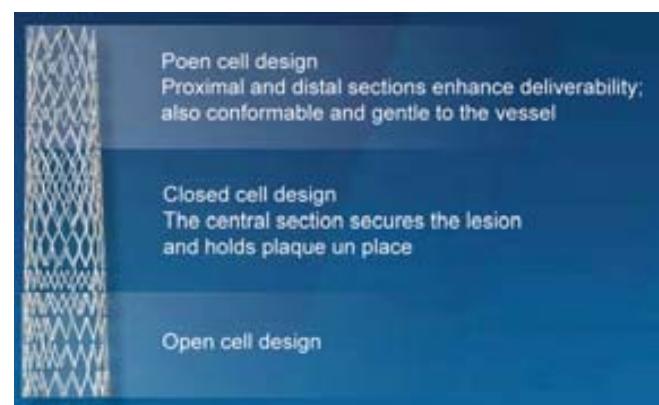

FIG 1: Hybrid cell design.

TABLE 8: Carotid artery stenting: Procedural factors likely to be associated with adverse procedural outcomes

Medical comorbidity	Anatomical criteria	Procedural factor
Elderly (>75/82 years)	Type III aortic arch	Inexperienced operator/center
Symptom status	Vessel tortuosity	EPD not used
Bleeding risk/ hypercoagulable state	Heavy calcification	Lack of femoral access
Severe aortic stenosis	Lesion-related thrombus	Time delay to perform procedure from onset of symptoms
Chronic kidney disease	Echolucent plaque	–
Decreased cerebral reserve	Aortic arch atheroma	–

EPD, embolic protection device.

TABLE 9: Complication related to carotid endarterectomy or carotid artery stenting

Recommendation	CLASS	LEVEL
Patients suffering a late ipsilateral stroke or transient ischemic attack (TIA) in the presence of an ipsilateral 50–90% restenosis should undergo redo carotid endarterectomy or carotid artery stenting	I	A
It is recommended that patients suffering a late ipsilateral stroke or TIA in the presence of an ipsilateral <50% restenosis should be treated medically	I	A
Reintervention may be considered in carotid endarterectomy patients with an asymptomatic 70–90% restenosis, following multidisciplinary team review	IIb	B
It is recommended that carotid stent patients who develop an asymptomatic restenosis >70% are treated medically	I	A

medicine on morning of procedure, having venous access and adequate hydration (N crystalloid plus volume expands) problem with IV expander is post-CAS in a state of decrease peripheral vascular resistance and hence IV vasopressor are more beneficial (preferably norepinephrine).

Restenosis

Symptomatic ipsilateral carotid territory symptom should undergo repeat CAS within 14 days. Regarding asymptomatic restenosis data is uncertain Kumar's meta-analysis suggested little or no benefit of intervention (0.8% over 4 year).⁵⁰

Carotid Stenosis Patients Undergoing Major Cardiac Surgery

Routine screening in view of low prevalence of perioperative stroke cannot be supported. It should only be done in patient who are elderly, presence of carotid, prior stroke or staged left

TABLE 10: Screening of cardiac stenosis patients for cardiac surgery

Recommendation	CLASS	LEVEL
Routine screening for carotid disease prior to open heart surgery is not recommended	III	C
Ultrasound screening for carotid disease prior to coronary bypass should be considered in patients aged >70 years, those with a history of transient ischemic attack or stroke, a carotid bruit or left mainstream disease so that the patient can be better informed of the increased risk associated with coronary artery bypass surgery in patients with concurrent carotid disease	IIa	C
Staged or synchronous carotid intervention should be considered in coronary artery bypass surgery patients with a history of stroke or transient ischemic attack in the preceding 6 months and a 50–90% carotid stenosis	IIa	B
Staged or synchronous carotid endarterectomy should be considered, instead of stenting plus coronary bypass in patients with a history of stroke or transient ischemic attack in the preceding 6 months and a 50–90% carotid stenosis	IIa	B
A staged or synchronous carotid intervention is not recommended in coronary artery bypass patients with an asymptomatic unilateral 70–90% carotid stenosis for the prevention of stroke after coronary bypass	III	B
A staged or synchronous carotid intervention may be considered in coronary artery bypass patients with bilateral asymptomatic 70–99% carotid stenosis, or a 70–99% stenosis with contralateral occlusion	IIb	C
The choice between carotid endarterectomy and carotid stenting in asymptomatic patients in whom a carotid intervention is deemed necessary prior to coronary artery bypass should be based on the urgency of performing surgery, choice of antiplatelet strategy during coronary bypass, individual patient characteristics, symptom status and local expertise	IIa	C

main triple vessel disease (TVD).⁵¹ Etiology of perioperative stroke can be multifactorial however intervention is indicated in patient with prior history of stroke or TIA⁵² or bilateral asymptomatic 70–99% stenosis.⁵³ However, evidence is less supportive in asymptomatic significant unilateral stenosis where risk of strokes is 20%.⁵³ Choice of strategy CAS versus CEA will depend on urgency of performing surgery, choice of antiplatelet (Table 10).

Carotid Artery Disease and Major Noncardiac Surgeries

Patient undergoing elective noncardiac surgery with history of stroke within last 6 months should undergo carotid artery

imaging (class I), if possible surgery should be deferred for 6 months (class 1) and patient who come out with ipsilateral 50–99% carotid stenosis should undergo CAS before elective non cardiac surgery. In patient of known asymptomatic carotid artery disease statin and antiplatelet should not be stopped. Prophylactic CAS is not recommended in this subject.

NEW ASPECTS OF 2017 GUIDELINES ADDED TO THE 2009 GUIDELINES

- Evidence supporting the prevention of stroke in patients with asymptomatic and symptomatic carotid disease
- Evidence supporting rapid interventions in recently symptomatic patients and the timing of interventions after thrombolysis
- Evidence supporting various CAS techniques including adjuvant medical therapy, wires, catheters, and stents, and CPDs
- Management of concurrent carotid and cardiac disease
- Management of patients with ACS undergoing major noncardiac surgical procedures.

Update 2018

Critical Limb Ischemia: Current Management

Narendra N Khanna, Chukwudi Nwagbara, Suparna Rao

INTRODUCTION

Clinically, critical limb ischemia (CLI) is defined as ischemic rest pain, tissue loss or gangrene in the presence of peripheral artery disease (PAD) and hypoperfusion of the lower extremity.¹ This definition is recommended by the Trans-Atlantic Inter-Society Consensus on management of PAD.² CLI is a severe manifestation of PAD and it is usually as a result of a combination of atherosclerotic and atherothrombotic disease process.³

The term CLI implies chronicity and it is reserved for patients with ischemic symptoms of more than 2 weeks.⁴ It differs from acute limb ischemia, which is a sudden loss of limb perfusion (defined as within 2 weeks) and typically caused by embolus or thrombus. Significance of CLI is the fact that it is associated with not only a high degree of loss to limb but also to life. Total 25% of patients with CLI die within 1-year following presentation and 30% undergo amputation during the same period.⁵

CLI is characterized by:

- Rest pain of more than 2 weeks duration
- Impending loss of tissue or ulceration because of severe multisegmental arterial disease
- Associated high-risk of loss of limb and life.

The goal of treatment is relieving pain, prevention or minimizing tissue or limb loss, healing of ulcers, and improving quality of life and survival. These goals are usually achieved by a combination of aggressive medical therapy, endovascular or surgical revascularization, and sometimes amputation. Treatment such as stem cell therapy, gene therapy, hyperbaric oxygen therapy, intermittent pneumatic compression, and spinal cord stimulation may also be of some benefit in relieving pain and promoting wound healing among those who are either unfit or unwilling to undergo revascularization or amputation.³ Other therapies include control of infection, local wound care, offloading and pressure relief, good analgesics and optimal therapy to modify atherosclerotic risk factors, and treatment of other comorbidities.³

EPIDEMIOLOGY AND RISK FACTORS

The incidence of CLI is approximately 22% per 100,000 per year, affecting 1–2% of patients with PAD.⁶ However with increasing life expectancy and the prevalence of diabetes, obesity, sedentary lifestyles, these estimates are likely to increase.⁷ A national survey by the Vascular Surgery Society of Great Britain and Ireland showed an annual incidence of 400 per million per year.⁸ In a Finnish study, 39% of patients presenting with CLI experienced symptoms of previous claudication, out of which 54% were diabetic and 89% had ulcers as the initial feature of CLI.⁹ About 10% of the patients with symptomatic PAD and another 5–10% of patients with asymptomatic PAD progress to CLI over a period of 5 years.¹⁰ In the PREVENT trial, more than 40% of patients with CLI had advanced coronary artery disease.¹¹

The major risk factors for the development of CLI are smoking, diabetes mellitus, age, and dyslipidemia. Studies have shown that diabetic PAD patients are more likely to need a major amputation than nondiabetic PAD patients.¹² A Danish national discharge survey showed that in 1980, the incidence of lower limb major amputations increased from 0.3 per 100,000 per year in those younger than 40 years to 226 per 100,000 per year in those older than 80 years.¹³ Also nondiabetic heavy smokers undergo major amputation more frequently among PAD patients.¹⁴

PATHOPHYSIOLOGY OF CRITICAL LIMB ISCHEMIA

The etiology of CLI is multifactorial; however, the common factor is impaired blood flow to the lower extremities due to occlusive lesions. As a result of this, there is reduced oxygen and nutrient supply to the affected region leading to ischemic pain. Patients with CLI usually have multilevel vessel disease such that even the resting blood supply cannot meet the nutritional requirements of the limbs leading to rest pain and ulcer formation.¹⁵ The cause of ulcer may be related to pressure, trauma, venous insufficiency or poor

hygiene.¹⁶ However, an increased level of blood supply is usually required when skin ulcers are present to successfully complete the healing process.¹⁷ Impaired blood supply can lead to cell death, endothelial dysfunction, inflammation, and an inability to provide proper local immunologic response to the infection.¹⁸ This leads to autonomic dysregulation, altered blood viscosity, and decreased erythrocyte fluidity.¹⁹

Abnormalities in the microcirculation is another contributory factor to the pathophysiology of CLI. Individuals with CLI have a reduced number of perfused skin capillaries. Other factors that contribute to the decreased capillary perfusion in CLI patients include platelet aggregation, reduced red blood cell deformability, increased leukocyte adhesiveness, fibrinogen, microvascular thrombosis, excessive vasoconstriction, and interstitial edema.²⁰

CLINICAL FEATURES

Symptoms

The classical symptom of CLI is pain which usually occurs at the lower extremity of the limb. The pain occurs usually at rest and worst at night. It is usually wakes the patient up and it is exacerbated by elevation of the limb and exercise. The pain is temporary relieved by cold and also by keeping the leg at dependent position. The pain of CLI should be carefully distinguished from other related disease conditions that causes limb pain like venous disease (the pain occurs usually at rest and increases in the evening which often disappears with some form of muscle activity), osteoarthritis (pain on walking but not relieved by rest), neuropathic pain (usually characterized by instability while walking and pain not relieved by rest), and complex regional pain syndrome (previously known as reflex sympathetic dystrophy). In addition to pain, CLI patients also have paresthesia.

Physical Findings

Clinical examination demonstrates features of poor tissue perfusion: hair loss, muscle atrophy, subcutaneous tissue and skin atrophy, skin fissures, thickened and brittle toe nail, discoloration of the skin of the affected tissue, weak or absent peripheral pulses, poor capillary refilling, loss of temperature, nonhealing ulcer, pallor, and gangrene.

CLASSIFICATION

Categorization of patients with CLI depends on the severity of the disease. The Rutherford classification has classically defined CLI as rest pain (class IV), tissue loss (class V), and gangrene (class VI) (Table 1).²¹

Alternatively, the Fontaine classification put rest pain as class III and tissue loss or gangrene as class IV (Table 2).²²

These classifications did not address the wound size, perfusion assessment, or infection. The Society for Vascular Surgery Lower Extremity Guidelines Committee came up with Threatened Limb Classification System: Risk stratification based on wound, ischemia, foot infection (WIFI).²³

TABLE 1: Modified Rutherford classification of peripheral artery disease

Grade	Category	Clinical presentation
	0	Asymptomatic
I	1	Mild claudication
	2	Moderate claudication
	3	Severe claudication
II	4	Ischemic rest pain
	5	Minor tissue loss: Nonhealing ulcer, focal gangrene with diffuse pedal ulcer
III	6	Major tissue loss extending above the transmetatarsal level, functional foot no longer salvageable

Source: Modified from Rutherford RB, Baker JD, Ernst C, et al. Recommended standard for reports dealing with lower extremity ischemia: revised version. J Vasc Surg. 1997;26:517-13.13.

TABLE 2: Fontaine classification of peripheral artery disease

Stage	Symptoms
I	Asymptomatic
II	Intermittent claudication
IIa	Pain free, claudication walking >200 m
IIb	Pain free, claudication walking <200 m
III	Rest and nocturnal pain
IV	Necrosis, gangrene

DIFFERENTIAL DIAGNOSIS OF LEG PAIN ON EXERTION

Vascular causes:

- Atherosclerosis
- Embolism
- Thrombosis
- Vasculitis:
 - Thromboangiitis obliterans
 - Takayasu arteritis
 - Giant cell arteritis.
- Aortic coarctation
- Fibromuscular dysplasia
- Irradiation
- Endofibrosis of the external iliac artery
- Extravascular compression:
 - Arterial entrapment (e.g., popliteal artery entrapment)
- Adventitial cysts

Nonvascular causes:

- Venous insufficiency
- Osteoarthritis; hip and knee
- Myositis
- Glycogen storage disease
- Lumbosacral radiculopathy:
 - Degenerative arthritis
 - Spinal stenosis.

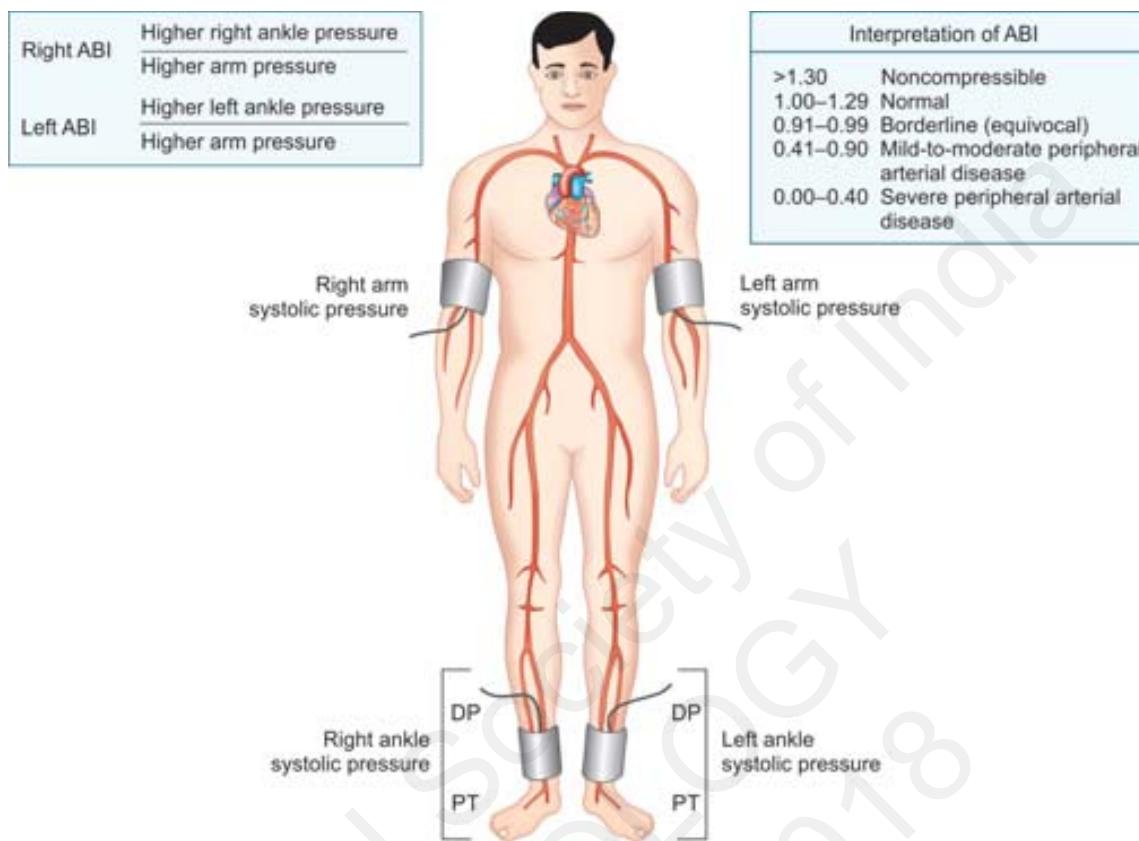

FIG. 1: Assessment of ankle brachial index.

EVALUATION OF CRITICAL LIMB ISCHEMIA

Ankle Brachial Index

Ankle brachial index (ABI) is the primary noninvasive test for the diagnosis of CLI. Determination of the ABI is a simple procedure and it can be done at the bedside. It is a ratio of systolic blood pressure (SBP) in the ankle and SBP in the arm. A pneumatic cuff placed just above the ankle is inflated to a value just above the systolic pressure and it then gradually deflated to obtain the onset of flow with a hand held Doppler instrument (5–10 MHz) place over the posterior tibial and anterior tibial arteries of each foot, the value obtained represents the ankle SBP (Fig. 1). The highest ankle systolic pressure is divided by the highest brachial systolic pressure, resulting in an ABI per leg. Measuring ABI after exercise increases the sensitivity of the test. For this, the patient is asked to exercise on a treadmill at 3.2 km/h at 10–20% slope until claudication occurs.

The normal ABI range is 1.00–1.40. ABI less than 0.4 is strongly suggestive of CLI. In patients with ischemic ulcers, the ankle systolic pressure is usually 50–70 mm Hg and 30–50 mm Hg among patients with ischemic rest pain. In patients with calcified vessels as seen among diabetics, end-stage renal disease patients and elderly, leg BP measurement are not reliable because the pneumatic cuff cannot compress the calcified vessels. ABI higher than 1.40 suggests a non-

TABLE 3: Features of critical limb ischemia (CLI)

Noninvasive vascular laboratory test for CLI	Value
Ankle-brachial Index	≤ 0.4
Ankle systolic pressure	≤ 50 mm Hg
Toe systolic pressure	≤ 30 mm Hg
Measures of skin microcirculation	
Capillary density	$\leq 20/\text{mm}^2$
Absent reactive hyperemia on capillary microscopy	
TcPO ₂	≤ 10 mm Hg
TcPO ₂ , transcutaneous oxygen pressure.	

compressible artery and a toe-brachial index (TBI) or toe pressure measurement is indicated for such patients. TBI with a ratio of 0.70 or toe pressure less than 30 mm Hg is suggestive of CLI (Table 3).

Duplex Ultrasound

Duplex ultrasound provides a direct, noninvasive means of assessing the anatomic characteristics of the peripheral arteries, morphology of the plaques and to monitor bypass grafts. It is a popular procedure due to its noninvasive nature, use of no contrast, and freedom from exposure to radiation.^{24,25} The lesions are identified by two dimensional ultrasonography and color Doppler mapping, while the degree of stenosis is estimated by Doppler waveform analysis,

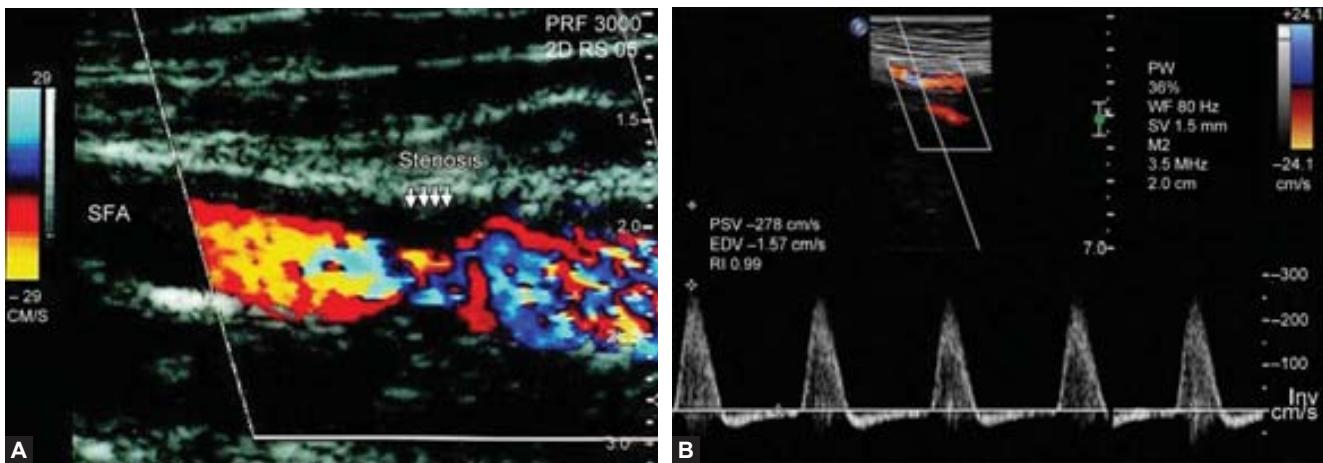

FIG. 2: Duplex ultrasound assessment showing stenosis of superficial femoral artery.

peak systolic velocities, and ratios (Fig. 2). The major pitfall of duplex ultrasound is its difficulty in assessment of the lumen in deeply calcified arteries as seen among diabetics, and also those with open ulcers or severe scarring. Another significant setback of duplex ultrasound when compared with other imaging modalities like digital subtraction angiography (DSA), computed tomography angiography (CTA), or magnetic resonance angiography (MRA) is its difficulty in providing full arterial road map.

Computed Tomography Angiography

Computed tomography angiography using multidetector CT technology allows imaging with high resolution. The advantage of CT is its ability to visualize calcifications, clips, stents, and bypasses (Fig. 3). CTA has some disadvantages which include ionizing radiation exposure, use of nephrotoxic contrast materials, and the visualization of artifacts due to blooming effect.

Magnetic Resonance Angiography

Magnetic resonance angiography is one of the most non-invasive sensitive imaging modality that is used for visualization of the lower limb vessels²⁶ (Fig. 4). MRA however cannot be used in the presence of pacemaker or metallic implants and also among patients with claustrophobia. MRA cannot visualize arterial calcifications, which may be a limitation for the selection of the anastomotic site for a surgical bypass. Another significant disadvantage is the occurrence of nephrogenic fibrosing dermopathy with gadolinium contrast agents.

Peripheral Angiography

Conventional peripheral angiography is essential in evaluation of arterial anatomy before endovascular revascularization procedure (Fig. 5). This is considered as the gold standard but it is now reserved only for patients undergoing endovascular intervention and also used when the diagnosis

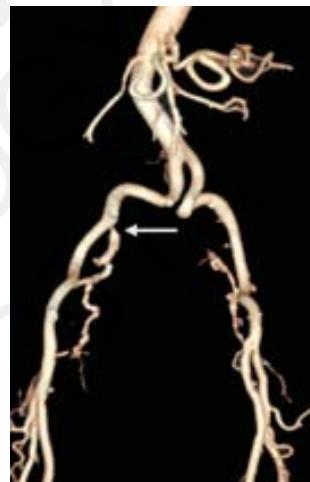

FIG. 3: Computed tomography angiography showing stenosis of right ostial internal iliac artery.

FIG. 4: Magnetic resonance angiography showing diffuse arterial disease.

FIG. 5: Peripheral angiography showing long segment total occlusion.

is not clear. It has an advantage of using digital subtraction technique to enhance resolution of the lesion.

TREATMENT OF CRITICAL LIMB ISCHEMIA

Critical limb ischemia treatment requires a multidisciplinary team approach that may be responsible to address all the contributory factors.

The goal of treatment includes the following:

- Risk factors modification
- Optimal medical treatment
- Wound care
- Revascularization.

Risk Factors Modification

Smoking Cessation

Smoking is one of the major risk factors for the development of CLI. In general population, smoking increases the risk of developing CLI by twofold to 6-fold. Smokers with CLI have an increased risk of amputation, higher morbidity, and mortality rate. Smoking cessation is a class 1 recommendation for smokers with CLI.

Blood Pressure Control

Blood pressure control reduces the risk of coronary artery disease and stroke among CLI patients. Studies have shown that intensive blood pressure control reduces cardiovascular events in diabetic patient with PAD.²⁷ In the Heart Outcome Prevention Evaluation study, the risk of heart attack, stroke, and death from vascular causes decreased by 22% for patients who received angiotensin-converting enzyme inhibitor.²⁸

Dyslipidemia

The presence of PAD is considered a coronary artery risk equivalent. Intensive statin (HMG-CoA reductase inhibitors) therapy consistently lowers cardiovascular events in patients with PAD than those are not on statin or low intensity statin. The mechanism by which statin reduces cardiovascular

events and mortality is through plaque stabilization and improvement of endothelial function.²⁹

Diabetes Mellitus

Intensive treatment of diabetes mellitus reduces the risk of microangiopathies. However, such benefits have not been observed in macrovascular complications.³⁰ The United Kingdom Prospective Diabetes Study has shown that a 1% increase in hemoglobin A1C was associated with a 28% increase in risk of incident of PAD.³¹

Optimal Medical Therapy

The definitive treatment of CLI is revascularization; however, the optimal medical treatment is targeted at symptoms (claudication), delay in progression of the disease, and reduction of cardiovascular events.

The drugs used are as follows:

- *Cilostazol:* It is a quinolinone derivative that inhibits phosphodiesterase 3, thereby decreasing the degradation of cyclic adenosine monophosphate and increasing its concentration in platelets and blood vessels.¹⁵ In a meta-analysis by Momsen, the maximal walking distance increased on an average by 70 m with 100 mg dose of cilostazol.³² Cilostazol is contraindicated in heart failure patients
- *Pentoxifylline:* It, also known as oxpentifylline, is a xanthine derivative. It improves tissue oxygenation by its ability to decrease blood viscosity and to improve erythrocyte flexibility
- *Naftidrofuryl:* It, also known as nafronyl, is a vasodilator which inhibits 5-hydroxytryptamine type 2 (5-HT2) thereby reducing erythrocyte and platelet aggregation. It is effective in treating muscle pain and cramps thereby improving walking distance³³
- *Statins:* Statin is a HMG-CoA inhibitor. In addition to cardiovascular risk reduction, it may improve symptoms of claudication and also reduce the risk of tissue loss.³⁴ This occurs through plaque stabilization and improvement of endothelial function²⁹
- *Antiplatelets:* These are used for the treatment of CLI mostly to prevent the risk of cardiovascular events, stroke, and vascular death. However, after revascularization, antiplatelets improve the stent patency rate.

Wound Care

The principles of wound care include improving perfusion to the limb, treatment of the infection, avoiding pressure on the wound by off-loading the foot, debridement, and good nutrition.

The local temperature of the limb can be increased using sheepskin boots and this may improve tissue perfusion.³⁵ Biosurgery with sterile maggots has been shown to have some beneficial effects in increasing vascularity and promoting wound healing.³⁶

Some adjuvant therapies include hyperbaric oxygen, intermittent pneumatic compressions, spinal cord stimulation, ultrasound therapy, noncontact low-intensity

frequency, topical therapy of platelet-derived growth factor (stem cell therapy), and low-dose diode laser therapy at the wound margins.

Hyperbaric Oxygen Therapy

Hyperbaric oxygen therapy is one of the adjuvant management modalities for the treatment of nonhealing wound among patients with CLI.³⁷ During hyperbaric oxygen therapy, patients are usually placed in the hyperbaric chamber and exposed to 100% oxygen at 2-3 times greater pressure than ambient atmosphere. Protocols usually vary depending on the indication. Hyperbaric oxygen therapy enhances collagen synthesis and maturation, fibroblast proliferation, epithelialization, increases leukocyte bacterial killing capacity, and induces angiogenesis. Hyperbaric oxygen therapy also exhibits some antibacterial effects on selected microorganisms thereby enhancing wound healing. Hyperbaric oxygen therapy should always be initiated along with other conventional treatment.

Stem Cell Therapy

Stem cell therapy involves the use of various cell-stimulating factors that promote angiogenesis and bone marrow-derived pluripotent cells in the management of CLI. These factors include fibroblast growth factor-1, vascular endothelial growth factor, and hepatocyte growth factor. Angiogenesis is defined as the expansion of the vasculature through the formation of new capillary network from the pre-existing vessels. In pilot studies, these therapies have demonstrated efficacy in improving outcome of CLI.³⁸

Revascularization

Revascularization is the gold standard for treatment of CLI and it is a class 1 recommendation for CLI treatment.⁵ Without revascularization, about 40% of patients with CLI will require lower limb amputation by 1-year. Adequate inflow and outflow are required in order to keep the revascularized vessel patent and functional.

The options of revascularization for patients with CLI include endovascular revascularization, surgical revascularization or hybrid procedure. Several factors influence the choice of revascularization strategy, including anatomical factors, comorbidities, available level of expertise, and patient preference.

One randomized controlled trial, BASIL (Bypass versus Angioplasty in Severe Ischemia of Leg), compared surgery versus balloon angioplasty among 452 patients with CLI; after 5 years of follow-up, both therapies had similar rates of amputation-free survival and mortality.³⁹ Recently, a review by the Agency for Healthcare Research and Quality that included the BASIL trial, in addition to 19 other observational studies, found no differences in all-cause mortality, amputation, and amputation-free survival between surgical and endovascular revascularization.⁴⁰

Despite the increasing nationwide numbers of endovascular revascularization for CLI, a personalized approach in selecting the best revascularization option is advocated.^{41,42}

Several factors which influence the choice of revascularization strategy include anatomical factors (such as availability of venous conduit, distal target, runoff, calcifications, previous procedures), patients age, comorbidities, life expectancy, kidney function, risk associated with anesthesia, and compliance.

Lesion Classification According to the Trans-Atlantic Inter-Society Consensus for the Management of Peripheral Artery Disease (TASC II)

Lesion classification according to the Trans-Atlantic Inter-Society Consensus for the Management of Peripheral Artery Disease has been shown in figure 6.

Endovascular Revascularization

Endovascular revascularization is a minimally invasive procedure. Majority of patients prefer endovascular procedure for the treatment of CLI because of its minimally invasive nature and reduced duration of hospital stay, lower health care cost, lower morbidity, and mortality rate. TASC recommends that in a situation where endovascular revascularization and open repair or bypass of a specific lesion causing symptoms of peripheral arterial disease give equivalent short-term and long-term symptomatic improvement, endovascular technique should be used first. In the United States of America, the rate of surgical revascularization has reduced from 13.9% in 2003 to 8.8% in 2011 while rate of endovascular revascularization have increased from 5.1 to 11% during the same period.⁴³ Table 4 shows personal experience of 196 cases of CLI treated by endovascular revascularization.

Angiosome Concept

A new concept of defining vascular territories by means of angiosomes is currently under review. An angiosome is an anatomic unit of tissue (consisting of skin, subcutaneous tissue, fascia, muscle, and bone) supplied by specific source of arteries and drained by specific vein (Fig. 7). There are five angiosomes in the leg and six angiosomes in the foot and ankle area as described by Taylor and Palmer in 1987. Utilizing the particular source of artery has shown promising results in terms of complete wound healing and limb salvage. Hence, they should be considered in planning the revascularization strategy.

Vascular Access Approach for Endovascular Revascularization

The choice of vascular access approach for endovascular revascularization depends on the site and type of the lesion. Retrograde vascular access and crossover is good for iliac-femoral lesions. Antegrade femoral vascular access is good for tibia-popliteal stenotic lesions. For tibia-popliteal occlusion lesions, retrograde pedal-tibial approach is a good option (Fig. 8).

Techniques for Endovascular Revascularization

Several techniques are now available for endovascular revascularization, which include the following:

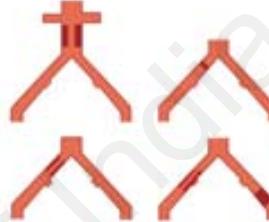

- Percutaneous transluminal balloon angioplasty (PTA):

Type A lesions

- Unilateral or bilateral stenoses of CIA
- Unilateral or bilateral single, short (≤ 3 cm) stenosis of EIA

**Type B lesions**

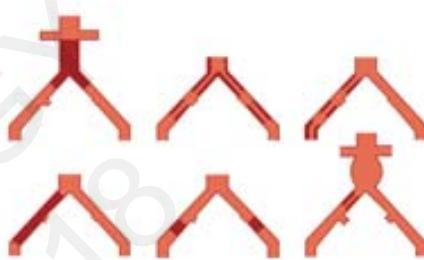

- Short (≤ 3 cm) stenosis of infrarenal aorta
- Unilateral CIA occlusion
- Single or multiple stenoses totaling 3–10 cm involving the EIA, not extending into the CFA
- Unilateral EIA occlusion not involving the origins of internal iliac or CFA

**Type C lesions**

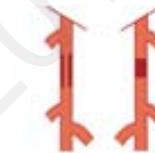

- Bilateral CIA occlusions
- Bilateral EIA stenoses 3–10 cm long, not extending into the CFA
- Unilateral EIA stenosis extending into the CFA
- Unilateral EIA occlusion that involves the origins of internal iliac and/or CFA
- Heavily calcified unilateral EIA occlusion with or without involvement of origins of internal iliac and/or CFA

**Type D lesions**

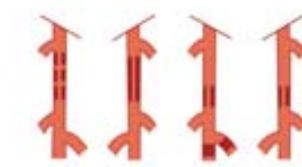

- Infrarenal aortoiliac occlusion
- Diffuse disease involving the aorta and both iliac arteries, requiring treatment
- Diffuse multiple stenoses involving the unilateral CIA, EIA, and CFA
- Unilateral occlusions of both CIA and EIA
- Bilateral occlusions of EIA
- Iliac stenoses in patients with AAA requiring treatment and not amenable to endograft placement or other lesions requiring open aortic or iliac surgery

**Type A lesions**

- Single stenosis ≤ 10 cm long
- Single occlusion ≤ 5 cm long

**Type B lesions**

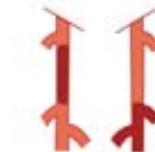

- Multiple lesions (stenoses or occlusions), each ≤ 5 cm
- Single stenosis or occlusion ≤ 5 cm, not involving the infrageniculate popliteal artery
- Single or multiple lesions in the absence of continuous tibial vessels to improve inflow for a distal bypass
- Heavily calcified occlusion ≤ 5 cm long
- Single popliteal stenosis

**Type C lesions**

- Multiple stenoses or occlusions totaling >15 cm with or without heavy calcification
- Recurrent stenoses or occlusions that need treatment after two endovascular interventions

**Type D lesions**

- Chronic total occlusions of CFA or SFA (>20 cm, involving the popliteal artery)
- Chronic total occlusion of popliteal artery and proximal trifurcation vessels

AAA, abdominal aortic aneurysm; CIA, common iliac artery; CFA, common femoral artery; EIA, external iliac artery; SFA, superficial femoral artery.

FIG. 6: Lesion classification according to the Trans-Atlantic Inter-Society Consensus for the Management of Peripheral Artery Disease.

- Plain balloon angioplasty
- Cutting balloon angioplasty
- Scoring balloons
- Drug-coated balloons (DCBs).
- Stents:
 - Bare metal stents
 - Self-expandable stents: Stainless steel and nitinol
 - Covered stents

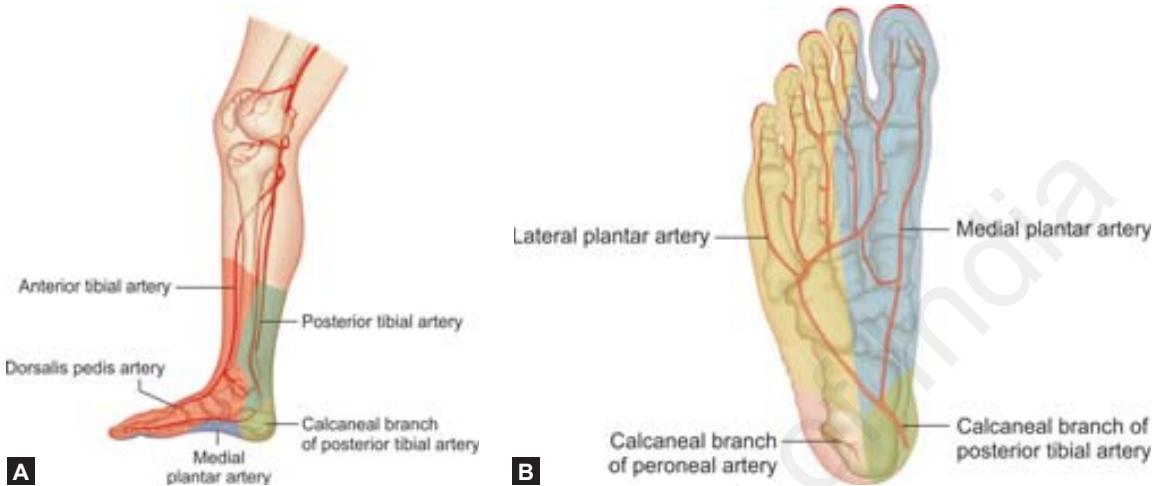

FIG. 7: A, Angiosome concept in lower limb; B, Angiosome concept in foot.

TABLE 4: Personal experience on endovascular revascularization

Endovascular treatment of CLI—personal experience of 196 cases	Number	Percentage
Total number = 196		
Femoral	107	54%
Below the knee	89	45%
Percutaneous transluminal balloon angioplasty	113	58%
Stents	83	42%
Drug-coated balloon	17	8%
Drug-eluting stents	27	14%
Adjuvant stem cell therapy	04	2%
Technical success	176	96%
Amputation free survival at 6 months	146	76%
Ulcer healing	147	75%

- Drug-eluting stents (DESs)
- Bioresorbable vascular scaffolds.
- Debulking devices:
 - Rotablation
 - Atherectomy devices: Directional atherectomy, Silver hawk, and orbital atherectomy device
 - Laser
 - Re-entry devices: Pioneer, outback catheter, and front runner.
- Other modalities:
 - Cryoplasty
 - Photodynamic therapy
 - Gene therapy
 - Autologous stem cell implantation.

Percutaneous transluminal balloon angioplasty

Percutaneous transluminal balloon angioplasty is found to be better than optimal medical therapy for CLI. The development of DCB is an important milestone in endovascular revas-

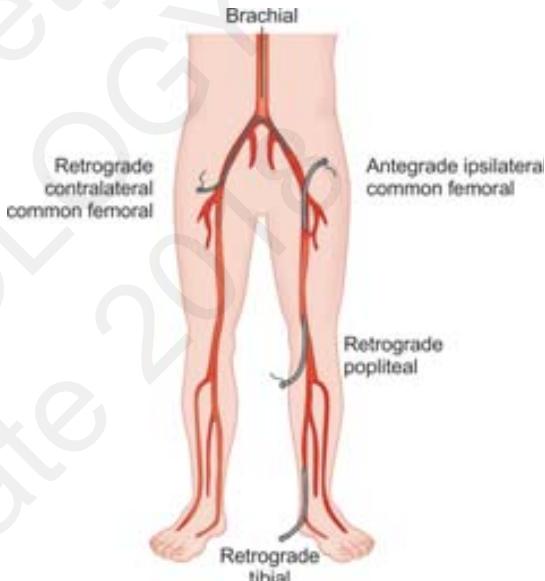

FIG. 8: Types of vascular access approach for endovascular revascularization.

cularization. In the above knee lesions, DCBs have shown to be superior to PTA as shown in the 2015 IN.PACT SFA Trial.⁴⁴ In the below knee lesions, DCB is preferred to PTA in the 2012 ACHILLES trial.⁴⁵ DCBs have been widely adopted in the femoral and popliteal arteries lesion and found to be superior than plain balloon angioplasty. DCBs are also favored over stenting in situations in which significant dissection or vessel recoil is absent.

Drug-coated balloons

The PACIFIER, LEVANT-1, FEM-PAC, and THUNDER trials were some of the first randomized controlled trials for treating SFA disease by paclitaxel coated balloons. In all of these trials, DCBs were found to have higher patency rates and lower incidence of target lesion revascularization (TLR) (Table 5). In the IN.PACT trial, DCBs were used to treat in-stent restenosis (ISR) in SFA lesions. 12-month

TABLE 5: Comparison of various trials of drug-coated balloon and drug-eluting stent

	Absolute	Resilient	Sirocco	Strides
Lesion length (cm)	~10	~6.7	~8.4	9.0
Diabetes mellitus	~38%	38%	~47%	39%
Ca ⁺⁺ (moderate/severe)	~82%	~35%	~77%	78%
Occlusion	~18	~18	~57%	47%
Restenosis	N/A	~3%	~7%	10%
12-month patency	63%	81%	82% (18 months)	63%
	Zilver PTX	Thunder	Fem-PAC	Levant
Lesion length (cm)	5.4	7.5	4.5	8.1%
Diabetes mellitus	46%	50%	47%	47%
Ca ⁺⁺ (mod/severe)	72%	46% (site)	52%	N/A
Occlusion	25%	50%	13%	41%
Restenosis	6%	22% (14% ISR)	27% (7% ISR)	11%
12-month patency	76%	75%	18% (6 months)	72% (6 months)

ISR, in-stent restenosis.

TLR and restenosis rates were 7.8%. Two types of coatings—crystalline or amorphous—are done on DCBs. Amorphous coatings have higher uptake and lower retention. Sirolimus-based nanocrystal balloon coating technology is also in the pipeline.

Debulking devices

Debulking devices include laser, rotablation, and atherectomy devices; directional atherectomy, silver hawk, and orbital

atherectomy device. Laser involves the delivery of a burst of ultraviolet energy in a short pulse that ablates tissue directly in contact with the catheter. There is usually a minor thermal injury following laser procedure. Rotablation uses the mechanism of concentrically rotating burr to debulk the plaque. Atherectomy devices are very beneficial in crossing heavily calcified lesions that are resistant to balloon and stent dilatation (Fig. 9).

Chronic total occlusions

Chronic total occlusions (CTOs) are commonly encountered in CLI and occur in about 40% of cases of symptomatic PAD.⁴⁶ It is usually a big challenge to some operators. Usually, the lesions are long and calcified and are accompanied by diffuse and extensive disease in the outflow tracts. The technical challenge is the difficulty in crossing the wire. However this difficulty can be overcome by using wire escalation, in which wires of increasing diameter, tip loads, and hydrophobicity are used to cross the lesion. Retrograde vascular access through the pedal-tibial approach is also beneficial in a situation of inability to cross the wire through femoral antegrade approach. Debulking devices are of great benefit in CTOs.

Subintimal angioplasty

Subintimal angioplasty is a minimally invasive procedure in which a guidewire is passed between the intima and the media to create a new track along the vessel wall thereby bypassing the atherosclerotic occlusion and angioplasty is done using an appropriate balloon along the new tract (Fig. 10). This technique of angioplasty was first reported by Bolia et al.⁴⁷ This technique is reserved when there is difficulty in crossing a lesion with 100% occlusion after all available options fail.

Procedural Specifications

All procedures are done under locoregional anesthesia, which has a number of advantages: accurate digital imaging by eliminating any artifacts due to limb movement on DSA, reduced arterial spasm, and also permits concomitant ulcer debridement.

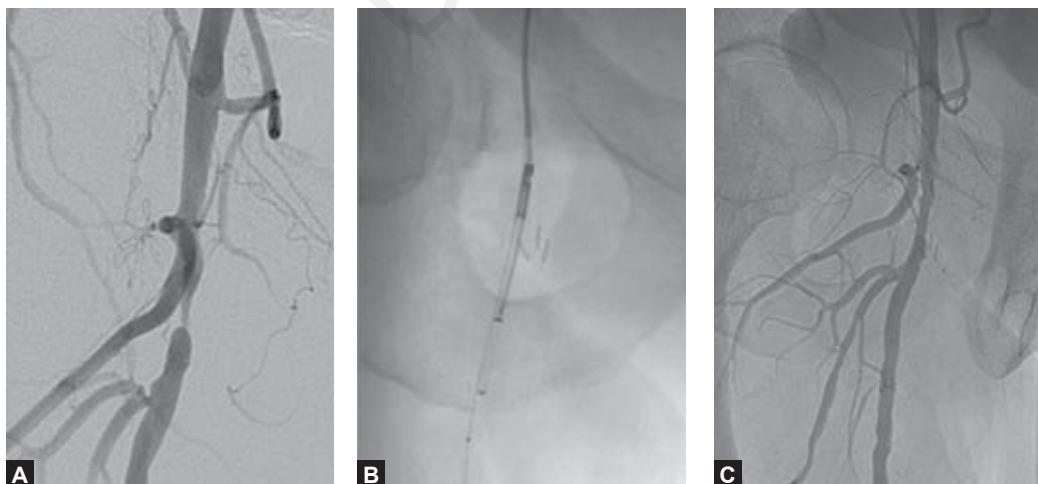

FIG. 9: A, Lesion at the ostial superficial femoral artery; B, been treated with atherectomy device; C, final result.

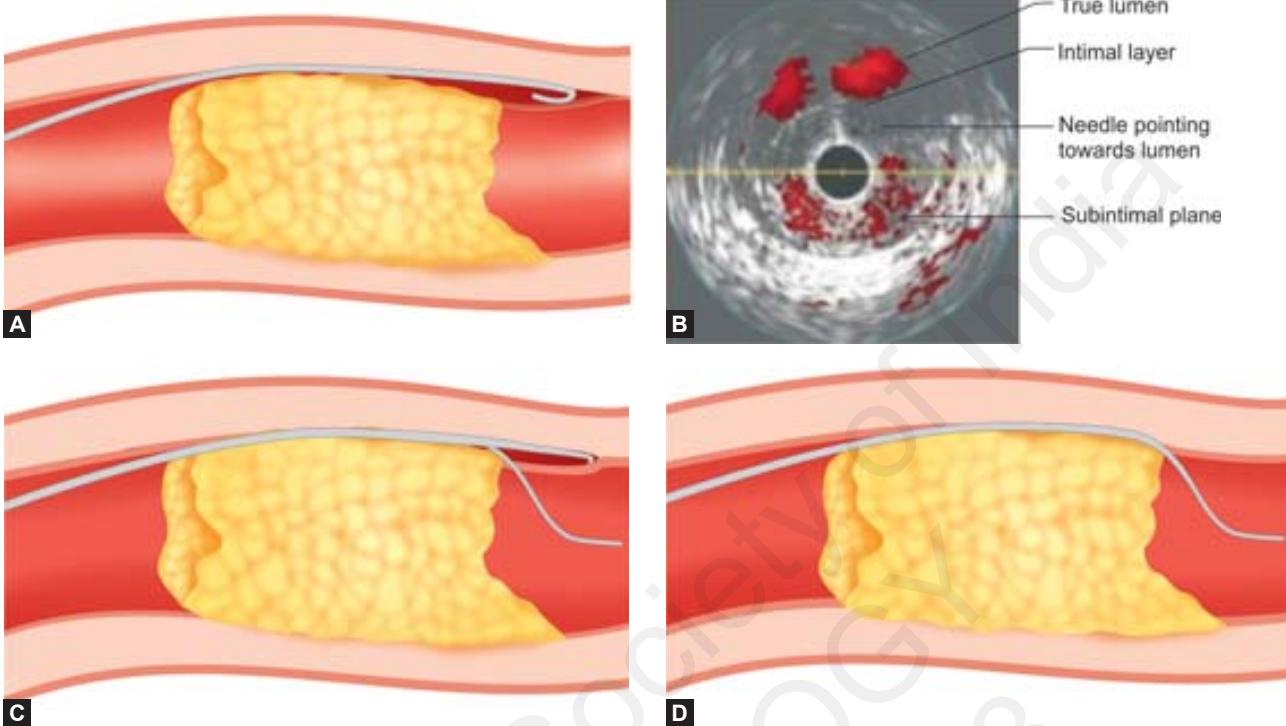

FIG. 10: Subintimal entry of device.

Technique for Femoropopliteal Segment Endovascular Revascularization

The procedure is done under strict aseptic and antiseptic procedure. Femoropopliteal disease can be approached by retrograde contralateral common femoral artery or antegrade ipsilateral common femoral artery route, the region is sterilized and locoregional anesthesia is given. The common femoral artery is accessed with a micropuncture needle and then 6-F introducer sheath is introduced. The sheath provides access for the guidewire. An appropriate-sized guidewire, 0.035", 0.025" or 0.018, is used to intubate the lesion under angiographic guidance. After crossing the lesion, the appropriate-sized catheter and percutaneous transluminal balloon is used to treat the lesion (Figs. 11 and 12).

Surgical Revascularization

Surgical revascularization is one of the modalities of revascularization in the treatment of CLI. There is preservation of limb viability and improvement of symptoms of CLI following surgical revascularization. The anatomical location of the lesion and other comorbidities should be considered before taking patient up for surgical revascularization. Preoperative preparation of the patient involves imaging to locate the exact anatomy of the lesion and access for the arterial inflow and outflow. Surgical revascularization has become more significant in complex and calcified lesions that are not adequate for endovascular revascularization and also in younger age groups because of its higher patency rate.

Hybrid Procedures

Hybrid procedure involves the use of both endovascular and surgical revascularization in the treatment of CLI. Hybrid procedures, due to their short procedure time and relatively lesser risk of intra- and postoperative complications represent an attractive option in patients who are older, frail or have limited autologous conduit for bypass. Multilevel disease is often treated with hybrid revascularization using endovascular techniques to treat inflow disease (e.g., iliac stenting) and surgical revascularization for femoral or infrainguinal disease (e.g., common femoral endarterectomy and femoral popliteal bypass).⁴⁸

In a hybrid procedure of 125 patients analyzed by Dougherty, the perioperative mortality was less than 1% and the primary patency was 39.6% over a mean follow-up of 27.6 months.⁴⁹ Similar results were seen by other authors when this technique was analyzed for freedom from amputation and event-free survival.^{50,51}

Amputation

Amputation is what every interventionist wants to prevent in the course of management of CLI. However, it is inevitable in some occasions.

Indications of amputation in CLI patients:

- Failed revascularization
- Patients with tissue loss or infection
- Potential nonambulating patients
- Patients unfit for surgical or endovascular revascularization.

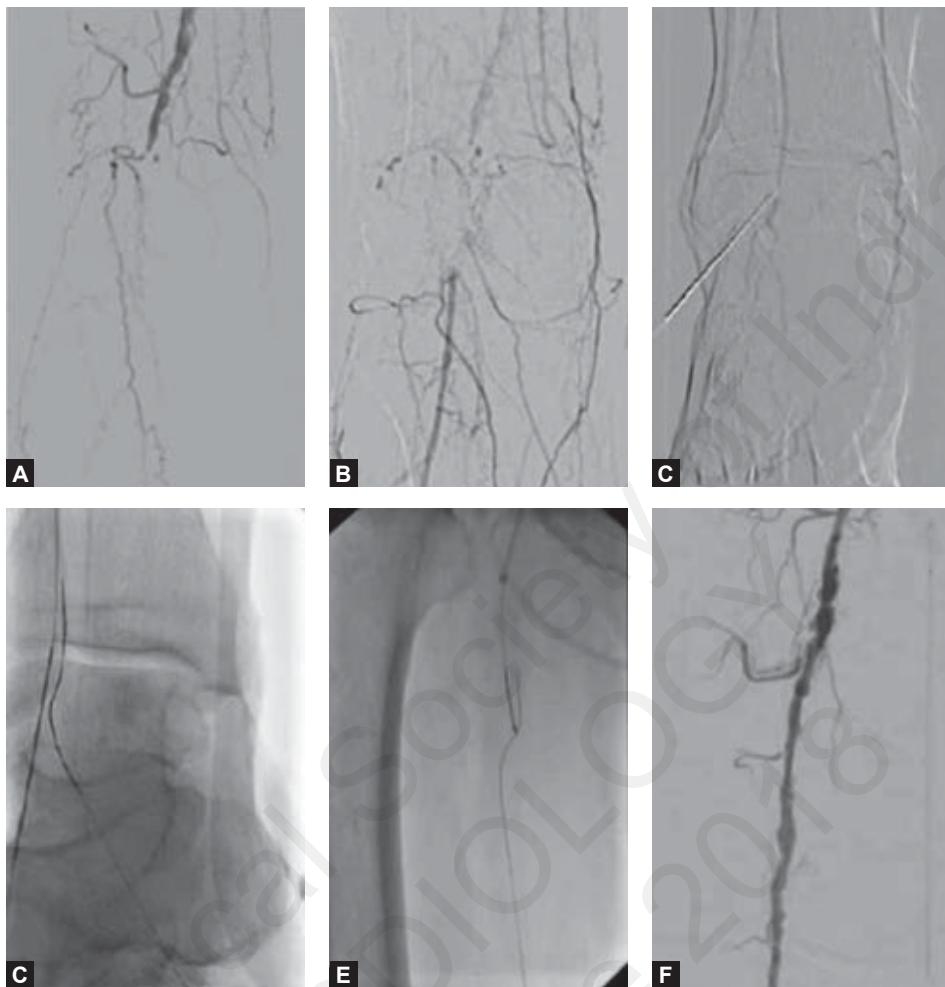

FIG. 11: A and B, Long segment total occlusion; C, Access through the dorsalis pedis artery; D, Retrograde entry of the wire; E, Wire snared through the antegrade puncture; F, Final result.

FIG. 12: A, Before revascularization; B, After revascularization.

Usually, adequate blood supply is required for proper wound healing following amputation. Minor amputations which include disarticulation of the toe or metatarsals do

not limit functional independence of the patient or require prosthesis. Major amputations (below knee or above knee amputation) are usually a great concern to patients and

usually require prosthesis. There are some factors which limits the use of prosthesis which include dementia, old age, bilateral or above knee amputation, and poor function before the amputation.⁵²

CONCLUSION

Critical limb ischemia represents an advanced stage of PAD. It is a significant cause of morbidity and mortality among patients with PAD. Patients with CLI have high risk of limb loss and increase risk of cardiovascular events. Multidisciplinary approach remains the key factor in the treatment of CLI. Intensive medical therapy is very important in reducing the cardiovascular events that is associated with CLI. Revascularization is the gold standard of the treatment of CLI. Selection of the revascularization strategy should be based on individual patient basis and factors such as patient age, anatomy of the arterial lesion, comorbidities, life expectancy, kidney function, risk associated with anesthesia, and compliance should be considered. All patients who present with rest pain, tissue loss or gangrene should be offered hemodynamic assessment followed by revascularization. Newer drug-eluting balloons offer better long term results after some endovascular procedure. Close postoperative care monitoring is essential in order to prevent recurrent disease.

Women and Heart Disease

Coronary Artery Disease in Women: Unfair Assessment and Outcomes

Roopa Salwan

"The learning and knowledge that we have, is, at the most, but little compared with that of which we are ignorant."

—Plato

INTRODUCTION

Cardiovascular disease (CVD) is the world's leading and arguably the most preventable cause of death and disability among women. Cardiovascular disease kills more women than lung cancer and breast cancer combined.¹ The incidence of coronary artery disease (CAD) in women is lower than in men during the fourth and fifth decade of life, it rises sharply after menopause and equals that of men by the sixth and seventh decade. Once CAD is clinically manifest, women experience similar, if not worse outcomes than men.

India has a population of 1,252 million, 48.5% are women, the life expectancy at birth is 65 years for men and 68 years for women. India is undergoing a rapid health transition with rising burden of coronary heart disease (CHD). As the lifespan is increasing, so is the prevalence of heart disease. In India, more than 10.5 million deaths occur annually, 20.3% of deaths in men and 16.9% of deaths in women are caused by CVD.² Increase in deaths from CVD is driven by a 55% increase in mortality due to the aging of populations and a 25% increase due to population growth.³ In a recent study from Kerala, the prevalence of any CAD was 14.3% in women and 9.8% in men, and the prevalence of definite CAD was 2.6% in women, 3.5% in men.⁴ An improved understanding of disease that could affect half the population is essential to be able to improve health and outcomes.

Women and men differ in their genetic complement by a single chromosome that affects the mechanism and expression of disease (biological differences related to X chromosome) as well as the psychosocial and behavioral characteristics and environment of the individual (gender bias), which may protect from or enhance the susceptibility to CVD. Medical research in women has traditionally focused on diseases of breast and reproductive system, i.e., bikini

boundaries and neglected sex and gender differences in the spectrum of CVDs.⁵ Women live longer than men, but the quality of life, of those added years, is burdened by chronic disease that is preventable and treatable.

Bernadine Healy described bias in treatment of women with CAD as "Yentl Syndrome". "Yentl" was a young lady, in a Jewish community in the 19th century, who had to dress and act like a boy to be able to get education.⁶ Two studies published in the New England Journal of Medicine in 1991 showed that women were significantly less likely to undergo coronary angiography or revascularization when admitted with unstable or stable angina, acute myocardial infarction (MI) or chest pain when women who underwent coronary angiography were studied, there was no difference between the sexes in treatment. Once a woman showed she was like a man by having severe CAD or MI then she was treated as a man would be.^{7,8} This led to an awareness that women have not been studied as thoroughly as men—the results from studies in men have been generalized to women, which may not be appropriate. These publications were followed by sex and gender-specific research in the last three decades that has improved understanding of the pathophysiology and management of coronary disease in women.

Loss of hormones with menopause contributing to CVD is oversimplification of a complex issue. The HERS (Heart and Estrogen Replacement Study) and WHI (Women's Health Initiative) were large hormone trials, which documented that hormone replacement therapy had no role in primary or secondary prevention of heart disease in postmenopausal women, in fact they did more harm. Estrogen and progestin therapy was associated with an increased risk of breast cancer, stroke, pulmonary embolism, and coronary events, estrogen alone increased the risk of stroke with no benefit for CAD.⁹⁻¹¹

RISK FACTORS FOR CORONARY ARTERY DISEASE

Traditional risk factors are similar to men; however, there is an increased prevalence and clustering of risk factors with age in women. The impact of risk factors is more adverse and placing them at a higher risk.

Established Risk Factors

Age

The prevalence of CVD increases with age, one in eight women 45–64 years have CHD while one in three women older than 65 have CHD. The highest mortality is seen in younger- and middle-aged women.¹² Women less than 50-year old have twice the likelihood of dying in hospital compared with age matched men. Why young premenopausal women who are protected by estrogens and are considered to be low-risk have worse outcomes is not known.

Hypertension

Women older than 60 years have a higher prevalence and poorer control of hypertension than men. It increases the prevalence of stroke and congestive heart failure in women. Hypertension rises 2- to 3-fold in women taking oral contraceptives. Hypertension is predictive of a higher risk in premenopausal women.

Diabetes

It confers greater cardiovascular risk for women than men. The risk of fatal CHD is three times compared to nondiabetic women. Impaired glucose tolerance may be more detrimental in women. Gestational diabetes increases the risk of diabetes later in life. Diabetic women have more complications and higher mortality following ST-elevation myocardial infarction (STEMI) and surgical revascularization.^{13–16} In the INTERHEART study, hypertension and diabetes were more strongly associated with MI in women than men.¹⁷

Smoking

It is one of the strongest risk factors for CAD, more so in women on oral contraceptives, there is a significant increase in risk of venous thromboembolism, stroke, and MI.^{18–20} It is of concern that smoking is increasing in women in India. The INTERHEART has documented increased risk with all forms of tobacco use including chewing tobacco or smoking beedies.²¹

Dyslipidemia

Adverse changes in lipids accompany menopause, with increase in low-density lipoprotein (LDL) cholesterol, triglycerides (TGs), and decrease in high-density lipoprotein (HDL). Low-density lipoprotein is the main atherogenic lipoprotein in the development of atherosclerosis. At any level of LDL, the risk depends on the level of HDL and TG. High-density lipoprotein cholesterol less than 30 mg/dL is strongly associated with increased cardiovascular mortality

in women. Secondary prevention to reduce cardiac events and mortality is equally effective in women and men.^{22,23}

Family History of Premature Coronary Heart Disease

Family history of premature CHD in a first-degree female relative is a relatively more potent family history risk factor than in male relative. A family history of premature CAD is seen more frequently in women with CAD.

Physical Activity and Fitness

Physical inactivity is more common in women, as they get older and is associated with higher blood pressure, worse cholesterol levels, poorer glucose metabolism, poor mental health, and obesity. Those with higher physical activity have lower rates of CVD. Physically fit obese women are at lower risk than lean women who are not physically fit.^{24,25}

Emerging Risk Factors

Metabolic Syndrome

It is more prevalent in women and increases the risk of developing CVD 2.6-fold. Obesity, a body mass index (BMI) more than 30 kg/m² increases the risk of diabetes, CVD and is a powerful predictor of mortality in women. High BMI in adolescents has been linked with early menarche; and later in life, obesity, insulin resistance, dyslipidemia, and metabolic syndrome.

Autoimmune Disease

Rheumatoid arthritis and systemic lupus erythematosus (SLE) are more prevalent in women and lead to accelerated atherosclerosis with 2- to 3-fold increase in risk of acute MI, congestive cardiac failure and stroke.^{26–28}

Gestational Hypertension

Pregnancy is like a stress test for future cardiovascular events—gestational hypertension and preeclampsia increase the risk of CVD, later in life, 2-fold.²⁹

Polycystic Ovarian Disease

Estrogen deficiency causing irregular menstrual cycles from polycystic ovarian disease (PCOD) or hypothalamic dysfunction in premenopausal women is associated with an increased risk of coronary atherosclerosis, diabetes mellitus, and adverse CVD events.^{30–33}

Breast Cancer

Women surviving breast cancer have an elevated risk of developing CVD. Radiotherapy exposes the heart to ionizing radiation that increases the risk of developing ischemic heart disease (IHD) within a few years after exposure that continues up to 20 years. The risk is proportionate to the mean dose of radiation to the heart and the presence of other CVD risk factors.^{34–36} There are similarities in predisposing risk factors—obesity, sedentary lifestyle, tobacco use, diet,

and age. Modification of risk factors during cancer treatment is not given its due attention.

Hysterectomy

Increased risk of CVD has been reported in observational studies after hysterectomy with or without bilateral salpingo-oophorectomy (BSO). Compromised ovarian function after hysterectomy has been reported even when the ovaries have been preserved is likely related to reduced ovarian blood flow. However, there is no independent association between hysterectomy and CVD after controlling for other major risk factors. Hysterectomy does not change CVD risk factors such as blood pressure and lipid profile. Women who have had a hysterectomy tend to have worse CVD risk profile.³⁷

In the Swedish registry, data on 184,441 women who underwent hysterectomy between 1973 and 2003 has shown that hysterectomy in women less than 50 years age substantially increases the risk for CVD later in life. Oophorectomy further adds to the risk of both CHD and stroke. In women older than 50 years, there was no significant association between hysterectomy and incident CVD.³⁸

There are no published guidelines specifically for the management of BRCA mutation carriers after prophylactic BSO.

Psychosocial Factors

Psychological factors and emotional stress can influence the onset and clinical course of IHD in women. Depression is twice as common and is a consistent predictor of CHD events in women.^{39,40} Psychological factors associated with increased risk are hostility, work stress, and anger suppression. Increased attention to emotional regulation may give a better understanding of role of negative emotions in CAD in women.^{41,42} Strain of multiple roles and lack of supportive relationships, low level of social integration is associated with increased risk of recurrent events and mortality.⁴³⁻⁴⁵ Optimism has been found to be associated with reduced risk of MI and mortality in WHI.

PATOPHYSIOLOGY OF IHD IN WOMEN

Ischemic Heart Disease

Ischemic heart disease comprehensively describes the spectrum of disease in women. Besides CAD, i.e., atherosclerotic disease of the epicardial vessels, it includes—ischemia related to endothelial dysfunction, coronary microvascular dysfunction (CMD), coronary spasm, supply-demand mismatch, spontaneous coronary dissection, and stress-related cardiomyopathy.

Atherosclerotic Coronary Artery Disease

Plaque rupture with disrupted fibrous cap, large necrotic core with macrophages is more prevalent in men and older women.⁴⁶ Plaque erosion is seen in younger women, the underlying lesion is fibroatheroma or intimal thickening characterized by smooth muscle cells in a proteoglycan and

collagen-rich matrix with absence of surface endothelium and increased frequency of distal microembolization from platelet-rich debris. Plaque erosion is associated with less thrombus burden, less calcification, less percentage vessel stenosis, less overall plaque burden, minimal inflammation, and negative arterial remodeling.⁴⁷ Infrequently, coronary event is from a calcified nodule, that represents fibrocalcific plaques with little or no underlying necrotic core but there is disruption of the luminal surface, i.e., absence of collagen and endothelium with luminal thrombosis overlying the eruptive dense calcified nodules.⁴⁸

Endothelial Dysfunction

Endothelium is responsible for the vasomotor tone of coronary vessels, platelet aggregation, leukocyte migration, and thrombogenicity. Patients with coronary endothelium dysfunction have an increased vasoconstrictor response to autonomic system leading to increased resistance in arterioles.

Coronary Microvascular Dysfunction

It is known that women have smaller coronary arteries per 100 g of left ventricular (LV) mass and their arteries have increased stiffness. The epicardial arteries are 500 microns to 5 mm in size, the prearterioles 100–500 microns, intramural arterioles 100 microns, and capillaries 5–10 microns—the coronary microcirculation regulates coronary blood flow and adapts to metabolic demands of the body. Coronary microvascular dysfunction may occur in the presence or absence of obstructive CAD, myocardial disease or may be iatrogenic. Intrinsic genetic factors also contribute to coronary smooth muscle reactivity.⁴⁹

Young patients with acute MI have been classified into five phenotypes in the VIRGO (Variation in Recovery: Role of Gender on Outcomes of Young Acute MI Patients) study: Class I patients with plaque-mediated obstructive culprit lesions (94.9% in men and 82.5% in women); Class II obstructive CAD (>50% stenosis) without evidence of plaque rupture or thrombosis (2% in men and 3.8% in women); Class III nonobstructive CAD (<50% stenosis, 2.7% in men and 11.35 in women); Class IV nonplaque mechanism of ischemia including vasospasm, dissection, and embolism (0.2% in men and 1.5% in women); Class V indeterminate (0.2% in men and 0.8% in women).

Further Class II and II are divided into “a” and “b” on the presence or absence of supply-demand mismatch: increased myocardial oxygen demand, defined as systolic blood pressure more than or equal to 180 mmHg; diastolic blood pressure more than or equal to 100 mmHg; heart rate more than or equal to 120 bpm; atrial fibrillation or flutter regardless of heart rate; ventricular tachycardia or fibrillation; acute life-threatening comorbid illness on presentation (e.g., severe pneumonia or exacerbation of chronic obstructive pulmonary disease; trauma; acute renal failure; stroke; sepsis; surgical complication; any fracture; diabetes ketoacidosis; hyperosmolar hyperglycemia syndrome/hypoglycemia; seizure; acute liver failure; and other acute and severe

infections), or decreased myocardial oxygen supply, defined as systolic blood pressure less than 90 mmHg, hemoglobin less than 10 mg/dL, hypoxia, gastrointestinal bleed, and other major bleeding.⁵⁰

ASSESSMENT OF ISCHEMIC HEART DISEASE IN WOMEN

Women have more symptoms, are older with higher risk factor burden, but paradoxically have less severe obstructive CAD. The relatively low prevalence of obstructive CAD in women produces a higher ratio of false-positive to true-positive results. Physicians underestimate women's cardiovascular risk and underutilize noninvasive diagnostic modalities for concern on the diagnostic accuracy of these tests.

Exercise Stress Testing

Exercise stress test is the initial diagnostic test for symptomatic women who can exercise more than 5 metabolic equivalents (METs), the negative predictive value of the test is comparable to men (78% vs. 81%). Integrating the Duke Treadmill score improves the accuracy. In women, resting electrocardiography (ECG) frequently has ST-T changes related to hormonal factors that leads to higher false-positive rate of exercise stress test. The positive predictive value of ST depression with exercise testing in women is significantly lower than men (47% vs. 77%). Stress imaging should be limited to women with indeterminate or abnormal ECG findings—ECG test leads to nuclear scan or stress echocardiography (ECHO) in one in five women.^{51,52}

Stress Echocardiography

Stress ECHO with exercise or dobutamine stress has high-diagnostic accuracy in women, sensitivity 79%, and specificity 83%. In institutions with high volume and expertise, stress ECHO has comparable accuracy to nuclear imaging. Echocardiography can also be helpful in assessing noncoronary etiologies for symptoms such as diastolic dysfunction, abnormal filling pressures, abnormal myocardial mechanics using tissue Doppler or speckle tracking.^{53,54}

Stress Myocardial Perfusion Single-photon Emission Computed Tomography

Stress myocardial perfusion single-photon emission computed tomography (SPECT) has sensitivity of 81% and specificity of 78%. While traditional imaging has been done with thallium, it was associated with lower accuracy due to breast tissue artifact in women. Use of Technetium 99m sestamibi and technetium 99m tetrofosmin has decreased incidence of false-positive results. The high energy results in less tissue attenuation, and simultaneous ECG gating has been shown to significantly improve the specificity over nuclear imaging for women. The overall radiation burden is higher with the use of stress myocardial perfusion SPECT than for cardiac computed tomography angiography (CCTA) or positron emission tomography (PET) imaging. To limit radiation, stress imaging should be performed first and if

findings are normal, elimination of resting scan can reduce radiation exposure considerably. In patients with left bundle branch block, dobutamine SPECT is more accurate than exercise perfusion imaging.⁵⁵

Stress Myocardial Perfusion Positron Emission Tomography

Stress myocardial perfusion PET has improved spatial resolution and increased diagnostic accuracy for detecting obstructive CAD in obese women when compared to SPECT (88% vs. 78%). Conventional cardiac PET using rubidium-82 or N ammonia has markedly reduces radiation exposure 2–3 mSv. It also allows measurement of coronary blood flow and coronary flow reserve (CFR) less than 2 indicated microvascular dysfunction in patients with nonobstructive disease on angiography.^{56,57}

Stress Cardiovascular Magnetic Resonance

Stress cardiovascular magnetic resonance (CMR) has comparable sensitivity to SPECT and ECHO. Cardiovascular magnetic resonance measures myocardial flow reserve on vasodilator stress, which may improve detection of CMD in symptomatic women. Stress MR demonstrates diffuse subendocardial perfusion defects in patients with microvascular dysfunction. Late gadolinium enhancement CMR imaging to improve detection of scarred or infarcted myocardium in women with previous undocumented MI.^{58–60}

Noninvasive Imaging of Atherosclerosis

Coronary Artery Calcium

Coronary artery calcium (CAC) is a marker of subclinical atherosclerosis, is highly predictive of CVD risk, and potentially identifies patients for more intensive risk factor modification. In the Multiethnic Study of Atherosclerosis (MESA) trial, increased severity of CAC is associated with higher mortality rates. Women with a CAC score more than or equal to 300 had an annual IHD event rate of 2.2%.⁶¹ The IHD event risk for women with a high-risk CAC score and multiple risk factors is 10% greater in women than men, comorbidity disproportionately accelerates risk in women. It has a sensitivity of 96–100% and specificity of 40–60% in detecting obstructive CAD in women.⁶²

Computed Tomography Coronary Angiography

The diagnostic accuracy of CCTA is similar in men and women, sensitivity of 85–99% and specificity of 64–90%, and is useful for evaluation of women with indeterminate stress test. In the PROMISE trial, CT Angiography as an initial evaluation approach does not improve clinical outcomes when compared to a functional test for CAD evaluation, however, is associated with fewer invasive angiographies.⁶³ In the ROMICAT II trial, women undergoing CCTA in emergency department for evaluation of chest pain suggestive of acute coronary syndrome (ACS) had a greater reduction in length of hospital stay and lower hospital

admission rate. CCTA-detected CAD in a third of patients, 58% had normal coronaries and 5% had obstructive disease. CCTA is able to visualize nonobstructive CAD, which is not detected during stress tests, that enables patients to be on better preventive therapy when indicated.⁶⁴ In the CRESCENT trial, with CCTA, in women, diagnosis was established earlier with lesser additional downstream testing and patients were more likely to have resolution of chest pain at 1 year.⁶⁵

Invasive Testing for Ischemic Heart Disease

In women with a high-risk on noninvasive testing, symptomatic on optimal medical therapy or with evidence of ACS, coronary angiography is indicated for diagnosis with revascularization when appropriate. Women are more likely to experience severe bleeding and access site complications, use of radial access substantially reduces these complications. Women have smaller arteries and a higher incidence of spasm, they are more likely to cross over to femoral access than men (11.1% vs. 6.3%).⁶⁶ Dose adjusting of antithrombotic/antiplatelet therapies to weight and creatinine clearance reduces bleeding complications. Despite worse symptoms, women usually have less obstructive disease and greater microvascular dysfunction.

Invasive Coronary Vasomotor

Invasive coronary vasomotor testing is a safe method for definitive diagnosis and assessment of CMD. Nitroglycerin (NTG) is an endothelium-independent vasodilator that acts directly on the smooth muscles and dilates coronary vessels greater than 200 mcm. Lack of response to NTG suggests endothelium-independent epicardial vessel dysfunction. Adenosine acts on smooth muscle cells of coronary vessels less than 150 mcm in diameter CFR ratio more than 2.5 is normal, abnormal response is seen with microvascular dysfunction. Acetylcholine produces a uniform endothelium-dependent dilation of both micro- and macrovasculature leads to more than 50% increase in coronary blood flow. Lack of response to acetylcholine reflects endothelial disease.

CLINICAL SPECTRUM OF ISCHEMIC HEART DISEASE

Although the Framingham study previously suggested that development of CAD in women lags approximately 10 years behind men, it is now believed, this lag is substantially less and women are susceptible to CAD at a much younger age. The mean age of women in the Kerala ACS registry was 64.4 ± 11.7 years, was older than men by 5 years (mean age in men 59.3 ± 11.9 years, $p < 0.001$).⁶⁷ Chest pain is the most frequent symptom, women are more likely to be overwhelmed with by a multiplicity of associated symptoms—back, neck and jaw pain, dyspnea, paroxysmal nocturnal dyspnea, nausea, indigestion, and weakness or fatigue. Thirty seven percent of women present without chest pain (as compared to 27%

men). Women were more likely to delay seeking care had more diabetes, hypertension, and heart failure with preserved ventricular systolic function. Women more commonly present with non-ST-elevation myocardial infarction (NSTEMI) than STEMI. Women are also more likely to have spontaneous coronary artery dissection (SCAD) or coronary artery spasm (CAS).^{68,69} Compared with men, women with ACS and those after coronary revascularization have longer hospitalizations, more bleeding complications, higher in-hospital mortality, and up to 30% more readmissions within 30 days after the index hospitalization. In the setting of ACS, normal coronary arteries do not have a benign prognosis. Worse prognosis of women has been attributed to advanced age, comorbidities, underutilization of life-saving therapies.

Young women with AMI had higher rates of cardiovascular risk factors and comorbidities than men, including diabetes, morbid obesity, congestive heart failure, and renal failure. They also have higher levels of depression, stress, poorer physical health, and lower quality of life at baseline. They are more likely to present with atypical chest pain or no symptoms (16% vs. 10%; $p = 0.008$) and more likely to present more than 6 hours after symptom onset (35% vs. 23%; $p = 0.002$).⁷⁰

The GLOW meta-analysis of gender-based outcomes in 731,990 patients (32% women), women with STEMI had more risk factors, longer door to balloon times, and with a greater than 2-fold higher in-hospital mortality. They were more likely to have more in hospital complications such as shock, heart failure, mechanical complications, reinfarction, recurrent ischemia, bleeding, and stroke as compared with men. Adjustments for comorbidities suggest that modifiable risk factors account primarily for the difference in mortality.⁷¹ With primary percutaneous coronary intervention (PCI), women have a lower 30-day mortality, 7.7% versus 9.6% for those presenting within 2 hours of symptom onset and 8.5% versus 14.4% for those presenting later than 2 hours.^{72,73} Thrombolytic therapy is indicated in patients presenting within 12 hours of symptoms, with no contraindications, who have an anticipated delay more than 120 minutes to a PCI-capable facility. Women often have multiple relative contraindications (advanced age, hypertension, and small body size) to thrombolysis and female sex is an independent predictor of intracranial bleeding.⁷⁴

Among patients undergoing coronary artery bypass grafting (CABG), however, women have a higher risk of morbidity and mortality and they experience less relief from angina than do men after CABG, when off-pump surgery is performed, women have a lower mortality rate.^{75,76}

Guideline-directed medical therapy is the same for all patients, women are less likely to receive optimal therapy. Lifestyle changes are pivotal. Statins in intermediate to high-risk women besides controlling lipids, have a pleiotropic effect, improve endothelial dysfunction, along with angiotensin-converting enzyme (ACE) inhibitors, and improve coronary flow reserve. Aspirin has no role in primary prevention in women less than 65 years; and for others, it should be given on long-term basis.

INDIAN DATA

In the CREATE Registry, 23.5% patients were women, in 47% of women, the presentation of ACS was STEMI. The mean age of the entire group was 57.5 (SD 12.1) years. The mean time to presentation was significantly longer for women 410 versus 340 minutes ($p < 0.0001$), 30.9% women were treated with thrombolysis (vs. 44.9% men, $p < 0.0001$), 5.6% underwent primary PCI (vs. 6.9% men $p < 0.0001$). The 30-day mortality was 8.9% in women versus 6.5% in men ($p < 0.0001$).⁷⁷

The Detection and Management of Coronary Heart Disease (DEMAT) Registry was specifically evaluated gender differences in ACS patients (334 women; 1,231 men). Women were less likely to present with STEMI (38% vs. 55%). Women were also more likely than men to have a history of hypertension (62% vs. 42%; $p = 0.001$) and diabetes (46% vs. 38%; $p = 0.01$) but were less likely to be tobacco users (2% vs. 33%; $p = 0.001$).⁷⁸ There was no gender difference in the in-hospital management, discharge treatment and 30 day mortality and major adverse CV event (MACE) (13.5% vs. 12.5%).

MYOCARDIAL INFARCTION WITH NONOBSTRUCTIVE CORONARY ARTERIES

Myocardial infarction with non obstructive coronary arteries (MINOCA) refers to patients with coronary-related ischemia in the absence of coronary artery obstruction (<50% disease) or from nonplaque-mediated mechanisms (coronary spasm, spontaneous coronary dissection, coronary embolism or unidentified mechanisms). The MINOCA represents 6–14% of all acute MIs—two-thirds cases are NSTEMI. In the VIRGO trial, 11.1% of patients had MINOCA, the presentation was STEMI in 21.4%. Young premenopausal women are five times more likely to have MINOCA (14.9% vs. 3.5%).⁷⁹ Hypertension is frequently associated, while hyperlipidemia and diabetes are less frequent. Hypercoagulable state is more frequent (3% vs. 1.3%). Autoimmune disease, cocaine or illicit drug use, and psychosocial factors did not differ by type of MI. Those with obstructive CAD are more likely to have history of gestational diabetes and early menarche.

The MINOCA is not benign—all-cause in-hospital mortality is 0.9%, with a 2% risk of death or reinfarction over 6 months, and 1-year mortality of 4.7% is reported. These patients tend to have a 15% readmission rate within 6 months because of persistent disabling symptoms. At 10 years, CVD death or MI occurred in 6.7% of those with no evident angiographic CAD and in 12.8% among those with nonobstructive CAD.⁸⁰ In the VIRGO trial, the 1-month mortality was 1.1% and 12-month mortality was 0.6%.

In the absence of obstructive CAD, postulated pathophysiological mechanism includes atherosclerosis with plaque disruption, distal embolization, and endothelial and microvascular dysfunction that would amplify the consequences of an upstream spastic or thrombotic event.

Coronary Artery Spasm

Coronary artery spasm can cause recurrent chest pain episodes at rest with associated transient ST-segment elevation, infrequently causes AMI. It is caused by autonomic imbalance, vascular smooth muscle hyperactivity, and endothelial dysfunction. Cigarette smoking, cocaine and other drug abuse may lead to coronary spasm. Studies of patients with stable CHD have reported higher rates of mental stress-induced ischemia in women.

Takotsubo Cardiomyopathy

Takotsubo cardiomyopathy (TTC) is characterized by acute and rapidly reversible systolic and diastolic LV dysfunction, triggered by profound psychological or physical stress. Signs and symptoms of myocardial ischemia occur in the absence of obstructive CAD. A distinctive abnormality of LV contraction consists of akinesia or dyskinesia of the apical and/or midventricular segments of the left ventricle (apical ballooning), together with hypercontractility of the base that usually recovers on follow-up.

Myocardial biopsy in patients with stress cardiomyopathy shows interstitial infiltrates consisting primarily of mono-nuclear lymphocytes, leukocytes, and macrophages; myocardial fibrosis; and contraction band necrosis.

Prevalence

Takotsubo cardiomyopathy accounts for 1.7–2.2% of all patients admitted with a presumed diagnosis of ACS; this rate increases up to 6–7%, if only females are considered. In the HORIZONS-AMI trial, TTC was diagnosed with a frequency of 0.5% of all patients and 2.1% of the female patients.

The cause of TTC remains unknown, the role of brain-heart axis, exaggerated sympathetic stimulation and the negative inotropic effect of high-dose epinephrine on the LV myocardium have been postulated. The LV apex contains a higher density of β -adrenoceptors, making it more susceptible to catecholamine-induced cell injury. The density of sympathetic nerve endings approximately 40% higher in the basal myocardium than in the apical myocardium, the heart is dependent on neuronal uptake for inactivating catecholamines in the extracellular fluid. Supraphysiological catecholamines induce a $\beta 2$ -adrenoceptor stimulation that leads to a Gi-mediated negative inotropy—which is more pronounced at the apex and completely reversible on removal of the catecholamine stimulus. The coronary microcirculation is innervated by neurons that originate in the brainstem and mediate vasoconstriction leading to myocardial stunning.

The International Takotsubo Registry is the largest data base of 1,750 patients.⁸¹ Takotsubo cardiomyopathy is predominantly a disease of postmenopausal women (89.8%), mean age— 66.8 ± 13 years, and 79.1% were women older than 50 years of age. Symptoms at presentation are chest pain (75.9%), dyspnea (46.9%), and syncope (7.7%). It may be triggered by physical (36%) or emotional (27.7%) strain, 55.8% patients had a previous neurological or psychiatric illness.

Takotsubo cardiomyopathy is a heart failure syndrome associated with significant elevation of brain natriuretic peptide and lesser elevation of troponin I. Apical TTC is the most common form (81.7%), the other being midventricular form (14.6%), basal (2.2%), and focal forms (1.5%). Early angiography is necessary to rule out ACS. In hospital, major adverse events were seen in 21.8% of patients, 9.9% developed cardiogenic shock, 17.3% required ventilatory support, 3% had ventricular tachycardia and a mortality of 4.1%. On long-term follow-up, the death rate from any cause was 5.6% per patient per year, the rate of stroke or transient ischemic attack was 1.7% per patient per year and the rate of recurrence of TTC was 1.8% per patient per year.

Spontaneous Coronary Artery Dissection

Spontaneous coronary artery dissection is a coronary artery dissection that is not atherosclerotic, traumatic, or iatrogenic. Spontaneous coronary artery dissection accounts for 1–4% of ACS, 80% of patients are female, average age is 42 years, 20–25% of cases occur in the peripartum period. The classic presentation is of a young healthy woman, without risk factors, and sudden onset of ACS. It results from an intimal tear, which allows blood from the true lumen to enter media and generate a false lumen or from spontaneous hemorrhage in the vasa vasorum within the vessel wall—formation of an intramural hematoma that compresses the true lumen leading to coronary insufficiency and MI. Histopathology is characterized by a periadventitial inflammatory infiltrate with predominant eosinophils. Fibromuscular dysplasia in extracoronary vascular beds is frequently seen, most common involved are the renal arteries (79.7%) and extracranial carotids (74.3%). Intracranial aneurysm is seen in 14–23%. The left anterior descending artery is the most commonly affected (32–46% of cases), left main is involved in 4%. In the majority of cases, the mid to distal segments of coronary arteries are affected; multivessel SCAD occurs in 9–23% of cases. Spontaneous healing of SCAD lesion is seen in majority of patients, angiography done more than 35 days after diagnosis, spontaneous healing seen in 88.5%. Recurrent MI is seen in 7–10% within the 1st week due to extension of dissection. In-hospital mortality is low, 2.6–8% require revascularization for ongoing ischemia, left main dissection, or hemodynamic instability. Angiographic three patterns are described: (1) type I multiple radiolucent lumens or arterial wall contrast staining (29.1%); (2) type II diffuse stenosis that can be of varying severity and length usually more than 20 mm (67.5%); and (3) type III Focal or tubular stenosis less than 20 mm in length that mimics atherosclerosis (3.4%). Percutaneous coronary intervention for SCAD has been associated with lower technical success and higher complications, the affected arteries are inherently weak and susceptible to iatrogenic dissection and extension of dissection. Recommended therapy includes a single antiplatelet, avoidance of statin, use of beta-blockade, avoidance of systemic hormones including oral contraceptives. Statins were associated with recurrent SCAD, therefore, these are recommended only when hyperlipidemia

is documented. The largest series of SCAD from Mayo Clinic has reported a high MACE (death, recurrent SCAD, MI, and HF) rate of 47.4%, recurrence rate of 17% (occurring solely in women), and a 10-year mortality rate of 7.7%.^{82,83}

CONCLUSION

The CVD is a leading cause of death in women. Synergistic effect of multiple risk factors contributes to the disease burden. Unique aspects of risk factors and manifestation of heart disease in women are better understood today. Aggressive risk factor control by physicians early in life with optimal use of guideline-directed therapy is essential to improve cardiovascular outcomes in women. Women must be educated that they are vulnerable to heart disease, and risk factors need to be prevented and controlled. Physicians need to be aware of the entire spectrum of disease in women, and be sensitive in their approach to diagnosis and treatment.

Hypertension in Pregnancy—A Stepwise Approach

Cherian Koshy, K Venugopal

INTRODUCTION

Hypertensive disorders of pregnancy, including preeclampsia, complicate up to 10% of pregnancies,¹ constituting a leading cause of maternal morbidity and mortality.¹ It is estimated that 50,000–60,000 deaths per year occur worldwide due to preeclampsia itself.²

CLASSIFICATION OF HYPERTENSIVE DISORDERS IN PREGNANCY

Chronic Hypertension

Chronic hypertension is defined as a systolic blood pressure (SBP) of 140 mm Hg or more or a diastolic blood pressure (DBP) of 90 mm Hg or more on two separate occasions at least 2 hours apart occurring before pregnancy or developing less than 20 weeks during pregnancy.³

Gestational Hypertension

Detection of hypertension after 20 weeks of gestation and BP falls back to normal within 12 weeks of delivery. Approximately, 15–25% of women with gestational hypertension will develop preeclampsia.

Preeclampsia

Hypertension after 20 weeks of pregnancy with proteinuria more than or equal to 300 mg in a 24-hour urine collection or a urinary protein/creatinine ratio more than or equal to 0.3.³ Thrombocytopenia, renal insufficiency, impaired liver function, pulmonary edema, and cerebral or visual symptoms can occur with severe preeclampsia.³

Chronic Hypertension with Superimposed Preeclampsia (ACOG 2013)

Patients with pre-existing chronic hypertension can develop features of pre-eclampsia as per the recommendations of the American College of Obstetrics and Gynecology. Any

one criteria is enough for the diagnosis of preeclampsia in patients with chronic hypertension.

Postpartum Hypertension

In addition preeclampsia can develop for the first time in the postpartum period and is called postpartum hypertension.

GRADING OF HYPERTENSION (NICE GUIDELINES)⁴

The grading of hypertension as per the National Institute for Health and Care Excellence (NICE) guidelines is described as:

- Mild hypertension: SBP 140–149 mm Hg or DBP 90–99 mm Hg
- Moderate hypertension: SBP 150–159 mm Hg or DBP 100–109 mm Hg
- Severe hypertension: SBP 160 mm Hg or DBP 110 mm Hg or higher.

MANAGEMENT

Gestational Hypertension

Control of hypertension in pregnancy has been a matter of debate regarding the nature of control, tight control versus less tight control.⁵ The NICE guidelines on hypertension in pregnancy advocate starting antihypertensive treatment in patients with systolic pressures 150 mm Hg or more. A systolic pressure more than 160 is an emergency and requires quick control of BP to prevent hemorrhagic stroke.

Drugs used in the Treatment of Gestational Hypertension

Alpha-Methyldopa

Most widely used drug in the treatment of hypertension in pregnancy. It is a centrally acting drug affecting the sympathetic outflow from the brain stem. It is safe to use in

pregnancy and has been the preferred agent in the national high blood pressure education program guidelines.

Labetalol

Labetalol is an alpha beta-blocker (combined). It is now being increasingly used in hypertensive situations in pregnancy, both for chronic hypertension as well as acute reduction of BP (parenteral).

Nifedipine

Among the calcium channel blockers, nifedipine has the maximum experience. It has also been used in emergency situations by rapidly acting oral preparations. Sublingual use has also been tried but caution has to be used to avoid precipitous fall in blood pressure in some patients.

In uncomplicated cases bed rest or inpatient management is not required. All patients need close monitoring of BP. Fetal growth and fetoplacental well-being assessment with ultrasonography (USG) and umbilical artery Doppler studies may be required.

Preeclampsia

Etiopathogenesis of preeclampsia is still not clearly understood. There is a genetic predisposition and usually seen more in primigravidas. There is abnormal immunological response of maternal tissue to trophoblasts, deficient trophoblast invasion, and hypoperfusion of placenta and increased circulating levels of interleukin and tumor necrosis factor (TNF) alpha. There is vascular endothelial activation leading to clinical symptoms of preeclampsia (Table 1).

INVESTIGATIONS

Urinary protein or urine protein/creatinine ratio, should be done in every antenatal visit in mild cases. Urinary protein or urine protein/creatinine ratio should be done daily in severe cases. Full blood counts, renal function tests, transaminases, bilirubin, lactate dehydrogenase (LDH), electrolytes, and peripheral smear are to be done in severe cases and repeated three times a week. Ultrasonography for fetal biophysical profile and Doppler velocimetry of the umbilical artery should also be done to optimize the timing of delivery.

TABLE 1: Risk factors for preeclampsia

Risk factor	Unadjusted relative risk (95% confidence interval) ⁴
Age >40 years, primigravida	1.68 (1.23–2.29)
Age >40 years, multipara	1.96 (1.34–2.87)
Family history	2.90 (1.70–4.93)
Nulliparity	2.91 (1.28–6.61)
Multiple pregnancy	2.93 (2.04–4.21)
Preexisting diabetes	3.56 (2.54–4.99)
Prepregnancy body mass index	4.29 (3.52–5.49)
Previous preeclampsia	7.19 (5.85–8.83)
Antiphospholipid syndrome	9.72 (4.34–21.75)

TABLE 2: The NICE identifies high- and moderate-risk factors for developing preeclampsia

High-risk factors	Moderate-risk factors
<ul style="list-style-type: none"> Hypertension in previous pregnancy Chronic kidney disease Autoimmune disease, e.g., SLE, antiphospholipid Type 1 or type 2 diabetes Chronic hypertension 	<ul style="list-style-type: none"> First pregnancy Age 40 or older Pregnancy interval >10 years BMI >35 at first visit Family history of pre-eclampsia

Advise women with one high-risk factor or 2 or more moderate-risk factors to take 75 mg aspirin daily from 12 weeks until the baby is born (*this is an unlicensed indication and should be discussed and documented appropriately*). BMI, body mass index; NICE, National Institute for Health and Care Excellence; SLE, systemic lupus erythematosus.

Prevention of Preeclampsia

High-risk women stand to gain maximum with low dose aspirin 75 mg to prevent development of preeclampsia [number needed to treat (NNT) of 19 to prevent one episode of preeclampsia]. One recent trial showed that a higher dose of aspirin 150 mg versus placebo from 11 to 34 weeks of gestation showed an absolute reduction of preeclampsia of 2.7% (1.6% vs. 4.3% $p = 0.004$).⁶

Table 2 guides the initial care provider in managing uncomplicated gestational hypertension and referring those with preeclampsia or severe hypertension to fully equipped centers.

Management of Severe Preeclampsia

Standardized, evidence-based clinical guidelines for the management of preeclampsia and eclampsia have been demonstrated to reduce incidence of adverse maternal outcomes. Treatment with first-line agents should be instituted as soon as possible, within 30–60 minutes of confirmed severe hypertension (BP greater than 160/110 mm Hg and persistent for 15 minutes) to reduce the risk of maternal stroke. Appropriate measurement of BP is of paramount importance (mercury sphygmomanometer or appropriately validated equivalent automated equipment, use of correct cuff size, positioning in sitting or semi reclining position with back support).

Intravenous (IV) labetalol and hydralazine have long been considered first-line medications. Immediate release oral nifedipine is also considered as first-line therapy, particularly when IV access is not available. Immediate release of oral nifedipine capsules should be administered orally and not punctured or otherwise administered sublingually (because of risk of hypotension).

Boxes 1–3 outline standardized order sets for the use of oral nifedipine, IV hydralazine, and IV labetalol in initial management of acute severe hypertension. Administration of above drugs does not require cardiac monitoring or other monitoring more than what is mentioned in boxes 1–3. In addition, personnel in all hospital settings, should be able to provide these initial medications without transferring to another unit (JNC 7 recommendations).

BOX 1 Suggested algorithm for management of severe intrapartum hypertension using immediate release Nifedipine <ul style="list-style-type: none"> • Monitor BP and treat if systolic blood pressure (SBP) ≥ 160 or diastolic (DBP) ≥ 110 mm Hg • Monitor fetal well being • If SBP or DBP remain persistently elevated for ≥ 15 min, administer 10 mg nifedipine orally • Short acting nifedipine should not be used • Monitor BP every 15–20 min, if still above range then administer additional dose • Maximal total dose of nifedipine is 30 mg • Use nifedipine with caution in patients on magnesium sulfate as it can marked fall in BP. Please note that the use of Nifedipine in treatment of hypertension in pregnancy is still controversial and is not generally preferred • If BP still above range, administer labetalol (40 mg IV over 2 min) • Assess fetal well being and consult obstetrician • Additional antihypertensive drugs may be administered as per need • Once BP returns to acceptable range, monitor BP periodically (repeat BP measurement every 10 min for 1 h, then every 15 min for 1 h, then every 30 min for 1 h, and then every hour for 4 h) 	BOX 3 Suggested algorithm for management of severe intrapartum hypertension using Labetalol <ul style="list-style-type: none"> • Monitor BP and treat if systolic blood pressure (SBP) ≥ 160 or diastolic (DBP) ≥ 110 mm Hg • Monitor fetal well being • If SBP or DBP remain persistently elevated for ≥ 15 min, administer labetalol 20 mg IV • Monitor BP every 15–20 min, if still above range then administer additional dose (20–40 mg IV) • If BP still above range, administer labetalol (40–80 mg IV over 2 min) • Maximal total dose of labetalol is 220 mg • Assess fetal well being and consult obstetrician • Additional antihypertensive drugs may be administered as per need • Once BP returns to acceptable range, monitor BP periodically (repeat BP measurement every 10 min for 1 h, then every 15 min for 1 h, then every 30 min for 1 h, and then every hour for 4 h)
BOX 2 Suggested algorithm for management of severe intrapartum hypertension using hydralazine <ul style="list-style-type: none"> • Monitor BP and treat if systolic blood pressure (SBP) ≥ 160 or diastolic (DBP) ≥ 110 mm Hg • Monitor fetal well being • If SBP or DBP remain persistently elevated for ≥ 15 min, administer Hydralazine (5 mg IV) • Monitor BP every 15–20 min, if still above range then administer additional dose (10 mg IV) • Maximal total dose of hydralazine is 25 mg • If BP still above range, administer labetalol (40 mg IV over 2 min) • Assess fetal wellbeing and consult obstetrician • Additional antihypertensive drugs may be administered as per need • Once BP returns to acceptable range, monitor BP periodically (repeat BP measurement every 10 min for 1 h, then every 15 min for 1 h, then every 30 min for 1 h, and then every hour for 4 h) 	<p>CHRONIC HYPERTENSION</p> <p>Hypertension which predates pregnancy is associated with adverse pregnancy outcomes. These patients require pre-conception counseling regarding antihypertensive use, reducing obesity, and stopping smoking and getting pregnant at an earlier age. Angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blocker (ARB), and chlorothiazide increase the risk of congenital anomalies and should be stopped before conception. It is also advisable to stop direct renin inhibitors and spironolactone. There is no known risk for other antihypertensive. Antihypertensive treatment, if BP is more than 150/100 mm Hg, will reduce the risk of severe hypertension, but there is no effect on perinatal outcomes. Low-dose aspirin is also advisable to reduce the chance of development of superadded preeclampsia. Increased surveillance during pregnancy like more frequent antenatal visits, ultrasound monitoring of fetal growth, and consideration of home BP monitoring is required.</p> <p>TIMING OF TERMINATION OF PREGNANCY</p> <p>Termination of pregnancy is the definitive treatment for preeclampsia. Factors which decide timing of termination of pregnancy include the severity of preeclampsia, and the period of gestation and fetal maturity. In severe cases where the patient has reached 34 weeks pregnancy should be terminated either by vaginal delivery or by cesarean section. In mild cases of preeclampsia pregnancy can be continued till term with frequent assessment of maternal and fetal conditions and judicious decisions can be taken. The HYPITAT (Hypertension and Preeclampsia Intervention) trial advocated delivery by 37 weeks of gestation to reduce adverse maternal outcomes.⁷ HELLP syndrome is a severe manifestation of preeclampsia characterized by hemolysis,</p>

Second-line Alternatives

In rare circumstances, when above-mentioned drugs fail, second-line drugs are recommended. They include nicardipine or esmolol infusion. Sodium nitroprusside is reserved for extreme emergencies. It should be used only for the shortest time in view of concerns regarding cyanide or thiocyanate toxicity and increase in intracranial pressure with worsening cerebral edema in the mother.

Magnesium sulfate is not recommended as an antihypertensive agent, but still remains the drug of choice for seizure prophylaxis in preeclampsia with severe features and for controlling seizures in eclampsia.

elevation of hepatic enzymes, and platelet abnormalities associated with grave maternal outcomes and requires urgent termination of pregnancy. In cases of severe preeclampsia, pregnancy should be terminated before 34 weeks in the setting of HELLP syndrome, renal failure, pulmonary edema, placental abruption, intracerebral bleed, and abnormal fetal biophysical profile.⁸

POSTPARTUM HYPERTENSION

Postpartum hypertension and preeclampsia is the cause for 0.3% of all visits to emergency department in the postpartum period. In women with preeclampsia or superimposed preeclampsia, BP starts decreasing within 48 hours of delivery, but increases again within 3–6 days. So, all women should be educated regarding symptoms of severe hypertension and report if needed as preeclampsia and eclampsia can develop up to 4 weeks postpartum. BP should be measured at 72 hours and 7–10 days postdelivery in all with gestational hypertension, preeclampsia, or superimposed preeclampsia. Antihypertensive therapy to be instituted, if BP is more than 150/100 mm Hg on two occasions at least 4–6 hours apart. Magnesium sulfate has to be given for features of impending eclampsia.

INDIAN DATA

The National Eclampsia Registry 2011⁹ indicates a prevalence of 9% of hypertensive disorders and preeclampsia of 5%.

KEY MESSAGES

- Hypertension during pregnancy is the second most common cause of maternal morbidity and mortality
- Careful measurement of BP as per guidelines should be done during each antenatal visit
- Once pregnancy is suspected ACEI, ARBs, mineralocorticoid antagonists should be stopped and replaced by appropriate antihypertensive treatment
- Patients with BP 150/100 mm Hg or more should be admitted for proper monitoring and appropriate mana-

gement. Severe BP elevation 160/110 mm Hg needs urgent control of BP

- Labetalol, alpha-methyldopa, and nifedipine are three key drugs in the management of hypertension during pregnancy. In severe cases parenteral labetalol, hydralazine, and rapid acting oral nifedipine should be used. Sublingual nifedipine is contraindicated because of severe hypotension which may ensue
- Timing of termination of pregnancy in preeclampsia depends on severity of preeclampsia and the fetal biophysical profile and should be decided judiciously
- Postpartum hypertension with preeclampsia can occur in the immediate postnatal period and can result in complications. This entity should be considered in postpartum periods and appropriate treatment should be instituted.

Peripartum Cardiomyopathy

Abhishek Roy, Debabrata Roy

INTRODUCTION

Occasionally, peripartum cardiomyopathy (PPCM) can be a serious pregnancy complication, often occurring in pregnant women who were earlier quite healthy. Women with this disorder usually have an infant to take care of, along with a frequently disabling heart condition, and a higher mortality risk.

The definition of PPCM is based on the following criteria:

- Symptomatic heart failure (HF) in the last month of pregnancy or within 5 months of delivery
- Absence of an identifiable cause of HF
- Absence of pre-existing heart disease prior to the last month of pregnancy, and
- Left ventricular (LV) systolic dysfunction [left ventricular ejection fraction (LVEF) <45% and/or fractional shortening <30% on echocardiogram].¹

The diagnosis of PPCM is thus made when no other etiology of HF can be readily identified.

Peripartum cardiomyopathy is not a very common condition. Estimations of the population incidence of PPCM are scarce due to several reasons. These include an inability to correctly diagnose the condition, as well as the absence of a reliable reporting system. In the United States, the incidence is estimated to be 1 in 1,000 to 1 in 4,000 pregnancies.^{2,3} On the other hand, Nigeria and Haiti appear to be global hotspots, where high incidence rates of almost 1 in every 100 to 1 in every 300 are reported.^{4,5} Why the incidence rates of PPCM have such extreme global variations is yet to be fully understood. However, it is encountered more often and portends a graver prognosis in women with an African ancestry.^{2,6-8}

The exact incidence of PPCM in the Indian subcontinent has not yet been properly elucidated. Reported incidence from a tertiary care hospital from southern India was 1 in 1374 live births.⁹ Apart from ethnic and racial differences, multiparous women, women with multifetal pregnancies, advanced maternal age, pregnancy-induced hypertension, and preeclampsia are classically associated with a higher risk of PPCM.^{1,10-15}

PHYSIOLOGY OF NORMAL PREGNANCY

Starting with the first trimester of pregnancy, maternal systemic vascular resistance decreases along with a proportional increase in the cardiac output.¹⁶ The renin-angiotensin-aldosterone system is activated, thereby retaining salt and water and thus helping to maintain the blood pressure. Estrogen, progesterone, and relaxin, the pregnancy hormones, promote vascular relaxation at the same time.^{17,18} There is also a significant increase in LV mass via physiological cardiac remodeling. Since coagulation factors increase throughout gestation,¹⁹ the risk for thrombosis during pregnancy is 4–10 times higher and reaches the maximum at term. The amount of oxidative stress is raised in pregnancy, and this is accompanied by an increase in antioxidant capability, though slightly delayed.²⁰ Hence, profound system-wide hemodynamic, metabolic, and hormonal adaptations are noted during pregnancy.

The dilemma in the diagnosis of PPCM lies in the fact that several of the presenting symptoms such as ankle, foot and abdominal swelling, easy fatigability, weakness, and a reduced exercise capacity maybe interpreted erroneously as the consequences of pregnancy rather than a failing heart.²¹

ETIOPATHOGENESIS OF PERIPARTUM CARDIOMYOPATHY

Through the decades, there has been wide speculation regarding the cause of PPCM. Several theories have been considered in the past, including myocarditis, fetal antigen autoimmunity, fetal microchimerism, selenium deficiency or excess salt consumption. Research carried out in recent times, however, suggests that PPCM is likely a vascular disease, triggered by placental and pituitary secretion of strong antiangiogenic agents late in gestation.

Prolactin

That apoptosis has an important role in PPCM has been suggested by several clinical observations and analyses of

plasma in affected women,^{22,23} but the cause of this apoptosis was not quite clear.

Denise Hilfiker-Kleiner and Helmut Drexler first provided experimental support for the hypothesis that PPCM was a vascular disease that was initiated by late gestational hormonal changes.²⁴ On deletion of transcription factor STAT3 (signal transducer and activator of transcription 3) in cardiomyocytes of pregnant mice, they developed PPCM. Protection of the heart against reactive oxygen species (ROS) is conferred by STAT3, and is essentially regulated by the expression of the gene for superoxide dismutase 2 (SOD2). SOD2 counteracts superoxides generated by the activity of mitochondria in cardiac myocytes. Hence, an increase in ROS was observed after the deletion of STAT3, which in turn led to the inappropriate secretion of peptidases, particularly cathepsin D, from the cardiomyocytes (Fig. 1). Prolactin is then cleaved into a 16-kD fragment by extracellular cathepsin D. This 16-kD prolactin fragment has potent vasculotoxic properties and causes endothelial cell apoptosis. Using bromocriptine to treat STAT3 cardiac knockout (KO) mice blocked the production of prolactin and dramatically reversed the clinical features of PPCM.

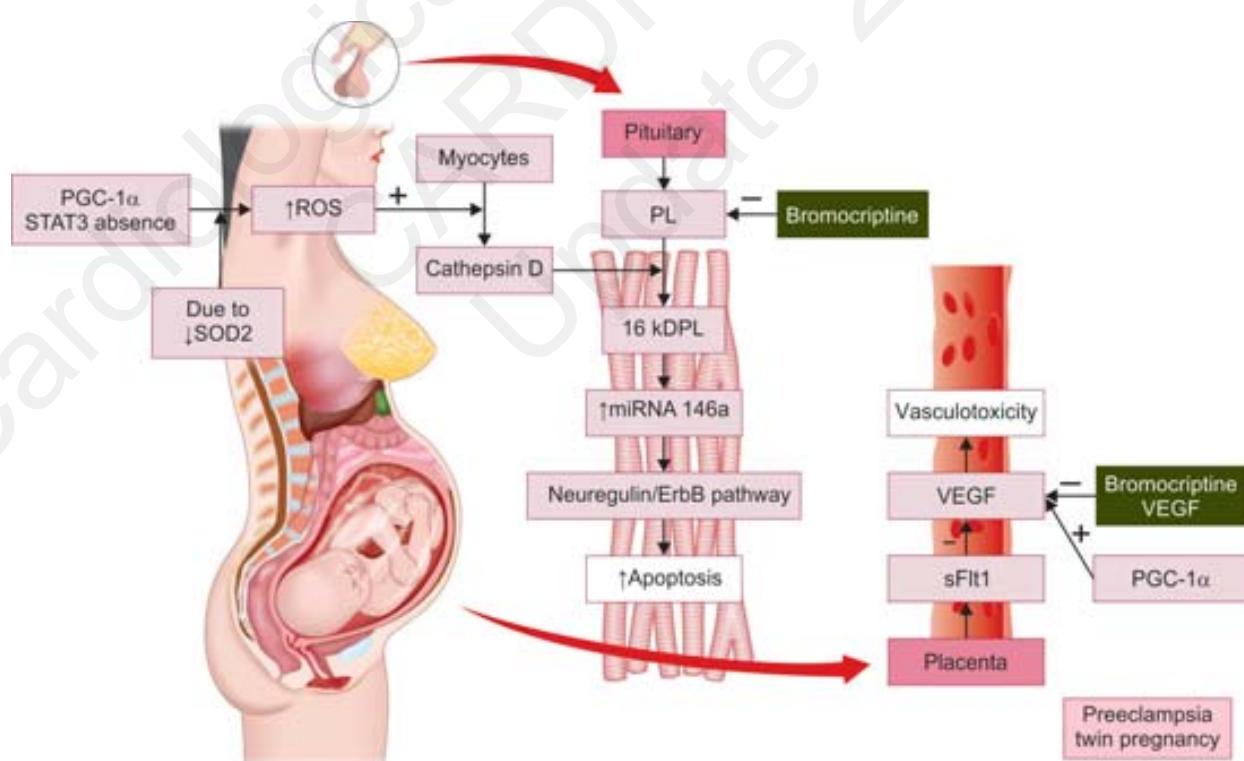

More recently, deeper assessment of the mechanism of vascular damage by 16-kD prolactin showed that there is increased endothelial expression of microRNA-146a on exposure to it.^{25,26} Ultimately target genes, especially the neuregulin/ErbB pathway, are suppressed in the cardiomyocytes via microRNA action. This is known to be vital in the prevention of cardiomyocyte apoptosis. There is a

profound increase in the levels of microRNA-146a in PPCM, and treatment with bromocriptine significantly reduces these levels. Micro-RNA146a could thus potentially be used as a PPCM biomarker or alternatively, be targeted therapeutically.

Soluble Fms-like Tyrosine Kinase-1 and Preeclampsia

A potent transcriptional regulator, PGC-1 α (peroxisome proliferatoractivated receptor gamma coactivator 1 α) is known to have important effects on various angiogenic and metabolic pathways. Similar to the STAT3 cardiac KO mice, those mice with absent PGC-1 α in cardiac myocytes developed PPCM.²⁷ Like STAT3, SOD2 expression is controlled by PGC-1 α , thus giving rise to increased ROS levels in PGC-1 α cardiac KO mice. However, only bromocriptine use was unable to revert the PPCM in these mice. The reason for this is because transcriptional induction of vascular endothelial growth factor (VEGF) is influenced by PGC-1 α , thereby directly regulating the health of the vasculature.²⁸ Thus, vasculotoxicity is caused by two different pathways in a PGC-1 α deficient heart: stimulation of a vasculotoxic 16-kD mediated pathway, and inhibition of a VEGF-mediated provascular pathway (Fig. 1). Consequently, these mice with PPCM could be successfully rescued only with dual therapy combining bromocriptine as well as VEGF.

The hormonal milieu of pregnancy is predominantly regulated by the pituitary and the placenta. Toward the end

PL, prolactin; PPCM, peripartum cardiomyopathy; ROS, reactive oxygen species; sFlt-1, soluble Fms-like tyrosine kinase 1; SOD2, superoxide dismutase 2; VEGF, vascular endothelial growth factor; PGC-1 α , peroxisome proliferator-activated receptor gamma coactivator 1-alpha; STAT3, signal transducer and activator of transcription 3.

FIG. 1: Mechanisms in peripartum cardiomyopathy.

of gestation, several compounds are secreted into the circulation by the placenta. This particularly includes a soluble VEGF receptor 1 or soluble fms-like tyrosine kinase 1 (sFlt-1). Members of the VEGF family present in the circulation are bound to and neutralized by this sFlt-1, leading to the neutralization of most of the circulating VEGF by the end of gestation.²⁹ Placental secretion of additional sFlt-1 during the later part of gestation establishes further hormonal damage to the cardiac vasculature. In defense, there is strong secretion of VEGF locally in the heart. This local secretion of VEGF is reduced in the absence of PGC-1 α , and this coupled with a high gestational sFlt-1, gives rise to vasculotoxicity. Accordingly, when nulliparous mice were administered sFlt-1, PGC-1 α cardiac KO mice started exhibiting signs of cardiomyopathy.

In preeclampsia, a disease of pregnancy characterized by hypertension and proteinuria, secretion of sFlt-1 by the placenta is profoundly increased.²⁹ This is in accordance with the fact that preeclampsia is one of the strongest risk factors associated with PPCM.³⁰ About 25% of PPCM patients are concomitantly diagnosed with preeclampsia. Twin pregnancies have higher sFlt-1 levels, probably due to increased mass of the placenta,³¹ and similarly are associated with 10–16% of PPCM occurrences.^{32–34} Collectively, these observations argue strongly in favor of the fact that placental sFlt-1, secreted toward the end of gestation, poses a formidable noxious challenge to the heart. When adequate defensive mechanisms are unavailable, PPCM is quick to develop.

A “Two-Hit” Hypothesis

When the available recent evidence is collectively considered, it appears that PPCM develops in the presence of two simultaneous “hits”: the first hit being the vasculotoxic hormonal milieu, involving prolactin and sFlt-1, late in gestation, and the second one is the incapability of certain women to counter this vasculotoxicity. Unfortunately, at this point, there is only speculation about the true nature of this susceptibility toward PPCM (the second “hit”).

One of the possibilities is that cardiac defenses might be weakened by an acute insult such as viral myocarditis. Even though such a rationalization would be consistent with earlier hypotheses about PPCM, evidence for it is scarce. Genetic predisposition could be another possible second hit. This notion is favored by a few studies. In a genome-wide association study (GWAS), an association was found between PPCM and a polymorphism close to the *PTHLH* gene, which apparently functions as an angiogenesis inhibitor.^{35,36} It is also interesting to note that mutations, especially titin, which are associated with familial dilated cardiomyopathy (DCM), have been identified in certain families with both PPCM and DCM.^{37,38} However, predisposition to PPCM in familial DCM is still unable to explain most cases of PPCM. This likely represents the heterogeneity of the disease.

CLINICAL FEATURES

Clinical features of PPCM are no different than in non-pregnant patients with systolic dysfunction. New or rapid onset of dyspnea, cough, paroxysmal nocturnal dyspnea, orthopnea, fatigue, palpitations, chest pain, and unexplained weight gain should always be promptly evaluated. Tachycardia, tachypnea, a subnormal SPO₂ and evidence of cardiomegaly are often found on physical examination. The jugular venous pressure is usually raised, blood pressure may however be normal, S3 is often auscultable and the P2 component of the second heart sound might be loud. Mitral regurgitation, tricuspid regurgitation, and bibasal fine crepitations are often found. Dependent edema may worsen and ascites along with congestive hepatomegaly are quite common. Arrhythmias are not infrequent and may give rise to cardioembolic phenomenon. Occasionally mild-to-moderate pericardial effusions are noted. Preeclampsia is suspected on detection of raised blood pressures and evidence of proteinuria. The hemodynamic alterations and overall clinical picture of PPCM cannot be reliably distinguished from other forms of DCM.³⁹ There are also few reported instances of PPCM with high output cardiac failure.⁴⁰

DIAGNOSIS

As there are no clearly defined specific symptoms of PPCM, especially during the last trimester of pregnancy, the diagnosis of PPCM is delayed many times. One should keep in mind the possibility of PPCM in all pregnant women presenting with symptoms of cardiac failure or in postpartum women who have a slower recovery to the pregestational state. In such cases, an in-depth family history should be taken to find out any familial trends of cardiomyopathy. Diagnostic testing that may be performed in suspected cases of PPCM are enumerated in box 1.⁴¹

- *X-ray chest:* An increased cardiothoracic ratio or evidence of pulmonary edema may be seen. Pleural effusion may also be occasionally noted. However, the routine use of X-ray chest during pregnancy should be discouraged as it is nonessential for the diagnosis of PPCM. It should only

BOX 1 Diagnostic testing for peripartum cardiomyopathy

BNP, brain-type natriuretic peptide.

be performed if absolutely necessary using abdominal shielding

- *Electrocardiography (ECG)*: A normal ECG does not rule out PPCM. Sinus tachycardia is the most common abnormality, though atrial fibrillation, abnormalities of conduction and other types of arrhythmias along with nonspecific ST-T changes are occasionally encountered.
- *Echocardiography*: Echocardiography is one of the most important modalities for the initial evaluation and subsequent monitoring of women with PPCM. Evidence of LV systolic dysfunction (LV ejection fraction <45% and/or fractional shortening <30%) is quintessential for the diagnosis of PPCM. Frequently, the left ventricle is also dilated, especially in patients who present late. Compensatory hypertrophy of the left ventricle may be present to a mild extent, however, pronounced LV wall hypertrophy might be suggestive of a primary hypertrophic cardiomyopathy. Small pericardial effusions are not infrequent in the immediate postpartum period. Morphologically, valves are generally normal. However, when extensive LV dilatation sets in, mitral regurgitation as a consequence of annular dilatation may be seen. On occasion, tricuspid regurgitation and pulmonary regurgitation may also be seen. Overall PPCM is indistinguishable from primary idiopathic DCM on the basis of echocardiography alone⁴²
- *Endomyocardial biopsy*: Features of myocarditis may be seen on endomyocardial biopsy since quite a few cases of PPCM appear to be related to myocarditis. The best time to perform endomyocardial biopsies in these patients is early after symptom onset. However, sufficient data about this diagnostic modality in the context of PPCM is lacking
- *Viral and bacterial assays*: Antibody titers for Coxsackie B virus may be estimated in carefully selected cases. However, the implications of such titers are currently more research related rather than diagnostic
- *Magnetic resonance imaging (MRI)*: MRI is the gold standard in the evaluation of cardiac volumes and ventricular systolic functions, and may complementarily be used in the workup of a patient with PPCM. Patterns of late gadolinium enhancement can often aid in making a definitive diagnosis. A cardiac MRI can also guide biopsy from an affected area, thereby increasing the yield and diagnostic accuracy
- *Right heart catheterization*: Right heart catheterization can assess filling pressures and reliably estimate the cardiac output in patients with refractory HF, unstable hemodynamics or target organ damage. Dilatation of all cardiac chambers, especially the left ventricle can also be readily established
- *Biochemical evaluation*: Creatine kinase or cardiac troponins are usually not raised. Evaluation of renal and liver function may provide valuable information about organ perfusion in patients with cardiac failure and compromised hemodynamics.

DIFFERENTIAL DIAGNOSIS

Diagnosis of PPCM should be made when all other probable causes of HF have been ruled out. Box 2 enumerates the differential diagnosis of PPCM.

The various causes of cardiomyopathy should be evaluated before making a diagnosis of PPCM. The closest in clinical manifestation is DCM, the possibility of which should be carefully looked into. PPCM is more common in the young and has a better prognosis, mostly occurring after delivery (78–93%) unlike DCM, which occurs by second trimester. Unlike DCM, PPCM can cause faster deterioration of clinical symptoms leading to poorer consequences. Clinical history, physical examination, and investigations should be done in order to exclude other probable causes of cardiac failure like coronary artery disease, diseases of the cardiac valves, pulmonary thromboembolism, pneumonia, and severe eclampsia.

Transthoracic echocardiography can rule out the most probable differential diagnosis which happens to be previously undetected valvular heart disease. The presence of normal systolic function can rule out PPCM and should point toward further probing into causes of high output HF like thyrotoxicosis and anemia. Even though this population is at low risk for ischemic heart diseases, women with known and important risk factors like type I diabetes mellitus should be evaluated by noninvasive methods for coronary ischemia, and if required angiography should be done. In women with persistent cardiac failure, unstable hemodynamics or in cases of organ dysfunction, catheterization of the right heart can be done to determine the filling pressures and cardiac output.

Fett et al. have devised an easy to use, efficacious, self-administered test to differentiate early clinical features of cardiac failure from healthy term pregnancy (Table 1).

MANAGEMENT

Insufficient evidence-based data on management of cardiac failure in pregnancy poses challenges in the treatment of PPCM.

Presently, it is treated as per the protocol of management of cardiac failure keeping in mind the pregnant condition

BOX 2

Differential diagnoses of peripartum cardiomyopathy

- Pre-existing dilated cardiomyopathy
- Pre-existing other forms of cardiomyopathy
- Pre-existing valvular heart disease, particularly valvular stenosis
- Pre-existing congenital heart disease
- Hypertensive heart disease including preeclampsia and eclampsia
- Acute myocarditis
- Acute pulmonary embolism
- Acute coronary spasm, coronary dissection, coronary thrombosis, and acute myocardial infarction
- Thyrotoxicosis
- Maternal sepsis

SECTION 21

Women and Heart Disease

TABLE 1: Probability scores for peripartum cardiomyopathy proposed by Fett et al.⁴³

Symptom/Sign	0 point	1 point	1 point
Dyspnea	None	When climb >8 steps	Walking
Orthopnea	None	Elevate head only	Elevate boy >45°
Unexplained cough	None	Night-time	Day and night
Pitting edema	None	Below Knee	Above knee
Weight gain 9 th month	<1 kg/week	1–2 kg/week	>2 kg/week
Palpitations	None	Night-time	Day and night

0–2 : low risk, continue observation

3–4 : mild risk, consider blood BNP

5 or > : high risk, blood BNP and echo

BNP, brain-type natriuretic peptide.

of the women. Therapy in late pregnancy should take into consideration both the mother's as well as the fetus' health (Table 2).⁴¹ Drugs like beta-blockers, thiazide diuretics or furosemide may be mandatory in few patients of PPCM before delivery of the fetus. In this regard, it is imperative to use lowest recommended dose of diuretics as they can cause impairment in perfusion of the placenta posing a threat to the fetus.

In patients of PPCM postdelivery, the therapeutic management is like that of HF which includes use of beta-blockers, mineralocorticoid receptor antagonists (MRAs), diuretics and angiotensin converting enzyme inhibitors (ACEIs)/angiotensin receptor blockers (ARBs). Due to lack of data on inotrope usage in PPCM patients and the fact that myocardial damage may be aggravated by the use of catecholamines, use of inotropes should be done only in cases of severe hypotension with or without evidence of cardiogenic shock. Once the patient becomes hemodynamically stable,

TABLE 2: Peripartum cardiomyopathy medications

Classification	Medication	Dose	Remark
ACEIs	Captopril	Starting dose 6.25 mg TDS	Contraindicated in pregnancy
		Increase upto 25–50 mg TDS	
	Enalapril	Starting dose 1.25 mg BD	Contraindicated in pregnancy
		Increase upto 10 mg BD	
	Ramipril	Starting dose 1.25 mg BD	Lack of data in pregnancy
		Increase upto 5 mg BD	
ARBs	Candesartan	Starting dose 2 mg OD	Contraindicated in pregnancy and lactation
		Increase upto 32 mg OD	
	Valsartan	Starting dose 40 mg BD	Contraindicated in pregnancy and lactation
		Increase upto 160 mg BD	
MRAs	Spironolactone	Starting dose 12.5 mg OD	Contraindicated in pregnancy and lactation
		Increase upto 50 mg OD	
β-Blockers	Extended-release Metoprolol	Starting dose 12.5 mg OD	Rare risk of bradycardia or respiratory distress in newborn
		Increase upto 50 mg OD	
	Carvedilol	Starting dose 3.125 mg BD	Same as metoprolol
		Increase upto 25 mg BD	–
Vasodilators	Hydralazine	Starting dose 10 mg TDS	–
		Increase upto 40 mg TDS	–
	Nitroglycerin	Starting dose 10–20 µg/min IV	Risk of hypotension
		Increase according to BP	
Diuretic	Hydrochlorothiazide	12.5–50 mg OD	Risk of insufficient uteroplacental circulation
	Furosemide	20–80 mg OD-BD (oral/IV)	Risk of insufficient uteroplacental circulation
Inotropes	Digoxin	0.125–0.25 mg OD	Risk of toxicity to drug
	Dobutamine	2.5–10 µg/kg/min	–
	Milrinone	0.125–0.5 µg/kg/min	–
Prolactin inhibition	Bromocriptine	2.5 mg OD for 1 week (short-term)	Thrombotic risk
		5 mg for 2 weeks, followed by 2.5 mg for 6 weeks (long-term)	

ACEIs, angiotensin-converting enzyme inhibitors; ARBs, angiotensin receptor blockers; BD, twice daily; BP, blood pressure; IV, intravenous; MRAs, mineralocorticoid receptor antagonists; OD, once daily; TDS, thrice daily.

tapering of the inotropes should be done and the treatment protocol for pregnant patients with HF should be adopted. In patients who have severely compromised ejection fraction, initiation of beta-blockers at very low doses appears to have a protective effect. Ivabradine may alternatively be used in patients of persistent sinus tachycardia where increase in beta-blocker dose is not recommended for fear of cardiac failure or hypotension.

In South Africa, a pilot study showed beneficial effect of bromocriptine in addition to drugs used for cardiac failure, in patients of PPCM where the onset was acute in nature.^{44,45} Similarly, a German registry of PPCM patients also showed that the above therapy gave better results in most of the patients (96%).⁴⁶ Another randomized multicenter trial in Germany explored the efficacy of bromocriptine. Treatment with bromocriptine had higher rates of full recovery of the left ventricle, along with reduced mortality and morbidity, in patients with PPCM, when compared with other cohorts of PPCM who were not administered bromocriptine.⁴⁷ However, considering use of bromocriptine suppresses lactation, how this data relates to other parts of the world where the survival of infants is affected by lack of availability of breast milk is yet to be fully ascertained.

The risk of sudden death is more in patients with PPCM and the outcome can be improved by the use of implantable cardioverter defibrillators (ICDs) and cardiac resynchronization therapy (CRT).⁴⁸⁻⁵⁰ For the purpose of primary prevention, a wearable cardioverter-defibrillator can be considered as many of the PPCM patients show significant improvement of systolic function of the left ventricle and some may even show complete recovery. Wearable cardioverter-defibrillators can be recommended for 3–6 months as interim management. The LV function should be assessed by echocardiography at regular intervals during this period. Another observational study conducted on a small group of PPCM patients who had severely compromised cardiac function with/without ventricular arrhythmias also showed the usage of wearable cardioverter-defibrillators to be valuable in such patients.⁵¹ The use of LV assist device may be done in patients who are critically ill; who do not show any signs of recovery over a period of many weeks. Cardiac transplantation should be considered as the last option as there is quite an improvement in the condition of most PPCM patients in the first 6–12 months.

PROGNOSIS AND FOLLOW-UP

The disease prognosis may range from full recovery to even death of the patient. In most of the cases, the LV function recovers either fully or partially. It has been seen that about 23–72% of patients have had full recovery of systolic function of left ventricle (i.e., LVEF > 50%).^{23,52,53} The recovery can be seen within 2–6 months after diagnosis of the disease, but in some cases, it may take upto 5 years.⁴ Those patients of PPCM who had LVEF less than 35% or had severe remodeling of the left ventricle [left ventricular end-diastolic diameter (LVEDD) ≥60 mm] are the ones who are at risk of slow recovery or nonrecovery.⁵⁴

The treatment for cardiac failure which includes beta-blockers, ARBs, and ACEIs should be done in patients with systolic dysfunction of the left ventricle for at least 12 months. This is because some patients may have late recovery.^{55,56} Also, in patients with normal function of left ventricle the therapy should be continued for at least 6 months. This is because normal ejection fraction or return of left ventricle size to normal does not mean stability in the long run.⁵⁶

Even after maximally tolerated therapy, 20–25% patients develop end-stage cardiac failure in later years. The requirement of heart transplantation or LV assist device is seen in 4–11% of patients with PPCM.⁵⁵ Most of the deaths occur within 3–6 months of diagnosis of the disease.⁵⁷ Recently, due to early diagnosis and better management of cardiac failure, there has been a decrease in mortality rates. Nonetheless, mortality due to PPCM is still quite high in young women who were previously healthy. Thromboembolism, progression to refractory cardiac failure and ventricular arrhythmias are some of the important causes of death. The factors which can predict the long-term prognosis are yet not clear. However, it has been seen that women with poor functional reserve, LVEDD more than or equal to 60 mm, LVEF less than or equal to 25–35% and women of non-European descent have poorer prognosis.^{52,53,55}

COUNSELING FOR FUTURE PREGNANCIES

Once a patient has suffered from PPCM, there is 30–50% chance of it occurring in subsequent pregnancies.^{58,59} In those women who have persistent LV dysfunction, risk of PPCM occurring recurrently is higher. Also, women with severe LV dysfunction have higher mortality and morbidity rates.^{58,60} Even a normal LVEF does not mean that the subsequent pregnancy will have a normal outcome. Hence, all women who have had PPCM should be cautioned regarding risk of PPCM in future pregnancies which can even lead to death. All relevant information regarding choice of contraceptive methods should be given to the patient.

In case a woman is already pregnant, her and her family's decision regarding continuation of the pregnancy should be of primary importance. This is because many pregnant women may remain healthy even if they have had a history of PPCM during previous pregnancies. This is particularly true in cases where the LV systolic function was not compromised. Hence, termination of pregnancy in all cases of recurrent PPCM is not warranted.⁶¹ A tailor-made plan can be adopted if the woman wishes to continue her pregnancy.

During the last trimester echocardiography should be done every 1–2 weeks for monitoring the status of the patient. Also, therapeutic management of cardiac failure can prevent serious unwanted complications.

CONCLUSION

Healthy pregnancy is jeopardized by PPCM. Having a clinical foresight is very important for diagnosing the condition early. The investigation of prime importance is

echocardiography which is required for screening, diagnosis, and even follow-up of the patient. Treatment for PPCM is the same as that of cardiac failure, although the treatment should be modified keeping in mind the safety of the fetus. In future, more studies are required in order to fully understand the pathophysiology of the disease, determine specific biomarkers and better treatment protocols. Studies are also needed to explore various measures for prevention of PPCM.

Mitral Stenosis in Pregnancy: The Last Straw on the Camel's Back!

AJ Swamy, Deepak Saha, Sarat Chandra

INTRODUCTION AND EPIDEMIOLOGY

Mitral stenosis (MS) is the most common manifestation of chronic rheumatic heart disease, and its age of occurrence, natural history, and hemodynamic load imposed on the circulatory system ensure that it will always be an important consideration if present in a pregnant patient. The earliest description was in the last quarter of the 19th century by James Mackenzie, a Scottish physician who observed a young woman with MS and pregnancy.¹ The patient had severe pulmonary congestion in the second trimester and succumbed during labor.

PREVALENCE AND INCIDENCE IN INDIA

In one large study, rheumatic MS formed 88% of the heart diseases complicating pregnancy in a tertiary referral center in India.² Significant MS causes maternal complications (pulmonary edema, atrial fibrillation, thromboembolic complications) and fetal complications (premature birth, intrauterine growth retardation, and still birth).³ Severe MS is particularly malignant: in one study of pregnant patients with severe MS, 67% developed a maternal cardiac event, and 44% of infants were born prematurely or died.⁴ These events can be prevented and outcomes improved by proper management during pregnancy and better perinatal care.⁵

HEMODYNAMIC CHANGES IN PREGNANCY

Pregnancy brings about significant changes in hemodynamics throughout gestation. The blood volume progressively increases throughout pregnancy starting at 6 weeks of gestation. It reaches peak at 32 weeks of gestation (at this time blood volume reaches 45% more than the prepregnancy level). Maternal heart rate gradually increases from fifth week of gestation till 32 weeks of gestation after which it plateaus. An increase of 15–20 beats/min is usual. Cardiac output (which is a product of stroke volume and heart rate) gradually

increases from sixth week of gestation and usually peaks at 32 weeks. A 50% increase of cardiac output is seen at peak level compared to prepregnancy measurements. Cardiac output fluctuates significantly with changes in maternal position in the latter half of pregnancy. The enlarged gravid uterus compresses the inferior vena cava (IVC) in the supine position leading to decreased venous return to the heart and thus decreased cardiac output.

Systemic vascular resistance (SVR) decreases significantly during pregnancy starting from fifth week reaching nadir at about 20 weeks of gestation, during which it decreases by approximately 35% compared to baseline levels. It remains constant till 32 weeks beyond which a mild increase in SVR is noted till term. Blood pressure starts decreasing from seventh week of gestation reaching nadir at 20 weeks wherein, an average fall by 5–10% is observed. Thereafter blood pressure gradually increases returning to base line level (sometimes exceeds by 5–10%) by term.⁶

The hemodynamic burden during pregnancy may unmask previously unrecognized asymptomatic heart disease which sometimes results in significant morbidity and mortality. Other disorders of the heart like peripartum cardiomyopathy, aortic dissection or spontaneous coronary dissection may be precipitated by hormonal and hemodynamic alterations during pregnancy.⁷

HEMODYNAMICS DURING LABOR AND DELIVERY

Women with heart disease require close monitoring during labor and delivery. Uterine contractions at the time of labor transfer approximately 400 mL of blood from the uterus to the general circulation. The cardiac output may further increase in the second stage owing to the maternal pushing efforts, pain and anxiety causing increased sympathetic tone leading to increased heart rate and systolic blood pressure (SBP). Additionally, cardiac output may increase up to 70% immediately after delivery with increase in venous return

caused by relief of vena caval compression and transfer of blood from the placental circulation.⁸

PATOPHYSIOLOGY OF MITRAL STENOSIS DURING PREGNANCY

Pregnancy burdens significantly the maternal heart suffering from MS. The increased blood volume, increased filling pressure, and increased heart rate all contribute to the rise in left atrial (LA) mean pressure and thus pulmonary edema. Additionally, due to decreased diastolic time due to tachycardia, there is significant underfilling of left ventricular (LV) leading to low-stroke volume and low cardiac output state. This is the major contributor to uteroplacental insufficiency and cause of fetal morbidity.^{8,9}

Natural History

Mitral stenosis causes significant maternal adverse events that are related to New York Heart Association (NYHA) class and severity of MS. Symptoms depend upon the severity of MS prior to conception. In a study of a Cohort of 80 patients with pregnancy and rheumatic MS by Silverside CK et al., the rate of cardiac complications (pulmonary edema/arrhythmia), was 26% in mild MS [mitral valve area (MVA) >1.5 cm²], 38% in moderate MS (MVA 1–1.5 cm²), and 67% in severe MS (MVA <1 cm²).⁴ Symptoms correlate closely with NYHA class with regard to maternal and fetal outcomes. Mortality rates for class I and II amount to less than 1%, whereas they range between 5 and 15% for class III and IV. The perinatal mortality rate for class III and IV may be high as 20–30%. In another 2001 study that reported the effect of valvular heart disease on maternal and fetal outcome in 46 pregnancies in 44 patients with MS, a high incidence of maternal morbidity but no mortality was found. Hospitalization due to heart failure was reported in 61% of moderate MS patients (MVA 1–1.5 cm²) and 78% of women with severe stenosis. In those with moderate or severe stenosis, deterioration in functional status was noted in 82% of class I and 61% of class II patients. Outcomes in patients with mild MS were not statistically different from controls.¹⁰

The major adverse events related to pregnancy are acute pulmonary edema, arrhythmia (atrial fibrillation), and thromboembolic phenomena. Maternal death is rare in pregnancy. The risk of maternal death is greatest during labor and during the immediate postpartum period. The sudden increase in the preload immediately after delivery, due to autotransfusion from the uterus, may flood the central circulation, resulting in severe pulmonary edema. In addition, there continues to be autotransfusion of blood for 24–72 hours after delivery. Thus, the risk of pulmonary edema extends for several days after delivery.^{7,8} Other studies have described additional markers of adverse outcomes in heart disease with pregnancy. These include prior heart failure, arrhythmia, transient ischemic attack or stroke, a baseline NYHA III class or more or cyanosis, systemic ventricular dysfunction (ejection fraction <40%) pulmonary hypertension (pulmonary arterial systolic pressure 50%

of systemic pressure), left heart obstruction, severe aortic stenosis (valve area less than or equal to 1 cm², Doppler jet velocity 4 m/s) symptomatic or severe MS, and severe aortic or mitral regurgitation with NYHA class III or IV symptoms.¹¹

Adverse fetal outcomes are also related to severity of MS and NYHA class, occurring almost exclusively in symptomatic patients. Fetal and neonatal mortality up to 30% has been reported in patients with severe MS.¹² This is caused by uteroplacental insufficiency due to low cardiac output and includes preterm delivery, intrauterine growth retardation, low birth weight, and fetal or neonatal death.^{8,10} A large multicenter study in 2001 identified five predictors of neonatal events including NYHA class, maternal left heart obstruction, smoking during pregnancy, multiple gestations, and use of anticoagulants during pregnancy. Thus, women with poor functional class are at maximum risk for adverse neonatal outcomes.^{9,13}

Diagnosis

The symptoms due to MS are due to pulmonary or systemic congestion or low cardiac output. Common presentation is with progressive breathlessness, fatigue and/or pedal edema, which may be sometimes confused with the physiological effect of pregnancy. In women without known diagnosis of MS, a high suspicion of underlying heart disease is the key for early detection and timely management.⁸

Good clinical examination will give a clue to the diagnosis. Electrocardiogram (ECG) may show LA enlargement, atrial fibrillation or features of right ventricular hypertrophy (RVH) due to pulmonary hypertension. Chest X-ray (CXR) is usually avoided in pregnancy. The cornerstone of diagnosis is an echocardiographic evaluation that will reveal the severity of MS, the gradient across the valve, degree of subvalvular disease, the presence of pulmonary hypertension, the LV function, the presence of any additional valve involvement, pericardial effusion, or rheumatic activity. The 2D derived valve area may be more reliable than that derived by pressure half time.^{7,14}

Management

The functional class of patient prior to conception usually governs the prognosis of maternal and fetal outcome. In general, worsening by one NYHA Functional Class is anticipated during pregnancy usually at second and third trimester. Patients with moderate or severe MS do not tolerate hemodynamic burden of pregnancy well. Women with symptomatic MS, MS with significant pulmonary hypertension or valve area less than 1.5 cm² must be advised intervention, ideally, before pregnancy.^{7,8}

In all patients, medical therapy is initiated to relieve the pulmonary congestion. Restricted physical activity, salt restriction, and iron supplements should be routinely advised.^{7,8}

Beta-blockers: Cardioselective beta-blockers, usually short acting, are ideal. Atenolol has been shown to be associated with intrauterine growth restriction (IUGR) and so

metoprolol is preferred.^{15,16} Maternal heart rate is slowed, thus reducing LA pressure and increasing cardiac output by increased LV filling. It may be used along with diuretics. Beta-blockade has been shown to improve NYHA Functional Class. It has been shown to decrease maternal adverse events without adverse events on the fetus.¹⁷ Digoxin may be added for control of heart rate in cases with atrial fibrillation.^{7,10}

Diuretics: Loop diuretics are preferred but need careful monitoring under obstetric care so that placental insufficiency is avoided.^{7,8,18}

Anticoagulants: Since, pregnancy is a hypercoagulable state, anticoagulation [with vitamin K antagonist (VKA)] must be considered to prevent stroke and systemic embolism even if the patient is in sinus rhythm. In patients with mild MS, anticoagulants are better avoided. In moderate-to-severe MS, the risk to benefit ratio favors the use of anticoagulation if the LA dimensions exceeds 55 mm, however, there is a lack of evidence in this subset.

Patients who have established or intermittent atrial fibrillation should be treated with anticoagulation. VKAs are associated with fetal anomalies if used in the first trimester, especially if warfarin dose exceeds 5 mg/day. Ideally, warfarin should be used between 12 and 36 weeks. The consensus is to use low-molecular-weight heparin (LMWH) in weight adjusted doses for the first and third trimester, warfarin between 12 and 36 weeks and switch to unfractionated heparin 24 hours before delivery or lower (uterine) segment cesarean section (LSCS).¹⁹ In patients on heparin, the drug should be withdrawn 4 hours before cesarean section or at the onset of labor and resumed 6–12 hours after either surgical or vaginal delivery.²⁰

PERCUTANEOUS BALLOON MITRAL VALVULOPLASTY

Percutaneous balloon mitral valvuloplasty (PBMV) is the treatment of choice for isolated, noncalcified MS in symptomatic, moderate (or more) MS. Ideally, this should be performed preconception. It should also be considered in patients with echocardiographically severe MS even if asymptomatic. Contraindications include LA thrombi, more than 2+ mitral regurgitation, and severe subvalvular stenosis. The procedure may electively be performed in second trimester of pregnancy in patients who are at high-risk of developing pulmonary edema in late stage of pregnancy. If feasible, the procedure may be postponed beyond 28 weeks to ensure viability of the fetus.⁸ In an emergency, it should be performed, irrespective of the timing of pregnancy.

Steps of balloon mitral valvuloplasty (BMV) are similar to conventional procedure. However, prolonged compression of the IVC in supine position due to a long procedure or prolonged balloon inflation may cause adverse hemodynamic effects especially on uteroplacental circulation resulting in fetal distress and higher incidence of cesarean section.²¹ All patients need abdominal shielding with lead shields from diaphragm to pubic symphysis. Two lead shields may be

placed for the patient to lie on and a light shield over the anterior abdominal wall so as not to compress the gravid uterus. Fluoroscopy should be monitored and minimum. Right heart catheterization is thus usually avoided. The risk due to radiation exposure to the fetus is considerably less than the adverse effect of hemodynamic instability in later phase of pregnancy.

Percutaneous balloon mitral valvuloplasty must be performed at high-volume centers with appropriate shielding and where the speed of procedure can be minimized with optimum care both to mother and fetus. Short- and long-term outcomes have been reported after BMV in pregnancy. Immediate short-term success approaches 100%.^{22,23} In one series with 71 women with Class III or IV who underwent PBMV in Brazil, mean MVA increased from 0.9 to 2.0 cm². A total of 98% were in NYHA Class I or II at conclusion of pregnancy.²³ In another study of PBMV in pregnancy, 49 pregnant women were included. The mean gestational age was 23.5 ± 5.2 weeks (range: 12–36 weeks). The mean 2D area increased from 0.93 to 1.75 cm² with a procedural success of 95.9%. One patient had a major complication with tamponade and another aborted 2 days after the procedure.²⁴ Other studies have reported similar results.^{25,26} Long-term outcomes have also been reported after BMV.^{27,28} A 17-year outcomes following BMV have been reported; subsequent pregnancies were normal with children exhibiting normal physical and mental development.

Echocardiographically guided PBMV has been reported²⁹ as has intracardiac echocardiography (ICE)-assisted BMV.³⁰

SURGICAL MITRAL VALVOPLASTY/ MITRAL REPLACEMENT

Closed mitral valvotomy has been largely replaced by PBMV in most centers. Although the surgical risk to the mother has been quite low (1–5% mortality), the fetal mortality due to surgery has been high (up to 30% of cases).³¹ Open valvotomy carries a higher risk than closed valvotomy especially with regard to fetal mortality (15–30% vs. 5–15%).²⁶ But both have been replaced by PBMV for the last two decades with evidence from registries and comparative studies. PBMV resulted in lesser fetal morbidity and mortality in a nonrandomized study.³²

In patients with mixed stenosis and regurgitation, mitral valve replacement is the treatment of choice, but due to higher maternal and fetal morbidity and mortality, it should be reserved for symptomatic patients who have failed aggressive medical therapy.⁸ Cardiopulmonary bypass should be done at normal temperature and high flow and pressure for as brief a time period as possible. Important principles include use of high-flow, high-pressure, normothermic bypass during the procedure, fetal heart and uterine monitoring to allow adjustments to the blood flow and pharmacological manipulations to ensure adequate placental perfusion, and if the fetus is more than 28 weeks of gestational age, to opt for cesarean section concurrently just prior to the cardiac operation.⁷

Management during Delivery or Labor

Tachycardia, secondary to labor pain, increases flow across the mitral valve, producing sudden rises in LA pressure, leading to acute pulmonary edema.³³ Good analgesia is of paramount importance during labor. Epidural anesthesia is ideal with vaginal delivery unless contraindicated. Cesarean section is recommended for obstetric indications only. In one study, only 29–31% of the 522 women with heart disease required caesarean section and nearly 70% of them underwent vaginal delivery under epidural analgesia.³⁴ Invasive monitoring with radial artery cannulation and pulmonary catheter are of use in real-time assessment of cardiac output and pulmonary artery pressure and to guide fluid and drug therapy and are often used in NYHA III and IV patients.³⁵

During the second stage of labor, maternal expulsive effort, i.e., always associated with the Valsalva maneuver should not be permitted and only uterine expulsive force should be allowed. Thus, the second stage should be cut short by instrumentation. Supplementary analgesia for instrumentation may be required.³⁶

Fetal heart rate monitoring should be carried out during all stages of labor. Supplemental oxygen administration and supplementary epidural anesthesia can be maintained throughout the immediate postpartum period. The epidural catheter may be left in situ to provide anesthesia for immediate or postpartum tubal sterilization if advised.³⁵ The goals of anesthetic management of a patient with MS are maintain slow heart rate, immediate cardioversion of acute atrial fibrillation, avoid aortocaval compression, maintain adequate SVR, and prevention of pain, hypoxia, acidosis and hypercarbia.

There is a lack of evidence regarding ideal anesthetic protocol during LSCS for patients with significant MS. Thus, the technique with which the treating team has maximum experience and safety in the available resources and expertise are recommended. Regional anesthesia is a safe technique for anesthesia for LSCS in patients with cardiac disease. Epidural and continuous spinal anesthetic techniques are favored. General anesthesia is associated with increased pulmonary arterial pressure and tachycardia during intubation. However, if general anesthesia is contemplated, drugs-associated tachycardia (atropine, ketamine, pancuronium and meperidine) should be totally avoided. A beta-blocker and an opioid are recommended during the induction of general anesthesia.

Whatever be the mode of delivery and anesthetic technique, autotransfusion of blood from the uterus adds significant hemodynamic stress. Therefore, intensive monitoring needs to be performed till all parameters return to normal.³⁶

CONCLUSION

Mitral stenosis is the commonest rheumatic valvular manifestation and occurrence of significant MS coincides with child-bearing age in women. The additional cardiac stresses imposed by pregnancy can be life-threatening to mother and

baby in severe MS. This high-risk pregnancy needs careful management by a team with cardiology, obstetrics, critical care, and neonatology elements working together. However, with close monitoring and coordination, this dangerous combination can be controlled and a gratifying result ensured in the vast majority of cases.

Heart Failure in Pregnancy

Kajal Ganguly, Anindya Mukherjee, Malay Acharya, Auriom Kar

INTRODUCTION

Pregnancy is a physiological stress test. In normal subjects as well as known patients of cardiac ailments, pregnancy and peripartum period with all its physiological changes poses as a challenge. There is 30–50% increase in cardiac output close to term.¹ Labor induces more hemodynamic stress and newly developed cardiovascular disease (CVD) during pregnancy and the effects of pregnancy on them continue even after delivery over several months.²

EPIDEMIOLOGY

Cardiac disease is not related to any complication of pregnancy itself. Hence, it is termed as an “indirect” cause of maternal mortality when it complicates pregnancy.³ In the article by Mulubrhan F Mogos et al. among the 50,995,050 pregnancy-related hospitalizations between January 1, 2001, and December 31, 2011, there were 7,542 antepartum, 15,620 delivery, and 34,110 postpartum hospitalizations with a diagnostic indication of heart failure (HF). Across the pregnancy continuum, the overall prevalence of HF among the study population was 112 cases per 100,000 pregnancy-related hospital discharges [95% confidence interval (CI), 107–118]. Although the postpartum period represented only 1.5% of pregnancy-related hospitalizations, this period saw the occurrence of 60% of the HFs related to pregnancy, followed by the delivery (27%), and antepartum (13%) periods.⁴ Incidence of HF due to peripartum cardiomyopathy varies in cosmopolitan societies. Genetic and social variations within individual communities give rise to these disparities. One out of 1,421 African-Americans develops HF in pregnancy in the United States of America compared with an incidence of 1:2,675 in Asians, 1:4,075 in Caucasians and 1:9,861 in people of Hispanic origin.⁵ Prevalence of cardiac disease in pregnancy differs from one country to another, but in various countries across various socioeconomic strata, it is a common cause of maternal death. HF is usually the most common mechanism of death.⁶

PHYSIOLOGY

The uterine enlargement and increased activity along with the increased blood flow into the choriodecidua space accounts for 12% of the total cardiac output in a pregnancy.⁷ Hyperaldosteronism leads to increased blood volume and thus leads to an increase in cardiac output. The cardiac output starts to rise from the first trimester and it peaks toward the end of the second trimester. The peak cardiac output during pregnancy is between 3.5 L/min and 6 L/min, which is 30–50% higher than nonpregnant values.^{8,9} From the first trimester, the peripheral vasculature is dilated with a progressive fall of systemic vascular resistance and it receives the progressively increasing cardiac output. There is increase in left and right ventricular mass and end diastolic volume as pregnancy progresses which is a reflection of the rising cardiac output and intravascular volume. These changes reverse in postpartum period.¹⁰ The summary of these adaptations are given in figure 1.⁶

ETIOLOGY AND PATHOPHYSIOLOGY

Preeclampsia, peripartum cardiomyopathy, and amniotic fluid embolism are the three causes of HF which are specific to pregnancy. Apart from these are the other causes of HF which are not related to pregnancy but may complicate pregnancy.⁶

Preeclampsia

Pulmonary edema is a common occurrence in preeclampsia. A South African confidential enquiry has found that pulmonary edema and cerebrovascular bleeding are the dominant causes of maternal mortality due to hypertension.³ Diastolic dysfunction directly and increased systemic vascular resistance indirectly, contributes to this pulmonary edema.^{6,11} Transient systolic dysfunction may occasionally occur in severe preeclampsia.⁶

Hypertension

Around 17–25% of preeclampsia develops in known hypertensive subjects, compared to 3–5% occurring in the general

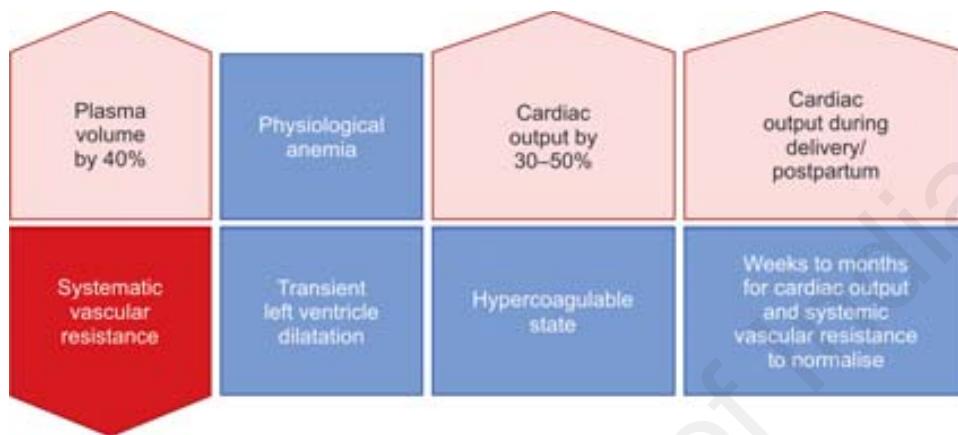

FIG. 1: Summary of physiological changes occurring during pregnancy.

population. Placental abruption, fetal growth restriction, and preterm birth are also more common in hypertensive patients.¹² At 32–34 weeks of gestation plasma volume expansion peaks. This increase in preload together with hypertension induced diastolic dysfunction predisposes some patients to develop mild pulmonary edema.^{13,14}

Pulmonary Hypertension and Right Heart Failure

Pulmonary hypertension has been classified in a consensus statement.¹⁵ Acute right-sided HF may occur in pregnant patients with primary pulmonary hypertension after delivery. These patients are at risk of sudden cardiac death.¹⁶

Diseases Affecting the Aortic Root

Takayasu's disease predominantly presents with hypertension and sometimes with HF.¹⁷ Patients of Marfan's syndrome with aortic root dilatation commonly present with arterial dissection and acute aortic regurgitation during pregnancy.¹⁸

Peripartum Cardiomyopathy

The most common cause of mortality developing during or after pregnancy is peripartum cardiomyopathy.^{19,20} Previously well women develop left ventricular (LV) systolic dysfunction with an ejection fraction of less than 45% during the last month of pregnancy or 6 months postpartum.²¹ A 16 kDa cathepsin cleavage product of prolactin has been proposed as a possible mechanism of peripartum cardiomyopathy. This mechanism is based upon the induction of myocyte apoptosis.^{21,22} Other proposed mechanisms include inflammation, oxidative stress, and autoimmunity to cardiac proteins.²³ Imbalance between angiogenic and antiangiogenic factors has been linked to association of peripartum cardiomyopathy with preeclampsia and multiple pregnancy.²⁴

Hereditary Cardiomyopathies

Symptom-free hypertrophic cardiomyopathy is tolerated well during pregnancy.^{25,26} In patients of dilated cardiomyopathy,

pregnancy outcome depends on the severity of symptoms before developing pregnancy.⁶ Risk of sudden cardiac death is always associated with arrhythmogenic right ventricular dysplasia and it is not altered by pregnancy or its complications.²⁷

Drugs

Drug abuse is rarely associated with HF during pregnancy.⁶

Autoimmune Diseases and Infections

Infective carditis or autoimmune disease-related myocarditis may result in dilated cardiomyopathy. Chronic HF can ensue in these cases of dilated cardiomyopathies.⁶

Amniotic Fluid Embolism

Large amounts of amniotic fluid may get released into the maternal circulation and results in acute pulmonary hypertension. This leads to left HF and associated arrhythmias.⁶

Ischemic Heart Disease

Heart failure rarely occurs during pregnancy in patients having myocardial ischemia.⁶

Valvular Lesions

Time for LV filling diminish during pregnancy due to tachycardia, which is further aggravated during labor. Thus in patients with mitral inflow obstruction, HF ensues.⁶ Mitral and aortic regurgitation are well tolerated in pregnancy.²⁸

Congenital Diseases

Congenital diseases can be classified as high-risk, moderate-risk and low-risk in pregnancy. Greatest risk of mortality lies with Marfan syndrome with aortic root dilatation and Eisenmenger syndrome. Moderate-risk lesions for HF are congenitally stenosed valves, cyanotic heart disease without pulmonary hypertension, a systemic right ventricle or Fontan circulation. The septal defects and repaired coarctation are the low-risk lesions for HF.²⁹

CLINICAL PRESENTATION

Normal subjects with pregnancy experience some breathlessness on exertion. Exertional dyspnea together with orthopnea, paroxysmal nocturnal dyspnea, syncope, and palpitations, signifies the presence of associated heart ailment and warrants for further investigations.

Pregnancy does mimic certain signs of heart disease.³⁰ A clinician must look for any cyanosis, clubbing, resting tachycardia, presence of any arrhythmia, a water hammer pulse, hypertension or hypotension, any signs of respiratory distress, an abnormal jugular venous pressure (JVP), any diastolic or pansystolic murmur, any thrill or murmur radiation beyond left sternal border or signs of pulmonary venous hypertension.⁶

INVESTIGATIONS

Normal pregnancy may be associated with ST-T abnormalities in electrocardiogram and supraventricular arrhythmias.³⁰ Echocardiography is a routine procedure nowadays to rule out cardiac diseases in pregnancy if the patient is symptomatic.

Assigning Severity of Risk

The morbidity and mortality of adverse events in pregnant women has been defined by Modified World Health Organization classification.^{29,31} Class I cardiac disease includes mild pulmonary stenosis, patent ductus arteriosus, mitral valve prolapse, repaired septal defects, and isolated supraventricular, and ventricular ectopics. These are not associated with any risk. Class II diseases are associated with a small increase in risk. All other arrhythmias apart from isolated supra-ventricular and ventricular ectopics, repaired tetralogy of Fallot and operated septal defects are included in class II. Category III include all forms of cardiomyopathy, prosthetic heart valves, Marfan syndrome with dilated aortic root, cyanotic heart disease, Fontan circulation, and a systemic right ventricle. In these diseases there is a significantly increased risk of morbidity and mortality. Class IV includes pulmonary hypertension, severe symptomatic LV inflow or outflow tract obstruction, previous peripartum cardiomyopathy with residual disease, severe LV failure (ejection fraction <30%) and aortic coarctation or Marfan's syndrome with dilated aortic root of more than 45 mm. Pregnancy is contraindicated in the class IV conditions.

DIFFERENTIAL DIAGNOSIS

In the patients developing pulmonary edema, all possible cardiac causes must be ruled out before a diagnosis of non-cardiogenic pulmonary edema is made. Even all the clinical and radiological armamentarium may sometimes fail to distinguish infection from pulmonary edema. Pulmonary thromboembolism is also an important differential diagnosis demanding special investigations, more so because pregnancy is a procoagulant condition.³² Diabetic ketoacidosis

and lactic acidosis both may mimic breathlessness due to acidotic breathing pattern. Subdiaphragmatic pathology may hinder respiration and cause rapid shallow breathing, which may appear as breathlessness.

MANAGEMENT PRINCIPLES

Diuretics

Diuretics form the first-line of treatment for HF in pregnancy.³³ Though there is a theoretical concern that diuretics limit the necessary increase in uterine and placental perfusion but there is no evidence that diuretics are an independent risk factor for fetal growth restriction. The use of diuretics reduces the increased preload, thus have positive effects on LV function as well as symptoms and this justifies the use of diuretic therapy as first-line treatment.

Elevated vascular resistance and LV diastolic dysfunction is the rule in preeclampsia presenting as acute severe disease.³⁴ Parenteral vasodilators reduce afterload and the fall of vascular resistance leads to increase in LV stroke volume and cardiac output which ultimately leads to reduction of left-sided filling pressures.³⁵ Diuretic therapy leads to depletion of an already contracted intravascular volume whereas there is no reduction in systemic vascular resistance.

Nitroglycerine is a combined arterial and venous vasodilator. It is used in pregnant patients with HF who are acutely ill and not responding to diuretics alone.

Angiotensin-converting Enzyme Inhibitors

These drugs are relatively contraindicated in pregnancy, pregnancy being a state of physiological hyperreninism.³⁰ Neonatal renal failure may develop in babies delivered by mothers who were treated with angiotensin-converting enzyme (ACE) inhibitors during pregnancy.³⁶ ACE inhibitors have sufficient data as a safe drug while breastfeeding.

Beta-blockers

Use of β-blockers as antihypertensive has been associated with intrauterine growth restriction and increased perinatal mortality.³⁷ When adverse perinatal outcome may result from either underlying maternal disease or its treatment, but there is risk of maternal mortality, β-blockers can be used in pregnancy with HF.

Spironolactone

Spironolactone is a mineralocorticoid receptor antagonist. Its antiandrogenic actions and teratogenic potentials contraindicate its use during pregnancy. This drug can be used after the delivery of the fetus. Less than 1% of the drug passes from mother to child in the breastmilk.⁶

Digoxin

Digoxin is the safest antiarrhythmic drug to be used during pregnancy. It is Food and Drug Administration category C

drug which is permeable through placenta and expressed in breastmilk.²⁹

Angiotensin Receptor-Neprilysin Inhibitor

These drugs should be discontinued as soon as pregnancy is detected. During the second and third trimesters of pregnancy these drugs cause oligohydramnios which may cause fetal injury (e.g., hypotension, neonatal skull hypoplasia, anuria, reversible, and irreversible renal failure) and death. It is unknown if angiotensin receptor-neprilysin inhibitor (ARNi) is distributed in human breast milk, hence use is not recommended during lactation.

Hydralazine-Isosorbide Dinitrate

This combination can be considered for afterload reduction in pregnancy, instead of ACE inhibitors or angiotensin receptor blockers, though definite recommendations and robust studies are lacking.²⁹

Ivabradine

Ivabradine is contraindicated in pregnancy and lactation due to lack of human data and animal studies showing adverse intrauterine and postnatal outcomes.

Bromocriptine

As discussed previously, a 16 kDa cathepsin-cleavage product of prolactin is incriminated for the pathophysiology of peripartum cardiomyopathy.³⁸ Bromocriptine suppresses lactation and is a reasonable treatment for this condition, though data is limited and needs further research.

Arrhythmias

Atrial fibrillation is the common arrhythmia in pregnancy. Beta-blockers are the drugs of choice and digoxin can be used if necessary. Implantable devices used for continuous monitoring may help to diagnose serious ventricular arrhythmias. Amiodarone is commonly used for treating sustained ventricular tachycardia. Implantable cardioverter defibrillators can be planned if indicated.³⁹

Assist Devices and Inotropic Support

Inotropic support is a necessity in managing patients with acute HF in pregnancy. Treatment and dosage depend on the clinical situation and physician discretion as there is no randomized data guiding the same. Assist devices may act as a bridge between the initial presentation of the patient and access to cardiac transplantation services. Inspite of limited evidence these are potential adjuncts in the management of intractable HF.³⁹

TREATING REVERSIBLE FACTORS

Structural heart diseases, like inflow or outflow tract obstructions, lead to HF during pregnancy. Second trimester balloon valvotomy of mitral, pulmonary and aortic valves in

these patient subsets have been reported to be beneficial in multiple studies. Anemia, infections, and hyperthyroidism lead to increase of heart rate and aggravate HF. Subclinical thyroiditis affects up to 5% of women in the first postpartum year.⁶ Urinary tract infection may frequently lead to genital tract sepsis during or after pregnancy and thus needs to be identified and managed properly.

SUPPORTIVE MEASURES

In HF patients during pregnancy thromboprophylaxis with once daily dosage of low molecular weight heparin is advocated.⁴⁰ If preeclamptic mothers develop pulmonary edema, the risk of maternal mortality is very high and thus medical termination of pregnancy is indicated.⁶ Other treatable causes of pulmonary edema must be searched for and treated before considering termination of pregnancy.

THE MODE OF DELIVERY

The onset of labor leads to acute increase in LV workload and intravascular blood volume. There is also pain-mediated increase in catecholamine secretion. These changes are compensated to some extent by blood loss during delivery. The mother may need to do valsalva maneuver during second stage of labor. Assisted vaginal delivery using forceps limit the duration of second stage of labor and also the CV effects of valsalva. Induced labor is unpredictable and the possibility of emergency cesarean section always remains. The risks of anesthesia, hemorrhage, and postoperative complications must be kept in mind while performing a cesarean delivery, either elective or emergency. The decision to allow either vaginal delivery or to perform an elective cesarean delivery is peculiar to the individual case with multiple factors to be considered including the parity of the mother, any other. Though there is no justification for routine cesarean delivery in pregnant females with HF, a case-specific approach is necessary considering the parity, obstetric comorbidities, and the severity of the cardiac lesion. European Society of Cardiology Guidelines on the management of CVD during pregnancy provide individualized recommendations.²⁹

THE PUPERIUM AND LONG-TERM MANAGEMENT

Fluid overload must be avoided in the immediate postpartum period. The placental delivery and associated uterine contraction leads to expulsion of blood from this vascular organ and resultant fluid overload in the systemic circulation. Herein lies the benefit of IV diuretic therapy at the time of delivery in patients of HF and severe cardiac valvular stenosis. In general, ergometrine is avoided and low-dose oxytocin is advocated for the active management of the third stage of labor. Prophylactic antibiotics are necessary to prevent infections and to limit the risk of bacterial endocarditis.⁴¹ Breastfeeding and its effects in patients of pregnancy with HF requires attention and further research.

HEART FAILURE WITH PRESERVED EJECTION FRACTION

No separate guideline exists for this group of patients in pregnancy till date. In the article titled Heart failure with preserved ejection fraction in women—the Dutch Queen of Hearts program, H. den Ruijter et al. have mentioned about preeclampsia as an important cause of HF with preserved ejection fraction (HFpEF) besides other known cardiac and systemic diseases. Diastolic dysfunction can develop in the patients of preeclampsia even 1 year after pregnancy. Management revolves around treatment of the cause and symptomatic relief with diuretics.

CONCLUSION

Women at increased risk of developing HF must be identified early and this would likely lead to proper monitoring and early intervention. Usual discharge from the hospital is planned within 2–3 days of delivery and next postdischarge visit is planned at around 6 weeks postpartum. Multidisciplinary team including cardiologists must keep proper surveillance on at-risk mothers during this period. This leads to better outcomes and fewer readmissions.^{42,43} In addition, information, education, and counseling of the pregnant patients with HF regarding their condition can help them seek timely medical attention. These women can spread awareness and support among their social network after delivery and discharge from hospital.⁴⁴ HF-related maternal morbidity and mortality are disproportionately more among poor, advanced maternal age, and black population. Increased awareness and public health measures are needed to address the problems and search for management strategies among these high-risk population subgroups.

Hypothyroidism and Heart

Niteen V Deshpande

INTRODUCTION

Thyroid hormones have a profound effect on the functioning of cardiovascular system and thus the common signs and symptoms of thyroid dysfunction are those arising from its effects on the heart and vascular system.¹ The relationship goes beyond the risk of atherosclerosis in hypothyroidism and atrial fibrillation in hyperthyroidism. Thyroid hormones modulate function of every component of cardiovascular system—the heart, blood vessels, and blood and thus alterations in cardiac contractility, myocardial oxygen consumption, systemic vascular resistance (SVR), cardiac output and blood pressure are observed in thyroid dysfunction. It is interesting to note that in almost all cases the cardiovascular abnormalities are reversible once thyroid dysfunction is recognized and treated.

Hypothyroidism affects between 4 and 10% of the population and has higher prevalence in women and patients over 60 years of age. Subclinical hypothyroidism is seen in around 10% population in various studies.²⁻⁴ Diagnosis of hypothyroidism rests on demonstration of low levels of thyroid hormones (levothyroxine—T4 and triiodothyronine—T3) coupled with elevated levels of thyroid-stimulating hormone (TSH). Subclinical hypothyroidism is diagnosed when TSH levels are elevated with normal values of thyroid hormones. Overt hypothyroidism is diagnosed when TSH levels are more than 20 mIU/L with suppressed levels of T4 and T3 while TSH levels between 3 mIU/L and 20 mIU/L with normal T4 and T3 constitute subclinical hypothyroidism.⁵⁻⁷ Estimation of TSH is thus appropriate initial test to evaluate thyroid dysfunction.

EFFECTS OF THYROID HORMONE ON CARDIOVASCULAR SYSTEM

The cardiovascular effects of thyroid hormone are mediated by T3. Heart relies mainly on serum T3 as the myocytes do not have significant deiodinase activity. Cellular actions of

T3 are mediated through its binding with thyroid receptors (TRs). These receptor proteins induce transcription by binding to thyroid hormone response elements (TREs) in the promoter regions of positively regulated genes (Fig. 1).⁸⁻¹⁰ Regulation of the key structural and regulatory genes by thyroid hormones thus modulates cardiac structure and function.² Thyroid hormone responsive cardiac genes include sarcoplasmic reticulum Ca^{+} adenosine triphosphatase (SERCA) and its inhibitor phospholamban which regulate calcium uptake in sarcoplasmic reticulum in diastole, α -myosin heavy chain and β -myosin heavy chain and a number of ion channels which regulate electromechanical response of the myocardium.^{1,8,11} Nongenomic effects of thyroid hormones include changes in various membrane ion channels for sodium, potassium, and calcium, effects on actin polymerization, adenine nucleotide translocator I in the mitochondrial membrane and a number of intracellular signaling pathways in the myocytes and vascular smooth muscle cells.¹²⁻¹⁴ As a result of these effects, thyroid hormones affect the action potential and repolarization currents in cardiac myocytes.¹⁵

Hemodynamic effects of thyroid hormones include decreased SVR, increased resting heart rate (HR), left ventricular contractility and blood volume (Fig. 2). Direct effect of thyroid hormone on vascular smooth muscle cells of the peripheral arterioles reduces SVR causing reduction in the mean arterial pressure. This reduction of MAP is sensed by kidney activating the renin-angiotensin-aldosterone system leading to sodium resorption. T3 also increases erythropoietin synthesis which increases red cell mass. Blood volume is increased as a result of these changes and preload increases. In hypothyroidism the effects of thyroid deficiency are diametrically opposite and cardiac output decreases by 30–50%.¹⁶ T3 also alters endothelial function and increased nitric oxide production may result as result of genomic and nongenomic mechanisms. In hypothyroidism, thus the arterial compliance is reduced leading to increase in SVR. In fact, impaired endothelium dependent vasodilatation

due to reduction in nitric oxide availability is demonstrated even in subclinical hypothyroidism.¹⁷ Hypothyroidism is often associated with increase in diastolic pressure and its combination with reduced cardiac output results in narrowed pulse pressure. This diastolic hypertension in hypothyroidism occurs with low renin levels and is sodium

sensitive.^{18,19} Levels of serum erythropoietin are depressed in hypothyroidism resulting in normochromic, normocytic anemia in almost one-third patients.

Thyroid hormones also exert significant effect on lipid metabolism and it is well known fact that hypothyroid patients have elevated lipid levels with significant increase

in low-density lipoprotein (LDL) cholesterol levels and apolipoprotein B.²⁰ The mechanism responsible for LDL-cholesterol elevation is reduction in the LDL receptor in liver and reduction in their activity.²⁰⁻²² Cholesterol metabolism is also altered by multiple mechanisms including biliary excretion leading to elevated cholesterol levels in hypothyroidism. This concept is supported by a recent study which showed that a liver specific thyroid hormone agonist—eprotirome had additive effect in statin treated patients in lowering total cholesterol.²³ A significant elevation in serum homocysteine levels and levels of C-reactive proteins are also common in patients with hypothyroidism.^{2,24}

CARDIOVASCULAR MANIFESTATIONS

The most frequent cardiovascular signs and symptoms of hypothyroidism include bradycardia, mild diastolic hypertension, narrowed pulse pressure, and fatigue. Hypothyroidism is associated with reduced cardiac contractility, decreased cardiac output, accelerated atherosclerosis, and coronary artery disease.²⁵⁻²⁷ Increased risk of stroke is also reported in hypothyroidism.^{28,29} Acceleration of atherosclerosis is due to dyslipidemia, hypertension and hyperhomocysteinemia which develops in patients with hypothyroidism. Increase in cardiovascular morbidity and mortality was observed in a study in untreated subclinical hypothyroidism.³⁰ Some studies have also shown increased abdominal aortic atherosclerosis and increased carotid intima-media thickness and decreased myocardial perfusion which resolves with thyroid replacement therapy.³¹ Small to moderate pericardial effusions occur in about 30% patients with hypothyroidism due increased volume of distribution of albumin and decrease in lymphatic clearance. The pericardial fluid may be golden in color due to presence of cholesterol crystals.³² Pericardial effusions resolve in period of weeks to months following institution of thyroid replacement therapy³³ and rarely cause cardiac tamponade. Approximately 4% of the patients develop pericarditis. These patients need observation for development of pericardial effusion or cardiac tamponade although pericardial effusions can occur without pericarditis. Thus it is important to check serum TSH levels in patients with nontraumatic pericarditis where no other obvious cause is detected.³¹ The electrocardiogram shows sinus bradycardia, low voltage complexes and prolongation of QT interval and rarely atrioventricular blocks. QT prolongation predisposes these patients to ventricular arrhythmias.³⁴ Echocardiography shows impaired relaxation in patients with overt as well as subclinical hypothyroidism. Early impairment can be demonstrated by prolongation of isovolumic relaxation time and reduction in E/A ratio.³⁵ More obvious findings include pericardial effusions and features suggestive of coronary artery disease with demonstration of regional wall motion abnormalities.

HYPOTHYROIDISM AND HEART FAILURE

Relationship of hypothyroidism and heart failure (HF) is recognized for long time. An early study by Schwimmer et al. showed improvement in HF and myxedema during therapy

with desiccated thyroid extract.³⁶ Cases of hypothyroidism and reversible dilated cardiomyopathy have also been reported more recently.^{37,38} Heart is a principle target of thyroid hormones and the transition from fetal to adult cardiac phenotype depends on the increase in thyroid hormones during the perinatal period.³⁹ In the adult life, normal thyroid hormone levels are required to maintain cardiovascular function. A number of attributes like inotropic and lusitropic properties of myocardium, cardiac growth, myocardial contractility, and vascular function are controlled by thyroid hormones. Hypothyroidism—overt or subclinical, has been shown to result in important changes in cardiac structure and function with their severity depending on the degree of deficiency.⁴⁰⁻⁴⁴ Hypothyroidism results in decreased cardiac output due to bradycardia and low-stroke volume^{40,41} and both systolic and diastolic functions are reduced at rest and during exercise. Impaired diastolic function and reduced blood volume lead to decreased preload and vascular function is also deranged.⁴³ Additionally, lower renal perfusion leads to impaired free water clearance and hyponatremia.⁴⁰ Experimental studies have demonstrated structural cardiac changes as well. Myocardial atrophy is seen in hypothyroidism due to decreased expression of α -myosin heavy chain genes and increased expression of β -myosin heavy chain genes. Dilatation of cardiac chambers and impaired myocardial blood flow are also observed in hypothyroidism.⁴⁵⁻⁴⁷ Subclinical hypothyroidism is increasingly being recognized to be associated with HF. A recent meta-analysis of six prospective cohort studies which included more than 2,000 patients with subclinical hypothyroidism⁴⁸ confirmed that patients with serum TSH more than 10 mU/L are at increased risk of developing HF. Other way round, in patients with chronic HF, subclinical hypothyroidism is a risk factor for cardiac death.⁴⁹⁻⁵¹ Data on thyroid function in patients with HF from the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) showed that HF patients who had abnormal thyroid function had higher risk of death even after adjustment for other factor associated with mortality.⁵² Similar findings on HF patients discharged from hospital and followed for 3 years were reported by Sato et al.⁵³ The definition of subclinical hypothyroidism used in this study was serum TSH more than 4 mIU/L with normal T4 levels. The prevalence of subclinical hypothyroidism was 12% in this study and patients had worse outcomes as compared to those with normal thyroid function. Thyroid hormone metabolism is altered in patients with HF. The conversion of T4 to T3 is impaired leading to development of low T3 syndrome.^{39,54-57} Low T3 syndrome is a strong predictor of mortality in patients with severe heart disease. Observed development of alteration in gene expression in failing heart is similar to that in experimental hypothyroidism indicating that thyroid dysfunction may play an important role in progression of HF.⁵⁸ More recently studies in rodent models have identified increased activity of cardiac type III deiodinase as a possible cause of diminished levels and action of thyroid hormones in HF.⁵⁹

As thyroid hormone has such profound impact on HF and heart can develop in patients with hypothyroidism

it is important to assess thyroid function in patients with HF. The American College of Cardiology guidelines for HF recommend a screening TSH test for all cases of newly diagnosed HF.⁶⁰

EFFECT OF HEART DISEASE ON THYROID FUNCTION

Alterations in thyroid hormones metabolism accompany a number of disease states like sepsis, starvation and cardiac diseases. The primary abnormality in such conditions is reduced levels of serum T3 which has multifactorial origin. Reduction in hepatic 5'-moniodiodinization is one of the important mechanism or reduced serum T3 levels.²⁵ Low serum T3 levels have been shown to correlate with increased all-cause and cardiovascular mortality in a population-based study.⁵⁷ Levels of T3 decline by almost 20% following uncomplicated myocardial infarction and thyroid replacement in experimental models may increase left ventricular function.²⁵ Serum T3 levels decrease predictably following cardiac surgery in the perioperative period in children and adults. However, intravenous T3 replacement in these situations has not resulted in mortality benefit although incidence of atrial fibrillation was reduced by 50%.⁶¹ The decline in serum T3 levels is even greater in neonate following cardiac surgery and intravenous replacement of T3 in neonates has been shown reduce need of postoperative inotropic agents.⁶² In patients with HF up to 30% patients have low serum T3 levels and this reduction in serum T3 levels correlate with functional class (NYHA).⁶³

TREATMENT OF HYPOTHYROIDISM AND HEART

Thyroid replacement therapy with levothyroxine improves lipid profile, diastolic dysfunction, HR and delays progression of atherosclerosis.¹¹ However, treatment with levothyroxine in the setting of established or suspected cardiac disease poses a challenge of precipitating myocardial ischemia or arrhythmias. In older patients with heart disease it is recommended to start low (25–50 µg/day) and go slow (increase the dose gradually no sooner than 6–8 weeks) with thyroid replacement therapy. A predictable improvement in thyroid parameters and cardiac function is expected if these simple rules are followed.²⁶ Concerns about the euthyroid state achieved following treatment adversely affecting the cardiac status are largely unfounded. In fact, patients with atherosclerotic cardiovascular disease often improve, rather than worsening after levothyroxine therapy as observed by Keating et al.⁶⁴

Treatment of subclinical hypothyroidism with levothyroxine has not shown to impact cholesterol levels or diastolic blood pressure in cohort studies.⁶⁵ A 18-month study of levothyroxine treatment in women with subclinical hypothyroidism however showed normalization of systolic and diastolic blood pressure, reduction in total cholesterol and LDL and decrease in carotid intima media thickness.⁶⁶

In patients with subclinical hypothyroidism and coronary artery disease levothyroxine treatment did not show any significant change while placebo treated patients had echocardiographic evidence of progression of diastolic dysfunction.⁶⁷ The elevated risk of cardiovascular disease in patients with subclinical hypothyroidism may be reduced with levothyroxine treatment as observed by a population-based study which found higher risk of cardiovascular events despite treatment in patients with TSH more than 4 mIU/L.⁶⁸ Interestingly the United Kingdom General Practitioner Research Database noted that treatment of subclinical hypothyroidism was associated with fewer ischemic heart disease events in patients younger than 70 years but not in patients older than 70 years. Based on the current evidence the European Thyroid Association guidelines recommend levothyroxine therapy for patients younger than 65 years of age and TSH levels above 10 mIU/L. Treatment for patients older than 80 years with TSH less than 10 is discouraged.⁶⁹ Treatment of subclinical hypothyroidism in patients with HF has shown to result in improvement of cardiovascular function.^{70–72} Thyroid replacement therapy in these patients improves diastolic dysfunction, vascular function, and coronary flow reserve when euthyroid state is restored. In the cardiovascular health study risk of HF was significantly lower in T4 treated patients and patients with TSH more than 10 mIU/L had an increased risk of HF during periods of levothyroxine withdrawal than during its use.⁷³ Thus it appears that thyroid replacement therapy in patients with TSH more than 10 mIU/L should be considered to prevent HF events.⁷⁰ It is important to monitor these patients on replacement therapy for development of drug-induced hyperthyroidism, especially the elderly patients.

Amiodarone and Hypothyroidism

Amiodarone is a commonly used antiarrhythmic agent for treatment of tachyarrhythmia. It has very high iodine content (37% by weight) which exposes the patient to very high iodine load, almost 300 times the daily recommended allowance.^{74,75} Due to its high iodine content, amiodarone can lead to thyroid dysfunction either hypothyroidism (5–25% of treated patients) or hyperthyroidism (2–10% of the treated patients).^{76,77} Conversion of T4 to T3 is inhibited as a result of inhibition of 5'deiodinase activity. Also iodine released can directly inhibit thyroid gland function leading to hypothyroidism. Pre-existent thyroid disease and Hashimoto's thyroiditis, both are risk factor for amiodarone-induced thyroid dysfunction. A periodic evaluation is therefore recommended for patients being treated with amiodarone and thyroid replacement is advocated if TSH is persistently elevated. The antiarrhythmic effect of amiodarone is not affected by thyroid replacement therapy and is independent of the effect of the drug on thyroid hormone metabolism.¹ Amiodarone effect on thyroid hormone is not dose dependent and can occur anytime during the therapy and due to high lipid solubility of amiodarone the effect may be seen up to 1 year after discontinuation of the therapy.⁷⁸

CONCLUSION

Thyroid hormones have profound effects on cardiovascular system through genomic as well as nongenomic mechanisms. Acceleration of atherosclerotic process leading to overt coronary artery disease occurs in hypothyroidism due to development of dyslipidemia, hypertension, and increased levels of homocysteine. Similarly, increased incidence of stroke is also associated with hypothyroidism. Subtle changes in cardiac structure and function are well documented in subclinical hypothyroidism. Association of clinical or subclinical hypothyroidism and HF is another area of current research and treatment. Population studies have shown a higher risk of developing HF in people with TSH levels exceeding 10 mIU/L. In HF patients hypothyroidism or low T3 syndrome is linked to higher morbidity and mortality. Thus recognition of these abnormalities and timely correction with thyroid replacement therapy can improve outcomes in patients with HF. However, correction of hypothyroidism is done gradually following the dictum “start low and go slow” to avoid precipitation of myocardial ischemia and arrhythmia.

Cardiorenal Syndrome: Current Update

Dipak Sarma, Ritesh Kalwar

INTRODUCTION

Recent advances in medical sciences, both basic and clinical, have improved our understanding of organ crosslink in pathophysiological processes of disease conditions. The cardiorenal syndrome (CRS) is one example in this regard.

DEFINITION

Cardiorenal syndrome has been defined as “disorders of heart and the kidneys when acute or chronic dysfunction in one organ may induce acute or chronic dysfunction of the other”.¹

Brook et al. thus defined CRS as each dysfunctional organ has the ability to initiate and participate disease in the other organ through common hemodynamic, neurohumoral, immunological, and/or biochemical feedback pathways.

CLASSIFICATION

Cardiorenal syndrome has been classified by Ronco et al. into five subtypes:¹

- *Type I—acute cardiorenal syndrome:* Acute worsening of cardiac function leading to renal dysfunction. For example, acute cardiogenic shock and acute decompensated heart failure (ADHF)
- *Type II—chronic cardiorenal syndrome:* Chronic abnormalities in cardiac function leading to renal dysfunction. For example, congestive heart failure (CHF)
- *Type III—acute renocardiac syndrome:* Acute worsening of kidney function causing acute cardiac dysfunction. For example, acute kidney injury (AKI) and glomerulonephritis
- *Type IV—chronic renocardiac syndrome:* Chronic kidney disease (CKD) causing decline in cardiac dysfunction. For example, chronic glomerulonephritis (CGN) and interstitial disease
- *Type V—secondary cardiorenal syndrome:* Systemic conditions both causing kidney and cardiac dysfunction. For example, sepsis and diabetes mellitus.

LINK AND PATHOPHYSIOLOGY

The kidney and the heart are both highly vascular organs and both are supplied by sympathetic nervous system (SNS) and parasympathetic nervous system. Both organs play prominent role in blood pressure regulation as well as in intravascular homeostasis. Both have roles in natriuresis, diuresis, and oxygenation. The heart secretes the vasodilator, natriuretic peptide. The kidney is the main organ involved in the renin–angiotensin–aldosterone system (RAAS)² with so much in common, it is hardly surprising that dysfunction of one organ leads to the dysfunction of the other.

With advances in experimental and clinical sciences, it is now realized that the crosslink between the kidney and the heart is quite complicated, much more than what was believed in the past.

Low-flow State Hypothesis

For a long time it was believed that in ADHF patients, the reduced cardiac output leads to reduced renal perfusion, which in turn leads to activation of the RAAS leading to sodium and water retention, increased preload thus worsening pump failure.³ Decreased glomerular filtration from afferent arteriolar constriction and profibrotic neurohormonal increase leads to ventricular remodeling, and further worsening of pump failure.⁴ However, the findings of the recent ESCAPE (Evaluation Study of CHF and Pulmonary Artery Catheterization Effectiveness) trial showed that there was no correlation between renal function and cardiac index and that improvement of cardiac function did not result improvement of renal function. These findings, therefore suggested that the pathophysiology of CRS is more complex than just the low-flow hypothesis.⁵

Renin–Angiotensin–Aldosterone System

The activation of RAAS by the reduced perfusion pressure in the kidneys is a protective phenomenon in the initial stage. But when chronically stimulated, as in both cardiac and renal failure, the pathophysiological effect becomes harmful

and severe. Renin which is produced by Juxtaglomerular apparatus in the kidneys in response to hypoperfusion carries out the conversion of angiotensinogen to angiotensin I and it is converted to angiotensin II (Ang II) by angiotensin-converting enzyme (ACE). Ang II has several deleterious effects on cardiovascular system (CVS), especially in the heart failure (HF) patients—increasing both preload and afterload thus myocardial organ demand. Ang II also converts nicotinamide adenine dinucleotide phosphate (NADPH) oxidase in cells, vascular and cardiomyocytes, mostly endothelial cells, vascular smooth muscle cell, renal tubular cell, and cardiomyocytes which lead to formation of reactive oxygen species (ROS) mostly superoxide which is responsible for the process of inflammation and organ dysfunction.⁶⁻⁹ Nitric oxide (NO) is responsible for vasodilation and assist in renal control of extracellular fluid volume (ECFV). Superoxide not only antagonize these effects but also reduces the bioavailability of NO.¹⁰ Oxidation stress damages deoxyribonucleic acid (DNA), proteins, carbohydrates, lipids and also shift cytokine production toward proinflammatory mediators, e.g., interleukin (IL)-1, IL-6, and tumor necrosis factor alpha (TNF- α). IL-6 also stimulates fibroblasts leading to increased cardiorenal fibrosis.¹¹

Sympathetic Nervous System

Like the RAAS activation the SNS stimulation is also initially a protective mechanism in CHF patients. The SNS stimulation helps to maintain cardiac output by positive chronotropic and inotropic effects on the myocardium, but sustains SNS overactivity has several negative effects. It causes reduction of β -adrenergic receptor density within the ventricular myocardium.¹² It also reduces adrenoceptor density in both renal and HF¹³ with the progression of ventricular systolic failure, there is diminution of renal blood flow and the perfusion pressure. This lead to baroreceptor mediated renal vasoconstriction, activation of renal sympathetic, and release of catecholaminergic hormones.¹⁴ Also there is reduced clearance of catecholamines by the kidneys in patients with HF with advanced renal failure.¹⁵

Sympathetic nervous system activation also increases the release of the vascular growth promoter neuropeptide Y, leading to neointimal proliferation leading to atherosclerosis and vasoconstriction. It also interferes with normal immune system function.¹⁶

Intra-abdominal Hypertension

Intra-abdominal pressure (IAP) is said to be elevated when the pressure is more than 8 mm Hg. Intra-abdominal hypertension (IAH) is defined as IAP more than 12 mm Hg. HF is marked by an elevated central venous pressure which reduces the pressure gradient across the renal capillary bed. Earlier studies shown rising venous pressure could reduce or even abolish urine production.¹⁷

Extrinsic compression of renal vein has also been shown to compromise renal function.¹⁸ A study of 40 patients with ADHF found that 24 had an IAP of more than 8 mm Hg and none had abdominal symptoms. The degree of reduction of

IAP with diuretic treatment correlated with an improvement in renal function.¹⁹

The ESCAPE trial found that the baseline right atrial pressure but not atrial blood flow correlates with baseline serum creatinine.²⁰

Arginine Vasopressin

Arginine vasopressin (AVP) has deleterious effect on CRS by retaining fluid and potentiating Ang II and potentiating activity. AVP also stimulates myocardial hypertrophy.²¹

Endothelin

Endothelin stimulates and potentiates noradrenergic, Ang II, aldosterone, and induces vasoconstriction.²²

Drugs

Some drugs have adverse effect in progression of CRS. High-dose diuretics produces hypovolemia, intravenous vasodilators may cause hypotension. Inotropic drugs enhance neurohormonal activation. All these factors need to be taken into consideration while formulating treatment of CRS.

Cardiorenal Anemia Syndrome

Hemoglobin is an antioxidant, anemia which is common in both HF and CKD may contribute to the abnormal renal oxidative state. Normally, anemia induces increased production of erythropoietin (EP). But in CRS there is decreased concentration of EP. There is evidence to believe that a combination of anemia and decreased EP may exacerbate the underlying factor causing CRS.^{23,24}

Biomarker in Cardiorenal Syndrome

Renal Biomarker

Creatinine

As standard indicators of renal function, serum creatinine level and glomerular filtration rate (GFR) are vital for effective identification of renal disease and prognostic prediction of patients with renal disease.

Microalbuminuria

It is not only related to HF and CKD development but also rehospitalization and mortality rates in general population.²⁵ Mechanism linking microalbuminuria to HF remains unclear.

Neutrophil Gelatinase-associated Lipocalin

Neutrophil gelatinase-associated lipocalin (NGAL) is released due to an inflammatory reaction. NGAL predicts worsening of renal function correlates with inflammatory reaction and mediates ventricular remodeling in acute heart failure (AHF).²⁶

In intensive care unit (ICU) adult patients with AKI secondary to sepsis, ischemia, nephrotoxins, NGAL is significantly increased in the plasma and urine.²⁷

Cystatin C

It is a better predictor of glomerular function than serum creatinine in patients with CKD. Cystatin C has outperformed serum creatinine and estimated GFR in risk prediction for events in patients with cardiovascular disease (CVD).²⁸

Kidney Injury Molecule-1

It is a transmembrane glycoprotein which is not normally detectable in urine.²⁹ It is measurable in urine after ischemic or nephrotoxic insults to proximal tubular cells.³⁰

Importantly, kidney injury molecule-1 (KIM-1) may be elevated before there is histological evidence of proximal tubular cell death.³¹

N-Acetyl D Glucosaminidase

It is not only found in elevated urinary concentration in AKI and CKD but also in diabetic patients, and patients with essential hypertension and HF.³²

Cardiac Biomarkers

Cardiac Troponin

As the component of the contractile apparatus in cardiomyocytes cardiac troponin-T and cardiac troponin-I are specific biomarkers of myocardial injury and infarction.³³ Elevated troponin T and I are related to myocardial injury, ventricular hypertrophy, HF and CKD.³⁴

B-Type Natriuretic Peptide

B-type natriuretic peptide (BNP) is released from cardiomyocytes and plays diuretic, natriuretic, vasodilative and other cardioprotective roles. Patient with HF have over activated RAAS and SNS and compensated release of BNP due to ventricular and pressure overloaded. BNP is still deficient, in its role and are resisted in these patients.³⁵

Myeloperoxidase

It predicts prognosis in patients with AHF. It has also elevated levels in CHF and can identify patients with HF irrespective of diastolic-systolic/right or left HF. Its positivity level correlate with CHF progression and predicts CV event in patients of CHF.³⁶ It also predicts CKD severity and mortality rates in patients with CKD.³⁷

Copeptin

Whether heart releases copeptin, it is controversial³⁸ but it is a liable biomarker of CVD as well as significant predictor of mortality.³⁹ It has regarded as a hallmark of activated hypothalamus pituitary adrenal axis and thus received attention as a marker of AHF and AKI.

Soluble Vascular Endothelial Growth Factor Receptor-1

Vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF) and soluble vascular endothelial growth factor receptor-1 (sFLT-1) have elevated levels in patients with HF. PDGF reduces infarct size and improves cardiac

dysfunction, whereas sFLT-1 inhibits these role of PDGF. sFLT-1 is a biomarker that predicts prognosis in patients with HF.⁴⁰ sFLT-1 also contributes to endothelial dysfunction in CKD and links microvascular disease with HF in CKD.⁴¹

Mid-regional Pro-adrenomedullin

Adrenomedullin (ADM) is a potent vasodilator synthesized in the adrenal medulla whereas vascular endothelial cells, heart and elsewhere in response to physical stretch and specific cytokines.⁴² It is very difficult to remove plasma ADM levels due to its short half-life and existing binding proteins.

Midregional pro-adrenomedullin (MR-proADM) is more stable and manufactured in a 1:1 ratio with active ADM.⁴³ MR-proADM thus a biomarker identity global disease burden in HF.⁴⁴ It also correlates with development of CKD and predicts the decline in renal function.

MANAGEMENT

Type-I Cardiorenal Syndrome

It occurs in the setting of ADHF or cardiogenic shock for a number of reasons.⁴⁵ While hypotension and decreased cardiac output with neurohormonal activation has been the traditional explanations for worsening renal function, however, recent evidence has implicated high venous pressure and raised intra-abdominal pressure leading to renal venous congestion as important contributor to impairment of kidney function,⁴⁶ as indeed many patient with ADHF and type-I CRS have preserved left ventricular ejection fraction and normal or high blood pressure. Hence diuretics, ultrafiltration (UF) and vasodilation are important steps in management.

Diuretics: Infusion or Bolus

Infusion therapy of diuretics has a greater efficacy than intermittent dosing.⁴⁷ However, in diuretic optimization strategies evaluation (DOSE) trial found that both bolus and infusion therapy have the same efficacy and similar renal outcomes. If the kidney function continues to worsen despite diuretic therapy, first possibility is that diuretic resistance secondary to mucosal edema decreased in intestinal absorption or excessive salt intake or concurrent use of nonsteroidal anti-inflammatory drugs (NSAIDs). Second possibility may be due to continuous blockade of RAAS with the use of ACE inhibitor (ACEi) or angiotensin receptor blockers (ARB) necessitating with holding or delaying the introduction of the same.⁴⁸

Vasodilator

It is a modality for patients with a preserved or elevated blood pressure, nitroglycerin (NTG) are often used.⁴⁹ Nesiritide-B type natriuretic peptide helps in relieving dyspnea in AHF by decreasing preload and pulmonary vascular resistance and increased cardiac output.⁵⁰

Inotropes

Positive inotropes like dobutamine or phosphodiesterase (PDE) inhibitor may be required, levosimendan with calcium sensitizing activity can be used, have shown mixed results.⁵¹

Other Measures

As a bridging therapy for the recovery of cardiac function or transplantation, more invasive therapies like intra-aortic balloon pump (IABP), ventricular assist devices or artificial hearts may be required.

TYPE-II Cardiorenal Syndrome

- Interruption of RAAS is the primary goal in the management of type-II CRS. Aldosterone blockers, spironolactone and eplerenone, are important adjunct therapy. However, use of these drugs, i.e., ACEI or acetate-free biofiltration (AFB) increases the risk of hyperkalemia, so have to avoid using the agent with serum creatinine more than 2.5
- Use of β -blocker: Interruption of sympathetic tone using β -blocker is another important strategy for patients with CHF or ischemic heart disease. Carvedilol has been demonstrated to have favorable effect on kidney function in CRS patients.⁵²

Both CHF and CKD are associated with anemia and treated with EP which also helps in reducing apoptosis, fibrosis and inflammation,⁵³ and another approach is to use parenteral iron. In FAIR-HF (Ferinject Assessment in Patients with Iron Deficiency and Chronic Heart Failure) study, the patients/subjects in the treatment group (ferric carboxy maltose) were randomized to ferric carboxymaltose or placebo and active treatment group experienced improvement in HF symptoms, 6-minute walk test, and quality of life.

Type-III Cardiorenal Syndrome

Many strategies including hydration, diuretic, natriuretic peptide, N-acetylcysteine, dopamine have been studied, however, most successful intervention is isotonic fluid, along with some controversy regarding N-acetylcysteine.⁵⁴ Use of low-osmolar nonionic monomer iopamide in the prevention of contrast nephropathy⁵⁵ has been studied.

Type-IV Cardiorenal Syndrome

The management focused on the reduction of CV risk factor and complications common to CKD patients which are anemia, hypertension, altered bone and mineral metabolism, dyslipidemia, albuminuria, and malnutrition.⁵⁶

Treatment of anemia seems to lessen CV events; however, randomized control trials have shown that higher hemoglobin targets associated with worse outcomes.⁵⁷

Observational studies have shown that elevated phosphate, parathyroid hormone, and inadequate vitamin D receptor activities are potential risk factor for type-IV CRS.⁵⁸ Phosphate-binding products, cinacalcet, a drug used for lowering parathyroid hormone, decreased hospitalization related to CVD.⁵⁹

Study of Heart and Renal Protection (SHARP) trial has suggested the use of statins in prevention of major atherosclerotic events.⁶⁰

Type-V Cardiorenal Syndrome

- It includes a heterogeneous group of disorders like sepsis, systemic lupus erythematosus (SLE), diabetes mellitus, and amyloidosis

- Treatment should be done according to cause
- De Backer and colleagues compared dopamine versus noradrenaline in septic shock patient where they found that there is a higher incidence of cardiac arrhythmia in dopamine group⁶¹
- Another study indicates that low-dose vasopressin was effective in limiting cardiac and kidney injury in sepsis.⁶²

CONCLUSION

The ability to make diagnosis of CRS will allow making early introduction of management strategies which will further help in better clinical and biochemical outcome.

Prognosis is not uniform in all subtypes and depend upon the underlying causes, worst is however for those patients with chronic dysfunction of both organ system.

Patient resistant to diuretic therapy may get benefit from UF. Infusion therapy of frusemide can be used in patients of ADHF with CRS.

It is a cross connecting process and difficult to understand and manage, more studies and trials are required for a better outcome. It is a challenging disease which has come across many physicians, cardiologists, and nephrologists.

Anemia in Heart Failure

Umesh C Samal, Harikrishnan S

INTRODUCTION

Anemia is a frequent comorbidity in patients with heart failure (HF) and it increases mortality, recurrent hospitalizations, and morbidity in terms of impaired exercise capacity and poor quality of life (QoL).¹

The World Health Organization defines anemia as a hemoglobin (Hb) value less than 13 g/dL for men and 12 g/dL for women.² Iron deficiency (ID) with or without anemia has been commonly associated with HF and is of renewed interest recently with new data.³

The major cardiology physician communities have understood the importance of this risk factor and has come out with specific guidelines addressing this issue.^{4,5}

Even though there is a clear cut evidence that ID is an important comorbidity, it is often ignored or considered clinically only in the context of anemia.¹

EPIDEMIOLOGY OF ANEMIA AND IRON DEFICIENCY IN HEART FAILURE

Most of the studies on HF indicates that the prevalence of anemia is more than 20%.⁶ In a large meta-analysis of 1,53,180 patients, the prevalence of anemia was 34%.⁷ In various studies, anemia was found to be associated with an increased risk of mortality in both HF with reduced ejection fraction (HFrEF) and HF with preserved ejection fraction (HFpEF).^{7,8}

The reported prevalence of anemia varies with different studies due to the variability in the definitions used, the proportion of male and female patients in the study or whether it was acute or chronic where dilutional anemia influences the values.⁴ The prevalence of anemia is higher in patients with advanced age, low functional capacity, and lower renal function.⁶

Iron deficiency is much more prevalent than anemia. In an international pooled analysis the prevalence of ID in HF was 50%.⁹ It was found in the analysis that, anemic patients were more often iron deficient than nonanemic patients (61.2% vs. 45.6%).⁹

In a small study of 150 patients from Rajasthan, India, ID was present in 76% patients with 48.7% patients having absolute and 27.3% patients having functional type of ID.¹⁰ Females had significantly higher (91.6% vs. 68.6%) prevalence of ID than males.

About one-fourth of the patients were having ID without anemia, which as the authors highlight, signifying the importance of workup to identify ID, rather than testing Hb alone.¹⁰

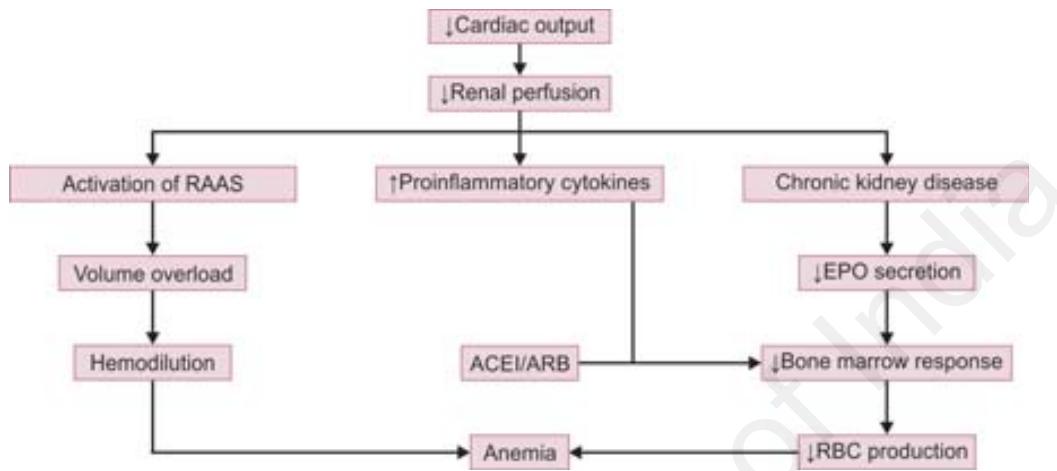

PATHOGENESIS OF ANEMIA IN HEART FAILURE

In HF, the sensitivity of bone marrow to erythropoietin (EPO) is low. Renin-angiotensin-aldosteron system (RAAS) activation which happens in HF even though leads to stimulation of EPO, it will not produce the desired effect. Also reduced renal perfusion in HF leads to renal dysfunction and we know that chronic kidney disease (CKD) is associated with anemia. Also some drugs acting on the RAAS system like angiotensin-converting enzyme inhibitor or angiotensin receptor blocker (ACEI/ARB) reduce EPO secretion and contribute to anemia (Flowchart 1).

CONSEQUENCES OF ANEMIA AND IRON DEFICIENCY IN HEART FAILURE

Iron deficiency often appears before the onset of clinically recognizable anemia and can be diagnosed by biochemical investigations.

To understand how ID can be diagnosed and managed, we have to know the details of iron metabolism in the body. Two body proteins (transferrin and ferritin) and a receptor (transferrin receptor) play the key role in the storage and transport of iron in the body. Transferrin carries iron in blood and other body fluids. The transferrin receptor present on cell membranes, internalizes transferrin, to make it intracellular iron. The protein ferritin stores iron in tissues.

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; EPO, erythropoietin; RAAS, renin–angiotensin–aldosterone system; RBC, red blood cell.

FLOWCHART 1: Mechanism of the development of anemia in heart failure.

Two important proteins are involved in iron metabolism—they are ferroportin and hepcidin. “Hepcidin is said to bind to ferroportin and induces its internalization, thus blocking iron export from intestinal cells and iron recycling in macrophages of the reticuloendothelial system (RES).”¹ So hepcidin is the main negative feedback component in the loop of iron metabolism. We know that hepcidin synthesis is induced by inflammatory states like HF and this contributes to ID.

HOW TO DIAGNOSE IRON DEFICIENCY?

Serum ferritin is the best indicator of iron stores, but ferritin is an acute phase reactant—its levels increase very rapidly in the presence of inflammatory states—HF is one such situation. Therefore, we cannot rely on low ferritin levels in HF to diagnose ID. Serum transferrin is less affected by changes in iron metabolism. A decrease of transferrin iron saturation indicates what is called the “functional ID”.

In the 2016 European Society of Cardiology (ESC) guidelines⁵ for the diagnosis and treatment of HF, systematic measurement of iron parameters [serum ferritin and transferrin saturation (TSAT)] is recommended in all patients suspected of having HF, as well as in the follow-up visits of HF patients. Transferrin saturation, measured as a percentage, is a medical laboratory value. It is the value of serum iron divided by the total iron-binding capacity (TIBC).

In the ESC guidelines 2016, ID is defined as follows:

- Serum ferritin less than 100 mg/L (absolute ID), or
- Serum ferritin 100–299 mg/L and TSAT less than 20% (functional iron deficiency). (TSAT = serum iron/TIBC).

TREATMENT OF ANEMIA AND IRON DEFICIENCY

European Society of Cardiology recommends detailed evaluation to find out the exact cause of anemia (e.g., occult blood loss, ID, B12 or folate deficiency, blood dyscrasias).

Iron therapy has proven to be effective in the treatment of ID and anemia. Erythropoiesis stimulating agents did not improve clinical outcomes in HFrEF patients.

Both oral and intravenous (IV) routes of iron have been tried in the treatment of ID. Because of intestinal edema which accompanies HF and also the high hepcidin levels which can impair absorption of oral iron, it is said that functional ID is more efficiently corrected by IV administration of iron because this can bypass the intestinal barrier and overcome the iron sequestration.¹

But oral iron therapy is much cheaper than IV iron. There is a recently published study from North India which suggests that improvement in QoL and exercise tolerance might be achievable with use of oral iron supplementation (ferrous sulphate 100 mg, twice daily for 3 months).¹¹

The Canadian HF recommendations⁴ suggest that for patients with documented ID, oral or IV iron supplement be initiated to improve functional capacity.

But the ESC Guidelines recommend only IV iron for treatment of ID.

Intravenous iron was trialled in two randomized controlled trials (RCTs) in patients with HF and ID both with and without anemia. IV ferric carboxymaltose (FCM) has been shown to improve symptoms, QoL and New York Heart Association (NYHA) class in the Ferinject Assessment in Patients with Iron Deficiency and Chronic Heart Failure (FAIR-HF) trial³ and in the CONFIRM-HF trial.¹²

In a meta-analysis of IV iron therapy in HFrEF patients with ID showed reduction in hospitalization rates and improved symptoms of HF, exercise capacity and QoL.¹³ ESC recommendations say that the effect of treating ID in HFpEF or HF with midrange ejection fraction (HFmrEF) and the long-term safety of iron therapy in either HFrEF, HFmrEF or HFpEF is unknown.⁵

In a practical recommendation in British Medical Journal, Alain Cohen-Solal et al. recommends “oral iron should be prescribed for absolute ID for at least 3 months with assessment of iron replenishment after 1 month; in

TABLE 1: Dosage and administration of intravenous iron complexes¹

Intravenous iron complexes	Dosage	Administration
Iron carboxymaltose (Ferinject 50 mg/mL)	Intravenous infusion at 15 mg/kg (for a total ≤1,000 mg) once/week Bolus intravenous injection of 200 mg/day (≤3 injections/week)	Intravenous infusion in normal saline (0.9%) with iron concentration >2 mg/mL: <ul style="list-style-type: none"> • From 100 to <200 mg: 50 mL of normal saline (0.9% NaCl) • From 200 to <500 mg: 100 mL of normal saline (0.9% NaCl, in ≥6 min) • From 500 to 1,000 mg: 250 mL of normal saline (0.9% NaCl, in ≥15 min) Bolus intravenous injection at a maximal dose of 200 mg
Iron hydroxide sucrose	100–300 mg/injection; 1–3 injections/week with a 48 h interval between each injection	Slow intravenous infusion (3.5 mL/min) with a duration ≥1.5 h; 1 ampoule diluted in ≤100 mL of normal saline (0.9% NaCl)
Iron hydroxide dextran	100–200 mg/injection (not exceeding 20 mg/kg); 1–3 injections/week with a 48 h interval between each injection	Intravenous infusion of 1 or 2 ampules (100 or 200 mg) in 100 mL of normal saline (0.9% NaCl) or 5% glucose Slow intravenous injection of 100–200 mg of iron (0.2 mL/min), preferably diluted in 10–20 mL of normal saline (0.9% NaCl) or 5% glucose

NaCl, sodium chloride.

case of inefficacy or intolerance, oral therapy is stopped and IV iron is administered. In case of functional ID, initial administration of IV iron is required since oral iron is ineffective in this clinical condition".¹

All IV iron agents are colloids that mainly consist of iron-carbohydrate nanoparticles.⁵ They are iron dextran, gluconate, sucrose, or FCM. Serious side effects, particularly anaphylactic reactions, have been reported with use of iron dextran, so it has become unpopular.

There are limited comparative data between the available IV iron preparations. Ferric hydroxide sucrose, ferric gluconate, and FCM are Food and Drug Administration (FDA)-approved for use in CKD patients. The recommended dose for FCM (750 mg) is higher than that for ferric sucrose (100–400 mg) or ferric gluconate (125 mg), so fewer injections of FCM may be needed to replenish the body iron stores (Table 1).

Serological iron profile should be performed 1 month after IV iron administration for evaluation of iron stores, and if necessary, repeat administration must be done.

CONCLUSION

Among patients with HF, one-third have anemia and half of the patients have ID. Anemia and ID have shown to affect the prognosis of patients with HF. The guidelines recommend the monitoring of iron parameters for all patients with HF. Iron supplementation, especially IV supplementation of iron, is shown to improve functional capacity and reduce hospitalizations.

When to Screen and How to Manage OSA in Cardiology Practice

GC Khilnani, Pawan Tiwari

INTRODUCTION

Obstructive sleep apnea (OSA) is the most common sleep-related breathing disorder in adults worldwide. OSA is characterized by symptoms during sleep (excessive snoring, restlessness, or witnessed apneas) and daytime due to incomplete or disrupted sleep (morning headaches, excessive daytime somnolence, poor concentration); diagnosis is made by demonstrating obstructive events during sleep (apneas, hypopneas, or respiratory effort-related arousals) using polysomnography (PSG). Shakespeare described a character Sir Falstaff in his historic play Henry IV, who was found “fast asleep behind the arras, and snoring like a horse.” The term “Pickwickian syndrome” originated with the obese character “Joe” in Charles Dickens novel. In 1965, Gastaut described the cardinal features of OSA, and first described use of polygraphy.¹ OSA was first successfully treated with tracheostomy in 1970s.² In 1981, Sullivan first described continuous positive airway therapy for treatment of OSA.³ Wisconsin study by Young et al. examined the prevalence of OSA in general community and resulted in increased interest of medical community in this disease. OSA has been associated with increased risk of hypertension, coronary artery disease (CAD), stroke, heart failure (HF), and complex cardiac arrhythmias in various large prospective observational studies.^{4–7} Due to ever increasing problem of obesity, and the fact that many patients may present with symptoms related to cardiovascular disease, a cardiologist is likely to be the first point of contact for patients with OSA. Thus, it is important for cardiologists to be proficient in management of OSA.

EXTENT OF THE PROBLEM

In a recent systematic review, the prevalence of OSA in adult population [defined as apnea-hypopnea index (AHI) >5 events per hour] ranges from 9 to 38%, with a higher prevalence in males (13–33%) as compared to females (6–19%); in advanced age groups, prevalence of OSA has

been reported to be as high as 84%. Prevalence of moderate-to-severe OSA (AHI >15 events per hour) ranges from 6 to 17% in adults.⁸ Prevalence of OSA in Asians has been reported to be similar to Western data, despite lower rates of obesity in this population.⁹ Population prevalence of OSA and OSA syndrome (OSAS) has been reported to be 9.3% and 2.8%, respectively in a community-based observational study from Delhi.¹⁰

RISK FACTORS FOR OBSTRUCTIVE SLEEP APNEA

Increasing age,^{5,11} male gender,^{5,11,12} and obesity^{5,13} are risk factors associated with increased prevalence of OSA. However, prevalence of OSA is increased in females postmenopause. Other risk factors include nasal congestion,¹⁴ smoking,¹⁵ positive family history,¹⁶ and substance abuse (alcohol, sedative drugs, and narcotics).¹⁷ Medical conditions that are associated with increased prevalence of OSA include pregnancy, chronic lung diseases (chronic obstructive pulmonary disease, asthma, and idiopathic interstitial fibrosis), congestive cardiac failure, acromegaly, hypothyroidism, polycystic ovarian syndrome, end-stage renal disease, and stroke.

Obesity remains the most consistent risk factor in development of sleep apnea. Incidence of OSA increased six times for each 10% increase in body weight in a prospective observational study.¹⁸ Similarly, in a community-based study, there was progressive increase in prevalence of moderate-to-severe OSA with increasing body weight. Among subjects with normal body mass index (BMI), prevalence of OSA was 11% in males and 3% for females; among overweight subjects, prevalence increased to 21% in males and 9% in females; obese subjects had highest prevalence, i.e., 63% in males and 22% in females.¹¹

Bony or soft tissue abnormalities of craniofacial region and upper airways are also associated with increased risk of OSA. This risk becomes more important in nonobese

patients.^{14,19} Recognition of these abnormalities is important as these may be amenable to surgical correction and potential cure for OSA.

CONSEQUENCES AND COMPLICATIONS OF OBSTRUCTIVE SLEEP APNEA

Obstructive sleep apnea is associated with higher all-cause mortality as compared to general population; positive dose-response relationship with higher mortality in moderate-to-severe OSA as compared to general population has been demonstrated, especially in middle-aged males.^{20,21}

Obesity and OSA seem to be interlinked. Obesity is the most consistent risk factor for OSA, at the same time, OSA also independently contributes to development and worsening of obesity. This may be due to central dysregulation of appetite control,²² leptin resistance,²³ increased ghrelin levels,²⁴ intermittent hypoxia, sleep disruption, arousals, increased inflammatory cytokines, and associated with OSA lead to obesity. Also, due to excessive daytime somnolence, there is decreased daily physical activity, aggravating weight gain. Both obesity and OSA are associated with similar comorbidities like hypertension and insulin resistance. Also, weight loss has been shown to improve severity of OSA in various studies.²⁵ Casual relationship between OSA and insulin resistance has been supported by large epidemiologic studies, with OSA conferring independent risk of diabetes mellitus.^{26,27} Continuous positive airway pressure (CPAP) use in OSA has been shown to improve glycemic control.²⁸

Association between OSA and hypertension has been reported in several large epidemiological studies.^{7,29} In a recent meta-analysis of 20 studies, OSA was associated with increased risk of essential hypertension with pooled odds ratio of 1.18 [95% confidence interval (CI) 1.09–1.27] for mild OSA, 1.32 (95% CI 1.20–1.43) for moderate OSA and 1.56 (95% CI 1.29–1.84) for severe OSA.³⁰ OSA has been cited as the most common cause of resistant hypertension.³¹ Use of CPAP for treating OSA has shown improvement in blood pressure control in various controlled trials and prospective studies^{32,33} including refractory hypertension.^{34,35} In a recent meta-analysis (30 studies, n = 1,900), CPAP use was associated with mean blood pressure reduction of 2.5 mm Hg, and was associated with significant reduction in cardiovascular events.³⁶ Recent guidelines also recommend screening for OSA in patients with refractory hypertension.³⁵

Obstructive sleep apnea, apart from comorbid disorders like hypertension and CAD, may contribute independently to the development of HF by periodic increase in intrathoracic pressures during spells of apneas and hypopneas, intermittent hypoxemia, and increased sympathetic drive resulting in increased afterload. Though HF is usually associated with central apneas, OSA is being increasingly reported. In patients with HF, 12–53% were detected to have OSA in various studies.^{37–40} In patients with OSA and low ejection fraction, fixed pressure CPAP reduces sympathetic activity and is associated with improvement in ejection fraction. However, advantages in HF with preserved ejection fraction are less clear.⁴⁰

Premature contractions and atrial fibrillation (AF) are associated with OSA. OSA has been demonstrated to be an independent risk factor for complex arrhythmias in various observational studies.⁴¹ The most common sustained arrhythmia associated with OSA is AF. Around 4.8% OSA patients had AF in sleep heart health study, as compared to 0.9% of controls.⁶ Higher prevalence of OSA has also been reported in patients with AF.⁴¹ Untreated OSA is associated with increased recurrence rates of AF; CPAP therapy is associated with decrease in AF recurrence.⁴² Fatal arrhythmias due to recurrent sleep disruption and increased sympathetic drive are the likely cause of increased risk of sudden death during sleeping hours in OSA patients. Higher risk of sudden cardiac death has been reported in severe OSA as compared to mild-to-moderate disease.^{43,44}

Coronary artery disease in OSA patients has been reported in up to 65% cases. Increased risk of myocardial infarction has been reported with history of snoring and severity of OSA.^{45,46} Pre-existent OSA is an independent risk factor for cardiovascular death in patients with CAD^{47,48} with decreased frequency and increased time to new cardiovascular events in patients treated with CPAP.⁴⁸ OSA has been associated with increased risk of stroke in various observational studies.⁶ OSA was an independent predictor of stroke and all-cause mortality in another cohort study with a hazard ratio of 2.0.⁴⁹

Other vascular complications of OSA include pulmonary hypertension. Usually, OSA causes only mild pulmonary arterial hypertension (PAH), unless there is associated cardiac or respiratory disease, or presence of obesity hypoventilation syndrome.⁵⁰ Postulated mechanisms for development of PAH include intermittent hypoxemia leading to pulmonary vasoconstriction with subsequent hypertrophy of smooth muscles and vascular remodeling.

Mood disorders including depression occur with increased frequency in patients with OSA, and can be presenting symptom of OSA in women.^{51,52} Fibromyalgia and suicidal tendencies are other psychosomatic manifestations of OSA. OSA also contributes to significantly increased risk of cognitive impairment and road traffic accidents.⁵³

SCREENING TOOLS FOR OBSTRUCTIVE SLEEP APNEA

As significant proportion of patients with OSA may present with cardiac symptoms, cardiologists should always evaluate patients for OSA. Patients presenting to cardiology services with hypertension, AF, coronary heart disease, HF, and PAH should be screened for OSA. Patients with comorbidities like obesity and diabetes mellitus should also be screened for OSA.

Screening tools for OSA include Berlin questionnaire (BQ), STOP-BANG questionnaire (SBQ), STOP questionnaire, and Epworth Sleepiness Scale (ESS). Commonly used scales are described in table 1. Modified Berlin scale is also available and has been validated for use in India. In a recent meta-analysis (108 studies, n = 47,989) comparing various screening tools (BQ, SBQ, STOP, and ESS) for the diagnosis of OSA, pooled sensitivity for mild OSA was 76%, 88%, 87%,

TABLE 1: Commonly used screening tools for identifying patients with obstructive sleep apnea

Modified Berlin Questionnaire*		Epworth Sleepiness Scale**	Score	STOP BANG***	Score
Category 1		Sitting and reading		Snoring (louder than talking/heard through closed doors)	
1. Do you snore?	Yes (1) No (0) Do not know (0)				
2. Your snoring is?	Slightly louder than breathing (0) As loud as talking (0) Louder than talking (1) Very loud—heard in adjacent rooms (1)	Watching TV		Tired/fatigued/sleepy during daytime	
3. How often do you snore?	Nearly every day (1) 3–4 times/week (1) 1–2 times/week (0) 1–2 times/month (0) Never/nearly never (0)	Sitting inactive in a public place		Observed stoppage of breathing during sleep	
4. Snoring bothering others?	Yes (1) No (0) Do not know (0)	Being passenger in motor vehicle for ≥ 1		Hypertension	
5. Has anyone noticed you quit breathing during sleep?	Nearly every day (2) 3–4 times a week (2) 1–2 times a week (0) 1–2 times a month (0) Never or nearly never (0)	Lying down in the afternoon		BMI $>35 \text{ kg/m}^2$	
Category 2		Sitting and talking to someone		Age >50 years	
6. Tired/fatigued after sleep?	Nearly every day (1) 3–4 times a week (1) 1–2 times a week (0) 1–2 times a month (0) Never or nearly never (0)	Sitting quietly after lunch (no alcohol)		Neck circumference $>40 \text{ cm}$	
7. Tired, fatigued or not up to par during waking time?	Nearly every day (1) 3–4 times a week (1) 1–2 times a week (0) 1–2 times a month (0) Never or nearly never (0)	Stopped for a few minutes in traffic while driving			
8. Nodded off or fallen asleep while driving a vehicle? If yes: 9. How often does this occur?	Yes (1) No (0) Nearly every day 3–4 times a week 1–2 times a week 1–2 times a month Never or nearly never			Male	
Category 3					
10. HTN	Yes/No/Do not know				
11. BMI	$>30 \text{ kg/m}^2$ or $\leq 30 \text{ kg/m}^2$				
Conclusion					

*Categories 1 and 2 are positive if score more than 2 points; Category 3 is positive if HTN present/BMI $>30 \text{ kg/m}^2$.

Subject classified as high risk if score positive in 2 or more categories, otherwise low risk for obstructive sleep apnea.

**Number for each situation: 0 = would never doze or sleep; 1 = slight chance of dozing or sleeping; 2 = moderate chance of dozing/sleeping; 3 = high chance of dozing or sleeping.

***To score 1 if answer is yes, 0 if answer is no.

BMI, body mass index; HTN, hypertension.

and 54%, respectively, whereas pooled specificity was 59%, 42%, 42%, and 65%. For severe OSA, pooled sensitivity was 84%, 93%, 90%, and 58%; pooled specificity was 38%, 35%, 28%, and 60%. The authors concluded that SBQ is best suited for screening for OSA in resource limited settings or when PSG is not available.⁵⁴ As stated above, the cardiologist should also be conscious of the varied presentations of OSA, and that all patients need not be obese or have excessive daytime somnolence. Refractory hypertension, recurrent arrhythmias, and ischemic events should prompt thorough history and polysomnographic evaluation to rule out OSA or concomitant sleep-related breathing disorders.

BARRIERS IN INTEGRATING OSA MANAGEMENT IN CARDIOLOGY PRACTICE AND SOLUTIONS

The barriers in integrating OSA diagnostics into cardiology practice stem from multiple factors. First and foremost barrier is the lack of awareness regarding OSA in cardiologists. Only visual screening of the patients for telltale signs of obesity or just relying on BMI may underdiagnose OSA, especially in high-risk patients. This can be taken care of by applying systematic screening tools as described above.

Second barrier or obstacle is referral of patient to a sleep physician. Though sleep medicine is rapidly expanding, certified, or experienced sleep physicians are few in number. Also, the patient may not understand the link between sleep and their cardiac disease, and may not make the effort to consult a sleep physician unless this is emphasized enough by the treating cardiologist. On the other hand, it may be difficult for cardiologists to provide sleep diagnostics and management adding more burden to already busy cardiology services. Also, due to limited number of quality PSG laboratories, full in-laboratory PSG may have a long waiting time. This can be sorted out by prior liaison with certified sleep physicians. Alternatively, cardiologists can improve their knowledge on sleep-related breathing disorders, to perform clinical evaluation on their own, and incorporate home-based sleep study as an initial method of diagnosis of OSA. Subsequently, patients can be managed in consultation with a sleep specialist. Patients with facial abnormalities or morbid obesity may be managed in consultation with surgical specialties.

Third obstacle is lack of connection with manufacturers of devices such as CPAP devices or mandibular advancement devices (MAD) for treatment of OSA. This is not a major problem and can be sorted out once cardiologist decides to incorporate sleep medicine in their practice.

DIAGNOSIS OF OBSTRUCTIVE SLEEP APNEA

Patients with OSA can primarily present with resistant hypertension, CAD, AF or pulmonary hypertension, without any overt manifestations of OSA. Patients should be asked for other symptoms of OSA including loud snoring, choking sensation, or gasping or witnessed choking spells during

sleep, morning headaches, sore throat or dry mouth on getting up in morning, cognitive deficits, decreased vigilance, morning confusion, personality, or mood changes, erectile dysfunction, and gastroesophageal reflux. Excessive daytime somnolence is an important manifestation of OSA syndrome. On clinical examination, increased neck circumference, craniofacial abnormalities, nasal congestion, low soft palate, uvular hypertrophy, enlargement of palatine tonsils, and macroglossia should be looked for. BMI and waist-hip ratio should be assessed.

Polysomnography is the method of choice for diagnosis of OSA. Attended level 1 PSG is the gold standard for diagnosis of OSA. Level 1 PSG records comprehensive physiologic parameters during sleep which include electroencephalogram (EEG), electrooculogram, electromyogram, snoring frequency, thoracoabdominal movements, nasal airflow, and oximetry. Thus, it can provide accurate sleep staging along with type of apneas. It can be used for titration of optimal CPAP pressure to obviate apneas and hypopneas in a separate study or during a split night study. It can be used to assess complex sleep disorders. It can also be combined with percutaneous carbon dioxide (CO_2) monitoring to detect concomitant hypoventilation. Disadvantages include requirement of attendance of trained technical staff, limited availability of PSG laboratories, and higher cost.⁵⁵

Home sleep apnea testing (HSAT) is an acceptable approach to diagnostic evaluation of suspected patients with OSA. These devices have been validated against in-laboratory PSG. As per American Academy of Sleep Medicine (AASM), minimum requirements of an HSAT device include sensors for nasal pressure monitoring, chest and abdominal respiratory inductance, and oximetry. Devices using peripheral arterial tonometry along with oximetry and actigraphy (e.g., WatchPAT) are also approved.

Advantages of HSAT devices for the patient include comfort of sleep testing at home, lesser waiting time, and lower cost. However, limitations include underestimation of AHI in mild-to-moderate OSA. Also, it is difficult to assess central and complex sleep apneas with HSAT devices. Therefore, these are not suitable for assessment of patients with comorbid disorders like chronic obstructive pulmonary disease (COPD), HF or other sleep disorders (hypersomnias, central sleep apnea, parasomnias, or periodic limb movement disorders). Also, CPAP titration using HSAT is not standardized, therefore, most patients diagnosed with OSA using HSAT devices may have to use auto titrating devices (auto CPAP) or retested with split night level 1 PSG.⁵⁵

Diagnosis of OSA is based on symptoms along with respiratory events during sleep. Apneas are defined as diminished airflow by 90% of baseline for 10 seconds or more; definition of apnea does not include desaturation as a criteria. Hypopnea is defined as diminished airflow by 30% of baseline for 10 seconds or more, along with arousal on EEG or desaturation by more than or equal to 3% on oximetry. Apnea and hypopnea should be obstructive in character, i.e., associated with paradoxical thoracic and abdominal movements. Respiratory event-related arousals are defined as airflow limitation for 10 seconds or more along with EEG

evidence of arousal, without satisfying criteria for apnea or hypopnea. The indices for defining severity of OSA can be AHI or respiratory disturbance index (RDI). AHI is defined as the sum of apneas and hypopneas per hour of sleep time. RDI comprises sum of apneas, hypopneas, and respiratory event related arousals per hour of sleep time.

Patients with 5–15 events per hour are classified as mild OSA, those with more than 15–30 events per hour are classified as moderate OSA. Patients with AHI more than 30 events per hour are classified as having severe OSA.⁵⁶

OVERVIEW OF MANAGEMENT OF OBSTRUCTIVE SLEEP APNEA

Once diagnosis of OSA is achieved, multimodality treatment is required. General measures applicable to treatment of all patients with OSA include lifestyle modifications like weight reduction, aerobic exercises, and dietary modifications. Patients who have respiratory events only in particular postures, e.g., supine predominant OSA can be counseled to avoid those postures during sleep. Patients can also be counseled to avoid or refrain from substances and drugs that are known to worsen OSA like alcohol and benzodiazepines. Patients with treatable craniofacial abnormalities may be good candidates for surgery. Patients with morbid obesity or concomitant hypoventilation may be advised for weight reduction surgery.

Continuous positive airway pressure therapy is the mainstay of treatment for OSA. The AASM recommends CPAP for all patients with moderate or severe OSA. Patients with mild OSA along with comorbidities including cardiac diseases like CAD, HF or AF should also be treated with CPAP as per AASM guidelines.^{57,58} CPAP works by splinting the upper airways and maintaining their patency during inspiration during sleep. CPAP therapy has been shown to reduce respiratory events during sleep, decrease daytime somnolence, improve alertness, improve systemic blood pressure, and improve glucose tolerance. CPAP has also been shown to reduce risk of nocturnal arrhythmias, recurrence of AF, and improve outcomes in patients with HF. Mortality benefit with CPAP has been shown in observational studies, but not in randomized trials.⁵⁹ Alternative to CPAP include MAD, however, they are less effective than CPAP,²⁸ and should only be offered as an alternatives in patients with mild-to-moderate OSA who are not willing or intolerant to CPAP. Hypoglossal nerve stimulation is another upcoming strategy for treatment of OSA.⁶⁰

Various drugs like cannabinoids are being studied for efficacy in OSA, but are not currently recommended as pharmacologic therapy.⁶¹ For residual sleepiness after CPAP therapy, modafinil or armodafinil have been used.

CONCLUSION

There have been great strides in management of HF, arrhythmias, and CAD. However, multiple factors lead to readmissions due to recurrence of these disorders. OSA has become increasingly prevalent, and is associated with

increased risk of cardiovascular diseases. This association presents the cardiologist with a unique opportunity to be at the forefront of screening and diagnosis of OSA. Home-based sleep testing has come of age, is easy and cost-effective in carefully selected patients, and can be used for diagnosis of OSA. This can be incorporated easily into existing cardiology services. Also, cardiologists can be an important part of the team in management of OSA and related disorders. Practicing cardiologists have both this opportunity and obligation to become thoroughly educated on sleep-related breathing disorders, and incorporate management of sleep disordered breathing in their practice to deliver best quality care to their patients. Cardiology training programs should also emphasize on screening, diagnosis, and treatment of OSA. Future research should further explore the horizons of relationship between sleep and the heart.

**Emerging Issues in
Cardiology**

mCardiology: mHealth in Cardiology

Ambuj Roy, Ajay S Vamadevan

INTRODUCTION

The term mHealth or mobile health refers to the use of integrated mobile telecommunication and multimedia technologies for wireless health care delivery systems. The first use of this term is widely attributed to Professor Robert Istepanian. He defined it as “mobile computing, medical sensor, and communications technologies for health care”.¹ The footprints of mHealth has gradually expanded over the years and it has been used in collecting routine demographic and clinical health information from the community, delivery of health-related information to practitioners and patients, real-time monitoring of patient vital signs, provision of care via telemedicine and electronic clinical decision support system (e-DSS). The electronic decision support system (e-CDSS) is a way to support health personnel in providing evidence-based care using standard medical management protocol algorithms loaded on a mobile device (smartphones, tablets, etc.) that can be used by doctors and support staff.

NEED FOR TECHNOLOGY

India has seen a rapid transition in epidemiology of diseases over the past two decades. Noncommunicable diseases (NCDs) now constitute the leading cause of disease burden all over India. Cardiovascular diseases (CVDs) are the leading cause of mortality among NCDs.² The dominant reason for this is the high burden of the risk factors like diabetes, hypertension, tobacco use, dyslipidemia, and physical inactivity in the population.³ The number of individuals with this conditions is mindboggling with over 175 million estimated to have hypertension and 73 million (2017) with diabetes in India. Given the dual burden of communicable and NCD, the primary focus of public health systems over the years being communicable diseases; and severe shortage of health care staff especially in rural India the health infrastructure is severely constrained in handling the NCD

burden. In this context innovations and use of technology such as mHealth may assist in addressing these challenges.

The use of mHealth in India has been evaluated through multiple pilot research projects in India and is planned to be taken up by the Government of India as part of the National Program for the Prevention and Control of Cancer, Diabetes, Cardiovascular Diseases, and Stroke (NPCDCS) for implementation at different levels of primary and secondary care hospitals. The program also envisages mass screening by ancillary health care workers to screen for risk factors like diabetes, hypertension, and common cancers in the population. The screening activities in the communities, management at various levels of care will be supported through a mHealth-based android “App” that combine’s electronic health record (EHR) and e-DSS capabilities. The App will connect all the levels of care by uploading patient data to central servers which would then facilitate seamless transmission of data across health centers. Screen detect patients from the communities could visit health facilities for confirmatory diagnosis, further treatment, referral care, and follow-up. The mHealth App thus will facilitate task sharing and avoid redundancy in human efforts and data collected. Some of the usage of mHealth in CV health is discussed below.

Electronic Decision Support System

mPOWER Heart Project

In 2012–2014, the All India Institute of Medical Sciences (AIIMS), New Delhi and the Centre for Chronic Disease Control (CCDC), New Delhi, in collaboration with the Himachal Pradesh Government implemented and evaluated a mHealth-enabled, nurse delivered NCD care delivery model in the Solan district. The project involved five Government community Health Centers (CHCs) and the District hospital. A copyrighted android-based smartphone App, *mPOWER Heart e-DSS*, was used in the NCD clinics primarily by nurses in helping the medical officers in screening, diagnosis,

and computing clinical management of hypertension and diabetes. The e-DSS had the following features:

- Computing clinical risk score for detecting patients at risk of diabetes
- Generation of personalized management plan for diabetes and hypertension
- Suggestion for choosing optimal drugs, and contraindications
- Storing patient data electronically to generate serial data to provide continuity of care during follow-up visits
- Utility to export data to statistical software packages for analyzing temporal trends.

A pre-post evaluation of the mHealth enabled care delivery model showed impressive results. A mean reduction of 14.6 mm Hg of systolic blood pressure (SBP), 7.6 mm Hg diastolic BP, and 50 mg/dL in fasting glucose level was observed among people with hypertension or diabetes during 18 months of follow-up.⁴ This model has provided the basis for replication of mHealth enabled interventions for chronic disease care in India.

SimCard Trial

The SimCard trial in India and China evaluated a simplified cardiovascular management program (SimCard) delivered by community health workers (CHWs) in their communities, with the aid of a smartphone-based e-DSS.⁵ People with high risk of CVDs, underwent the “2+2” SimCard intervention model: two lifestyle recommendations (dietary salt reduction and smoking cessation) and prescription of two accessible, effective, and low-cost drugs (aspirin and a diuretic or calcium channel blocker). The trial was conducted in 47 villages (27 in China and 20 in India) involving 2,086 “high CV risk” individuals (aged 40 years or older with self-reported history of coronary heart disease, stroke, diabetes, and/or measured SBP \geq 160 mm Hg). Participants in the intervention villages were managed by CHWs through an Android e-DSS App on a monthly basis focusing on two medication use and two lifestyle modifications. Compared with the control group, the intervention group had a 25.5% ($p < 0.001$) higher net increase in the proportion of patient-reported antihypertensive medication use at 12 months of follow-up. There were also significant differences in certain secondary outcomes such as aspirin use (17.1%, $p < 0.001$) and SBP (-2.7 mm Hg, $p = 0.04$). The results from the trial indicated that the e-DSS facilitated simplified cardiovascular management program improved quality of primary care and clinical outcomes in resource-poor settings in China and India.

mWELLCARE Trial

This Wellcome trust funded trial expanded the e-DSS to include another important and undertreated NCD condition—mental health. This prospective, multicenter, open-label, cluster randomized controlled trial involving 40 CHCs in 20 districts of Haryana and Karnataka, evaluated the effect of mHealth system for the integrated management of five chronic conditions (high BP, diabetes, tobacco use, alcohol use disorder, and depression) versus enhanced usual care among patients with hypertension and diabetes.⁶

The android-based App was again capable of e-DSS features along with storing health records, sending alerts and reminders for follow-up and adherence to medication. A total of 3,702 participants from 40 CHCs in the intervention and control (enhanced care) arms were recruited. The primary outcome was the difference in mean change (from baseline to 1 year) in SBP and glycated hemoglobin (HbA1c) between the two treatment arms. The secondary outcomes were the difference in mean change from baseline to 1 year in fasting plasma glucose, total cholesterol, predicted 10-year risk of CVD, depression, smoking behavior, body mass index (BMI), and alcohol use between the two treatment arms and cost-effectiveness of the intervention. The trial has been completed and the study results would be available soon.

Noncommunicable Disease Initiative, Tripura

This was a very important landmark for the mHealth in clinical hypertension and diabetes care, as it went from research to service mode, which is the ultimate goal for all translational research. The “NCD initiative in Tripura” was launched in May 2017 to address burden of CVDs. As part of the initiative, the *mPOWER Heart e-DSS* was used for management of diabetes, hypertension, and secondary prevention of CVD in health facilities all over the state of Tripura. A total of 40 NCD clinics running at governmental primary and secondary health care facilities rolled out the e-DSS. The nurses and medical officers manning these clinics were trained in use of the e-DSS. In addition, the doctors and nurses were oriented to evidence-based management of these chronic conditions in separate orientation courses prior to launch of the NCD initiative. At the NCD clinic screening of all eligible subjects (30+ years) were done for diabetes and hypertension and the nurse records the clinical parameters into e-DSS on a tablet device that generated a personalized prescription, based on evidence-based algorithms. The prescription was subsequently vetted by the medical officer and changes made were recorded by the nurse in the App. She/he is also provided additional lifestyle counseling as per prompts of the e-DSS. The App served also as an EHR and was used for follow-up assessment of the patient. The initiative has screened more than 80,000 individuals and treated over 30,000 for hypertension, 8,000 for diabetes, and 4,500 for both. The program was monitored real-time, using big-data analytic tools, for informed decision-making. Data from e-DSS server (<https://tripurancd.org/m-powerheartplus/login>) are reliable source for health administrators to monitor real-time process or health outcomes in individual health facilities and overall in the state. Major challenges in implementing this initiative were making technology user-friendly, which we overcame through multiple iterations with the support of all stakeholders.

Text Messages for Behavior Change Support

Indian SMS Diabetes Prevention Study

The Indian SMS diabetes study in Southeast India investigated whether mobile phone messaging that encouraged lifestyle

change could reduce incident type 2 diabetes (T2D) in Indian Asian men with impaired glucose tolerance, through a 2-year, prospective, parallel-group, randomized controlled trial.⁷ Participants in the intervention group received frequent mobile phone messages compared with controls who received standard lifestyle modification advice at baseline only. At the end of the study, the cumulative incidence of T2D was lower (18% vs. 27%) in those who received mobile phone messages than in controls. Additional 3-year follow-up of these participants, even after withdrawal of the active intervention, also showed beneficial effects of intervention on diabetes prevention.⁸

Similar to these interventions, the Ministry of Health and Family Welfare (MoHFW), Government of India, in collaboration with the WHO country office for India and other partners, has launched a SMS-based initiatives for tobacco cessation (mCessation Program), and the prevention and care of diabetes (mDiabetes Program). Potential beneficiaries are encouraged to register their mobile numbers online (websites: <https://www.nhp.gov.in/QUIT-tobacco> & <http://mdiabetes.nhp.gov.in/>) to receive messages to support behavior change to effect quitting tobacco and prevention or self-management of diabetes, respectively. Reports on large scale evaluation of these efforts are yet to be available.

TEXTME Trial

This trial conducted in Australia assessed impact of a lifestyle-focused semipersonalized support program delivered by mobile phone text message on CV risk factors in patients with coronary artery disease.⁹ It was a parallel-group, single-blind, randomized clinical trial that recruited 710 patients to two groups; those receiving text messages and control. Patients in the intervention group ($n=352$) received four text messages per week for 6 months in addition to usual care. Text messages provided advice, motivational reminders, and support to change lifestyle behaviors. Messages for each participant were selected from a bank of messages based on baseline characteristics (e.g., smoking) and delivered through an automated computerized message management system. The program was not interactive. The primary end point was levels of low-density lipoprotein cholesterol (LDL-C) 6 months. Secondary end points included SBP, BMI, physical activity, and smoking status. At 6 months, levels of LDL-C were significantly lower in intervention participants and there were concurrent reductions in SBP and BMI, significant increase in physical activity and a significant reduction in smoking. The majority of participants reported the text-message program to be helpful (91%), easy to follow (97%), and optimum in frequency (86%). The groups have since developed text messages contextual to and in local language in North India.¹⁰

Evidence from Systematic Reviews

A Cochrane review of the impact of messaging in secondary prevention reports that overall there is improved adherence in the intervention arm. However, the studies are small and have not evaluated the impact of intervention on CV

outcomes. It suggests sufficiently powered, high-quality randomized trials are needed, particularly in low- and middle-income countries.¹¹

Another Cochrane review of similar studies for primary prevention reported mixed results. The quality of data was overall poor and results heterogeneous. The authors concluded that there was uncertainty around the effectiveness of these interventions at present. However, there are six ongoing trials being conducted in a range of contexts including in low-income settings with potential to generate more precise estimates of the effect of primary prevention medication adherence interventions delivered by mobile phone.¹²

Smoking Cessation Meta-analysis

A Cochrane meta-analysis of five studies with over 9,000 participants has shown that mobile phone interventions increase the long-term quit rates by 71% as compared with control programs, using a definition of abstinence of no smoking at 6 months since quit day but allowing up to three lapses or up to five cigarettes. Statistical heterogeneity was substantial as indicated by the I^2 statistic ($I^2 = 79\%$) among the studies. They suggest that more research is needed into other forms of mobile phone-based interventions for smoking cessation and that it should be studied in other contexts like in low income countries and the cost-effectiveness of the intervention should be assessed.

Systematic Review of mHealth-based Heart Failure Interventions

This review evaluated nine studies using mHealth technology as part of an heart failure (HF) monitoring system, which typically included a BP-measuring device, weighing scale, and an electrocardiogram recorder.¹³ The impact of the mHealth interventions on all-cause mortality, CV mortality, HF-related hospitalizations, length of stay, New York Heart Association functional class, left ventricular ejection fraction, quality of life, and self-care were studied and they were inconsistent across these studies. The authors concluded that further research is needed to conclusively determine the impact of mHealth interventions on HF outcomes. The limitations of the studies were small sample size, quasi-experimental design, use of older mobile phone models, etc. This should be taken into consideration in planning larger trials as it may help improve dismal outcomes in HF patients especially in low resource settings like India.

CONCLUSION

The field of mHealth in cardiology is in its infancy but rapidly expanding. It provides a great opportunity to use technology to improve health care delivery. mHealth is not a substitute for conventional delivery of health delivery processes but it complements it to improve the efficiency of the system. It helps in task-sharing, evidence-based treatment, maintain records, and aid in follow-up even in resource poor setting. Mobile text messages have also shown promise in health promotion and improving medication adherence in various CVDs.

Telemonitoring in Cardiology

Pramod Sagar Arsikere, Aditya Kapoor

INTRODUCTION

Telehealthcare can be broadly defined as personalized healthcare delivered from a distance and represents an effective fusion of information and communication technologies with medical science. Among the range of medical specialties in which telemedicine has been successfully applied, cardiology is one of the most important. The usual components include—(1) acquiring patient data [e.g., blood pressure, pulse, weight, general well-being, symptoms, investigations like electrocardiography (ECG), echocardiography, etc.], (2) electronic transmission of patient data to a healthcare setup, (3) delivery of feedback tailored according to the individual patient need, which may range from ordering new investigation, drug titration or advising hospitalization.

The first recorded concept of telemedicine perhaps dates back to 1900s, when Willem Einthoven, a Dutch physiologist, developed the first electrocardiograph in his laboratory in Leiden and used a string galvanometer and telephone wires, recorded the ECG of patient in a hospital 1 km away.¹

Data acquisition and transfer can be either real-time (synchronous), store-and-forward (asynchronous), or a combination (hybrid systems). While synchronous techniques mandate that patient and healthcare professional be available together at the same time with real-time data processing, store-and-forward techniques allow for flexibility. The key components utilized in telehealthcare comprise of portable data acquisition or imaging devices (e.g., blood pressure apparatus, ECG, echocardiography systems), computer/smart phones, and a stable wireless communication infrastructure that can transmit data. This data can be viewed immediately or stored at the receiving station for later review. The following four generations of telehealthcare for remote management of patients have been practiced:²

1. Nonreactive data collection and analysis, with store-and-forward transmission of data (e.g., with ECG loop recorders)

2. Systems with real-time data transfer but nonimmediate decision-making structure. Therefore, although the healthcare provider can view data and recognize changes, delays can occur in analysis, especially if the system is only active during daytime
3. Systems with 24-hour ongoing, continuous, and consistent analytical, decision-making support, even outside office hours
4. Fully integrated telehealthcare where data from medical devices (invasive and noninvasive) are linked to telemedical platforms that are available for both the primary care provider and the telemedical center.

VARIOUS APPLICATIONS OF TELECARDIOLOGY

Various applications of telecardiology include:

- Teleauscultation
- Tele-ECG and its role in management of ST elevation myocardial infarction (STEMI)
- Remote monitoring for heart failure (HF)
- Remote monitoring for patients with implantable devices
- Others:
 - Patients with pulmonary hypertension
 - Tele-echocardiography services
 - Patients with prosthetic valves
 - Arrhythmia diagnosis
 - Radio Detection and Ranging (RADAR) systems.

Teleauscultation and Digital Stethoscope

Auscultation is an integral tool to establish diagnosis in cardiology and digital stethoscopes like ViScope offer high-resolution visual display combined with conventional auscultation (Fig. 1). Visual waveforms displayed in the format window of the phonocardiogram are transmitted to the cardiologist at the main server for analysis and interpretation. Using these tools for remote hearing has been shown to be more sensitive than traditional stethoscopes.³

FIG. 1: Digital stethoscope.

Tele-electrocardiography

Although ECG equipment is widely available, and lack of interpretation skills at the primary care level is an important issue. This is especially true for the developing world where medical outreach to communities is low and getting accurate ECG reports with specialist input is challenging. In India, there is acute shortage of physicians to provide medical care in remote areas and the reported doctor patient ratio in 2016 was ~1:1,300 as opposed to the World Health Organization (WHO) recommended ratio of 1:1,000.⁴

Inability or errors in diagnosing cardiac arrhythmias, acute ischemic syndromes, channelopathies, etc. is common due to varying levels of skill in primary care physicians. Hence, it is important to have reliable ECG interpretation at the primary care level, so that correct diagnosis can be made especially in cases of atypical presentations and when needed, urgent referrals can be done. Advances in telecardiology have helped rapid and reliable remote ECG recording and interpretation, using hand-held ECG units, that encode the ECG into sound, play it telephonically to the telecardiology service where the audio input is decoded and displayed as a 12-lead ECG. Tele-ECG electronic devices can also record ECGs, display it on the phone via Bluetooth, and then send it to specialists via mobile cellular networks.

- Of all patients with chest pain and suspected acute coronary syndrome (ACS) or STEMI and referred to tertiary care centers only 25–50% turn out to have ACS/STEMI.⁵ Hence, it is sensible to develop strategies to reduce such unnecessary referrals and limit the cost burden on health services
- Patients with STEMI are candidates for early reperfusion and primary percutaneous coronary intervention (PCI) remains the preferable strategy, if it can be performed in a timely manner and the patient can reach a PCI-enabled center. An early diagnosis is hence the cornerstone of managing such patients and can help in referring them to PCI centers in due time. Therefore prehospital diagnosis done via an ECG recorded in the field, interpreted

by paramedics with field triage, followed by wireless transmission to emergency physicians or cardiologists at the tertiary care hospital has emerged as a successful method to help early diagnosis and appropriate management of STEMI patients^{6–9}

- Techniques of prehospital (in-ambulance) ECG recording and transfer have evolved from the early days of single-lead telemetry (which primarily helped to diagnose arrhythmias) followed by successful implementation of satisfactory quality 12-lead ECG transmission using error-correcting digital transmission via cellular phone links
- Telecardiology for such patients also facilitates prehospital continuous ECG surveillance that provides useful prognostic information (failed thrombolysis, ongoing ischemia, arrhythmias, etc.) which can potentially help to improve further triage with individualized treatment protocols
- Successful implementation of such programs has been reported to significantly shorten transfer times, decrease treatment delay, and is associated with a lower mortality.^{10,11} While the early focus of most such studies was on prehospital fibrinolysis, Terkelsen et al. were one of the earliest to demonstrate the benefit of prehospital ECG diagnosis, field triage followed by transfer to a primary PCI center in patients with STEMI. The study reported that time from first medical contact to balloon was approximately 81 minutes shorter with prehospital diagnosis compared to patients diagnosed in the hospital. Even shorter (34 vs. 97 min, p <0.001) door-to-PCI times have been reported in subsequent studies using better techniques and technology and studies from different countries have reported similar results, despite diverse geographic settings, healthcare structure, and prehospital logistics^{12,13}
- *Body surface mapping:* A major limitation of the 12-lead ECG, whether in-hospital or prehospital phase, is the low sensitivity since the entire anatomic left ventricle is not completely covered by conventional leads. Hence, inferoposterior myocardial infarction (MI) could be missed on 12-lead ECG, a limitation, which can be overcome by using additional leads, like V7–V9. Body surface mapping using 80-lead ECG improves the ability to detect ischemia in all regions of the left ventricular (LV) including inferoposterior area, right ventricular (RV) MI, and can therefore improve sensitivity compared to conventional 12-lead ECG.^{14,15} However, body surface mapping for evaluation of patients with chest pain has not gained widespread popularity because it is time consuming; development of newer, easy to apply technologies for this purpose could change this scenario in future
- *Development of new ECG lead systems:* Since recording ECGs in prehospital settings is fraught with technical issues including poor general condition of status and time is of essence, focus has been on developing novel ECG monitoring systems for easy and rapid electrode application. The EASI lead system, using only four leads

to extract a complete, diagnostic “12-lead” ECG, has been reported to be as effective as the conventional 12-lead ECG system. The 5-lead system tested in the synthesized 12-lead ST monitoring and real-time tele-ECG initiative was also shown to be effective.^{16,17}

Remote Patient Management Systems for Heart Failure

Recurrent hospital admissions and episodes of cardiac decompensation are common in the first 6–12 months after the initial diagnosis as well as during the late phase of HF. Approximately, 50% of HF patients are rehospitalized within 6 months of hospital discharge. Follow-up of HF patients, even in the West, is inadequate at best, with suboptimal support at home and at the level of general or family physicians. Patients themselves have low adherence to drugs and fail to recognize early signs of cardiac decompensation. Telemonitoring of patients with chronic HF is now emerging as an innovative concept to detect early signs of acute decompensation, so that therapeutic measures can be instituted in time and recurrent hospitalizations are prevented. The use of telemonitoring for HF patients ensures “continuity of care” extending seamlessly from the hospitals to the patients’ home.

- Although telemonitoring has been shown to be useful in detecting early warning signs of HF decompensation, the best monitoring room remains elusive. Simple tools like only monitoring body weight may be fraught with inconsistencies, and multiparametric monitoring of weight, heart rate, blood pressure, ECG, O₂ saturation, natriuretic peptide levels, symptoms, and drug intake may be more beneficial. Ideal systems provide for face-to-face two-way communication between patients and healthcare providers using telephone or satellite connection. Preferably, the patient’s device should be portable with videoconferencing and data transmission ability, which can be managed by the healthcare professional using a remote control
- *Phone-based systems:* Use mobile phone-based telemonitoring equipment, a centralized center for automated data transfer and analysis, an internet-based graphical user interface with alert notifications for physicians-on-call. Patients measure their blood pressure, heart rate, body weight, etc. and enter this data along with daily dose of HF medications on the mobile phone. This data is then transferred to the central server via mobile networks
 - The Randomized Trial of Telephone Intervention in Chronic Heart Failure (DIAL) examined structured telephone support (STS) wherein nurses changed the diuretic dose and recommended nonscheduled medical consultations. This resulted in fewer HF readmissions (RR reduction 29%, p = 0.005) and better quality of life in the short term and even 1–3 years after stopping intervention¹⁸
 - The Trans-European Network-Home-Care Management System (TEN-HMS) study used twice daily home telemonitoring (HTM: self-measurement of

weight, blood pressure, heart rate, and heart rhythm with automated devices linked to a cardiology center) or specialist nurses telephone support (NTS) or usual care. Although the number of admissions and mortality were similar among patients receiving NTS or HTM, the mean duration of admissions was lesser with HTM. Those receiving usual care had significantly higher 1-year mortality than patients getting HTM or NTS¹⁹

- The Austrian Mobile Phone-based Telemonitoring for Heart Failure patients (MOBITEL) trial used an automatic algorithm to alert physicians, if the body weight gain exceeded a threshold of 2 kg within 2 days. Per-protocol analysis revealed that rate of reaching the primary endpoint (death and hospitalizations) was reduced by 54% (p = 0.04) and telemonitored patients who were hospitalized for worsening HF had a significantly shorter length of stay (6.5 vs. 10 days, p = 0.04)²⁰
- The Telemonitoring to Improve Heart Failure Outcomes (Tele-HF) study assessed the use of a telephone-based interactive voice response system in patients within 30 days of HF hospitalization. Readmissions, death, and number of days in the hospital were not reduced by telemonitoring. The study concluded that a thorough and independent evaluation of these strategies is important before their adoption in clinical practice²¹
- *Near-field communication (NFC) technology:* Difficulties in manual data entry via the mobile phone keypad often leads to inability to initiate data transmission. This is especially common for older patients or those from low socioeconomic and educational status. E-mail notifications about patient events also occasionally result in overloading the server due to inappropriately adjusted technical thresholds. Near-field communication technology, which supports a touch-based method for data acquisition and unlike Bluetooth, does not depend on device pairing and is likely to circumvent these problems.²² This is a wireless connectivity-based technology that involves contactless identification based on magnetic inductive coupling, working in the frequency band of 13.56 MHz. Apart from ease of data acquisition, NFC also has the ability to provide access to data stored on radiofrequency identification (RFID) tags. This can facilitate acquisition of nonquantitative data, like medication intake and patient well-being stored on electronic barcodes. Specially designed blood pressure monitors (UA-767 plus NFC, AND, Japan) with integrated NFC module (AIT: Austrian Institute of Technology, Austria) to allow for wireless transmission of measurement values have been developed. In addition, body weight scales (UA-321, AND, Japan) with NFC extension have also been designed to help HF patients in acquiring data by just a touchscreen technology using NFC-enabled mobile phones. Patient identification on the central server is done using contactless smart cards (patient-specific ID cards)

- Use of implantable electronic devices (IEDs) and implantable hemodynamic monitors (IHMs) in HF patients:** Although patients can be trained to recognize signs and symptoms of worsening HF and monitor body weight, the sensitivity of weight gain to detect decompensation is modest at best (<20%).²³ Implantable devices provide information about the filling pressures of the ventricles and help in guiding HF management optimally by measuring intrathoracic impedance, LV/RV filling pressures, RV oxygen saturation, pulmonary hypertension, etc. as surrogate markers of patient hemodynamics. Most devices (e.g., Chronicle® system) include a monitor, a passive fixation sensor lead, an external pressure reference along with data retrieval, and viewing components (Fig. 2). Studies have shown that the sensors function well over time, reliability is good, and the IHMs are usually well tolerated.^{24,25} Many cardiac resynchronization therapy and implantable cardioverter defibrillators (CRT, ICDs) have the technology to monitor intrathoracic impedance and in-built algorithms alert patients by an audible alarm, if there is volume overload and incipient clinical worsening. Patients can then either increase drugs doses (e.g., diuretics) or instructed to get in touch with their home nurses/physicians
 - In the SENSE-HF study, OptiVol®(ICD/CRT-D) device measured intrathoracic impedance showed modest sensitivity for predicting recurrent hospitalizations²⁶
 - In the MUSIC study, a noninvasive external device attached to the chest, measured bioimpedance, heart rate, respiratory rate, physical activity duration and intensity, and body posture. A multiparametric algorithm based on fluid index, breath index, and personalization parameters had a sensitivity of 65% and a specificity of 90% in predicting acute HF decompensations²⁷
 - The Evolution of Management Strategies of Heart Failure Patients with Implantable Defibrillators (EVOLVO) study, randomized patients of HF to remote monitoring (ICD/CRT-D) of intrathoracic

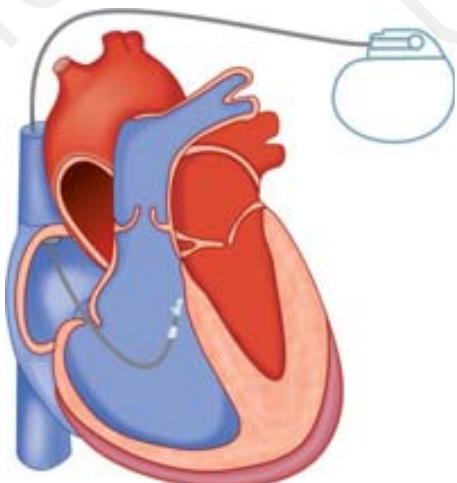

FIG. 2: An implantable hemodynamic monitoring device with lead placed near right ventricular outflow tract.

impedance, atrial arrhythmias and ICD-shocks versus usual care (scheduled visits every 4 months). A significant reduction of emergency visits by ~35% was reported in the remote monitoring group when compared to usual care²⁸

- In the Implant-based Multiparameter Telemonitoring of Patients with Heart Failure (IN-TIME) trial, daily multiparametric monitoring of data transmitted by devices was associated with benefit in clinical composite scores [all-cause death, hospital admission for HF, change in New York Heart Association (NYHA) class] in the telemonitoring group (risk reduction by 37%)²⁹
- However the OptiLink HF study, in patients of HF with ICD/CRT-Ds, reported that despite fluid status alerts, no significant effect was noted in the composite endpoint of all-cause death and hospitalizations.³⁰ The multicentric Remote Management of HF using IEDs (REM-HF) study, also reported no significant difference in death/hospitalizations between the remote monitoring group and usual care³¹
- Data on the effectiveness of STS telehealthcare in reducing hard endpoints like morbidity and mortality in HF has been conflicting. While some meta-analyses have reported that STS reduces all-cause mortality and HF hospitalizations, other studies did not confirm this.^{21,32-34} Recent data confirm the benefit of telemonitoring in reducing death, emergency admission rates, and reduced duration of hospital stay in patients with HF and obstructive pulmonary disease³⁵
- Telemonitoring of HF patients using invasive data (acquired from IHMs) has shown to be of greater benefit. In fact, intrathoracic impedance, LV-filling pressures, and pulmonary artery (PA) pressures monitoring have been reported to have greater sensitivity to predict worsening HF as compared to simple parameters like acute weight gain.³⁶ Use of wireless implantable hemodynamic monitoring systems to measure and monitor PA pressure has been reported to reduce rate of HF and duration of hospital stay.³⁷ Telemonitoring of left atrial pressure has also been reported to be associated with reduced risk of acute decompensation and HF death.³⁸ Trials with new generation telesystems that combine noninvasive and invasive parameters are required to further elaborate of the use of telehealthcare in HF
- The 2016 European Society of Cardiology Guidelines for HF recommend for the first time “remote patient monitoring” with a recommendation of grade IIb, LOE B.³⁹

Remote Monitoring in Patients with Pacemakers and Implantable Cardioverter Defibrillators

The number of patients with implantable devices like pacemakers and ICDs is rising exponentially as indications of implant have widened to include more diverse patient groups. Generally, patients with devices need follow-up at 6 months to 1 year and sometimes more frequently

depending on the clinical situation. These follow-up visits usually include evaluation of the device function (battery status, capture thresholds, and any events) and a general clinical examination. In most of these visits, no technical change is performed in device parameters rendering these hospital visits as clinically irrelevant. Studies have shown that only 5–15% of in-hospital visits for ICD checks are done for an unscheduled event (e.g., a shock, device alert).⁴⁰ Patients often travel from afar (with accompanying attendants) just to be told that everything is normal and these time-consuming visits mean long-waiting times and time off work leading to noncompliance. Hospital resources like physical space and manpower are also required to manage such visits; nurses, technical staff, and even doctors often compromise their time for attending to issues that are uneventful and only need reassurance.

- Recent technical innovations in devices have led to advancements in remote monitoring and data can be wirelessly transferred on a regular basis to servers that examine and analyze the data, so that remote follow-up can be performed. Information available from current devices can range from arrhythmia detection, battery and lead parameters, impedance, volume status, pulmonary and left atrial pressure, etc. Systems allow automatic transmission of data stored in the device to the outpatient clinic using wireless network for mobile communication network or via a landline. The alerts can be based on a change in device parameters (battery status and lead impedance), programming issues [sensing or capture margins, inadvertent disabling of ventricular fibrillation (VF) therapy] and clinical events (arrhythmias and lung fluid accumulation)
- Physicians in charge of the patients can be notified immediately, if any events or technical malfunctions are detected. Additional notification by E-mail, SMS, fax, or even phone messages can be sent, if critical data are available for consultation. This helps in earlier detection of relevant findings and conserves healthcare resources only for clinically important events. Depending on the clinical need and specific issues involved, follow-ups are still needed since due to safety issues systems do not yet allow routine remote device programming
- The technical reliability of such systems is in excellent and transmission of information is much faster than what would occur with face-to-face visits. Clinical benefit of telemonitoring in patients with implantable devices is well documented with nearly 50% reduction in follow-up visits without compromising patient safety.^{40–42} It has been documented that telemonitoring to follow-up 100 ICD patients needed only 1.5 hours and 15 minutes per week nurse- and physician-time, respectively, and leading to significant reduction in unnecessary hospital visits.^{43,44} In addition, unscheduled visits following ICD shocks can also be minimized, when after an event and patient upload of data, analysis reveals that the shock was inappropriate and a physical visit is not needed.

Others

Telemonitoring in Patients with Pulmonary Hypertension

The aim of pharmacological management of patients with primary/idiopathic pulmonary hypertension is alleviation of PA pressures. Although PA pressure can be measured by right heart catheterization or Doppler echocardiography, both provide only a single time snapshot of the hemodynamic status. Telemonitoring by devices like the Chronicle® system or CardioMEMS® system can help in continuous assessment of PA pressures and monitor long-term efficacy of new drug therapies.^{45,46} Pressure sensors, in close contact with the PA, collect and store data of PA pressures and then transmit it to the central server.

Tele-echocardiography

Transmission of real-time echocardiography images between small peripheral hospitals and specialized tertiary care centers is especially important for diagnosing or excluding congenital heart disease (CHD) in newborns. In India nearly 180,000–210,000 children are born with CHD every year, and 30–50% of these have critical disease that requires early intervention. Nearest echocardiography machines and experienced pediatric cardiologists are often hundreds of kilometers away meaning that only a minority receives requisite therapy due to delay in diagnosis. Tele-echo services have been developed that involve training technicians or physicians to perform echocardiography on remote sites and then transferring images to the pediatric cardiologist via tele-echo links. This helps to make early diagnosis and ensure proper and early referrals when needed. Transmitting echocardiogram images needs efficient compression techniques without compromising image quality. After transmission, images are decompressed at the specialist making interpretation feasible and easy.

Patients with Prosthetic Valves

Patients with mechanical valvular heart prostheses can encounter life-threatening complications like endocarditis, valve thrombosis, pannus, and thromboembolism. Devices (the ThromboCheck device) can analyze and transmit the sound frequency spectra of valve motion. A baseline frequency spectrum is obtained immediately postoperatively. The device continuously monitors the sound frequency of the prosthetic valve motion and if the spectrum deviates from baseline, the signals are transmitted to the medical center via telephone or Internet.⁴⁷ If the nurse/physician in charge suspects prosthesis valve dysfunction, patients are instructed to come in and get an echocardiogram or fluoroscopy. The positive-predictive value (97%) and sensitivity (~100%) of ThromboCheck devices has been reported to be excellent. Patients living in remote or outreach areas, poorly compliant on anticoagulation or those with previous history of valve thrombosis are the optimal candidates for such monitoring.

Arrhythmia Diagnosis

Telecardiology is very useful for establishing diagnosis of paroxysmal arrhythmias, which are often missed by single time ECG/Holter recordings. Event and loop recorders record continuous ECGs (3–7 days) and transmit the data to physicians electronically, helping make remote diagnosis. In patients with paroxysmal atrial fibrillation, alerts can identify initiating episodes and identify triggers, which can call for unscheduled follow-up visits with tailoring of management (antiarrhythmic drugs, anticoagulation, external cardioversion, or device reprogramming).

RADAR Systems

Many currently available telemonitoring systems use sensors that need to be placed in close contact with the cardiac chamber and therefore require invasive techniques for insertion. RADAR systems using ultra-wideband (UWB) can potentially overcome these limitations and expand the use to a wider spectrum of population including sicker adults and even children without compromising patient mobility and comfort, and avoiding the complications of an invasive procedure. This technology can acquire and transmit large amount of digital data and high-resolution images. Although microwave radiation exposure was concern, the average emission level used (>1 µW) is much lower than international standards for continuous human exposure to microwaves, making these devices safe and useful. This technology has found application in monitoring cardiac volumes, respiration, early diagnosis of sudden infant death syndrome (SIDS) and in patients with obstructive sleep apnea.

CONCLUSION

An increasingly aging patient population, rising trends of coronary artery disease (CAD) and HF, and the widespread availability of new drugs and devices have highlighted the need for continuous and close contact between the patient and healthcare givers to ensure optimal care. Since there is a dearth of qualified healthcare professionals and medical resources, especially in developing countries like India, telehealthcare is a cost-effective way for evidence based care to be delivered at the doorstep of patients. It is mandatory that the remote monitoring system is organized comprehensively with seamless and rapid data transfer, fast reaction schemes with effective alert notifications and feedbacks systems for patient education and counseling. The system should be tiered to filter out only relevant events and hence not overburden the providers with unnecessary information.

Initiation into home follow-up telemonitoring systems should begin early after hospital discharge to help patients become familiar with these systems as early as possible. Physicians and para-medical staff should also be educated about the operational technicalities of the system. Keeping in mind cost and long-term sustainability issues, it is important to identify specific subgroups of patients that would maximally be benefited by such interventions. Although the cost of creating, operating, and monitoring such effective telemonitoring systems is a factor, this needs to be considered

in light of the fact that only few (<10%) of routine hospital visits require subsequent physician evaluation as compared to more than 50% of those with unforeseen events. This large unmet clinical need of optimization of healthcare resources can help to make these systems cost-effective.

Executive Cardiac Checkup: Is it Really Needed?

Brian Pinto, Neeraj A Desai

INTRODUCTION

Since independence, India has seen a drastic change in lifestyle and diet, moving from agrarian diets and hard physical labor to junk food, and sedentary lifestyles due to a capitalist economy ushered in, especially in the 80s and 90s. This has occurred in a much shorter duration compared to other nations. Hence, high mortalities related to cardiovascular diseases (CVDs), diabetes, and stroke have skyrocketed since then. In comparison with the Europeans, CVD affects Indians at least a decade earlier and in their most productive midlife years.^{1,2} In the west, 23% of CVD deaths occur before the age of 70 years; while in India, this number is 52%.³ Regarding case fatality related to CVD in developing countries like India, it is much higher compared to developed nations.^{4,5} The World Health Organization (WHO) had reported that, due to burden of CVD, India had apparently lost \$237 billion from the loss of productivity and spending on health care over a 10-year period (2005–2015).⁶ The current and future forecasts is no different and shows continuing trend in the coming decades, where CVDs will lead to major loss of the human resource pool of the country. Slated to be one of the youngest nations in the world, India is set to give up this productive population to CVD morbidity and mortality which can hinder the economic growth in an otherwise beneficial phase of demographic transition.

In India, the preventive healthcare sector is growing. India's total preventive healthcare market now estimates over \$800 million.⁷ The current scenario in Indian markets offers a tremendous opportunity to bring in innovative technology solutions. Healthcare companies are moving in the upward direction empowering patients to engage more in health awareness. This has led to people spending more time and resources on health which has given a boost to preventive healthcare at urban and to some extent semi-urban market.

It makes good sense for India Inc. to protect their top talent from the growing dearth of noncommunicable diseases which have reached a point of epidemic stature, irrespective of socioeconomic and cultural background. The healthcare

industry in India is at a very important juncture. It is on the brink of a transformation, as it adopts new pathways, including latest innovative technology, to help executives manage their health in a better manner. Preventive healthcare is becoming an area of focus in most countries, and India is no different.

As the cost of healthcare increases in the corporate sector, there is an increasing interest in workplace for raising awareness about various diseases especially CVD and a need to practice prevention in healthcare. The ASSOCHAM (Associated Chambers of Commerce and Industry of India) report in January 2018 on preventive healthcare and its impact on corporate sector states that ₹1 spent on prevention saves ₹133 in absenteeism costs and ₹6.62 in healthcare costs. Hence, proper healthcare and wellness programs can change employees' perception about health and improve his risk profile and productivity.

Currently the executive cardiac health checkups in India offer a battery of test listed below:

- Routine blood and urine investigations [including lipid profile, apolipoprotein B (ApoB), lipoprotein(a), and serum homocysteine levels]
- Chest X-ray
- Electrocardiogram
- Two-dimensional echocardiography
- Treadmill test
- Cardiac consultation
- In some centers cardiac computed tomography (CT) (to assess calcium score).

Costs vary, but executive cardiac health programs can be cost-effective.⁸ Considerable disparity exists among programs in terms of testing and other clinical services. Some executive checkups provide comprehensive, efficient, effective, and individualized patient-based care at a reasonable cost.

Although executive checkups have been around for 100 years, literature search has been futile and very few studies have documented the potential impact of a cardiac executive checkup on medical expenditure. In a study published in 2002, periodic executive cardiac checkup participants experienced

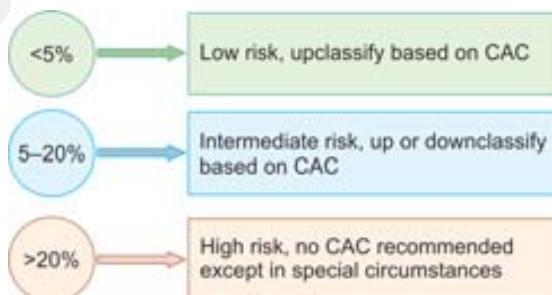

an average 0.93 (or 2.78 for 3 years) short-term disability days absent per year in comparison with an average of 1.34 (or 4.02 for 3 years) short-term disability days absent for nonperiodic health checkups. The net return on investment (ROI) for a worksite-based executive health examination which cost approximately \$400 per executive whose total compensation (salary and benefits) is at least \$125,000 is estimated to be 2.3:1, which compares favorably with other preventive health programs.⁸

The best available evidence suggests that patients benefit from cardiac executive health checks through its association with improved delivery of some important preventive clinical tests through reduction of patient worry. The available evidence does not reveal harms associated with the executive health checkup. Given that short- and long-term studies have shown that appropriate implementation of currently recommended preventive services improves health in short- and long-term studies.⁹

The main appeal of an executive health check stems partly from its variety. It usually includes a comprehensive exam, extensive blood work, and other checks for heart disease. The exclusive versions also call for a CT scan of the heart to assess for coronary artery calcium (CAC) scoring.

COMPUTED TOMOGRAPHY CORONARY CALCIUM SCORING

Several studies have shown how CAC can reclassify individuals previously stratified as per the atherosclerotic cardiovascular disease (ASCVD) risk factors.¹⁰ Hence, preventive cardiac checkups in asymptomatic diabetic and age 40–75 years but with estimated ASCVD risk of 5% or higher or those in less than 5% 10 years risk group can definitely benefit from additional CAC scanning. The higher risk (>20% 10 years ASCVD risk) has little role except that it provides a persuasive confirmation of high-risk patients reluctant for statin therapy (Fig. 1). The 2013 American College of Cardiology/American Heart Association (ACC/AHA) prevention guidelines emphasized on absolute risk assessment of preventive therapy to determine maximum benefit.¹¹ CAC = 0 appears the strongest negative predictor of cardiovascular event when compared to other markers like ankle brachial

CAC, coronary artery calcium.

FIG. 1: The role of coronary artery calcium in reclassifying the 10-year atherosclerotic cardiovascular disease risk categories and guiding treatment.¹³

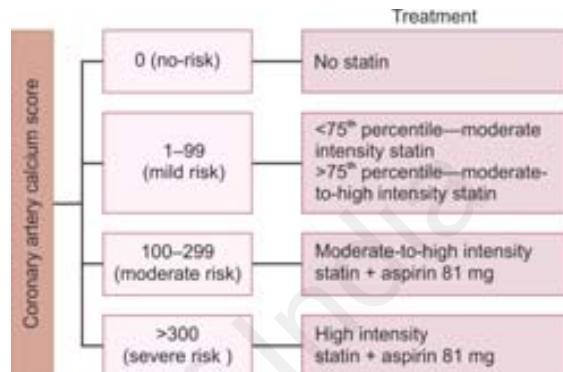

FIG. 2: Primary prevention based on coronary artery calcium score determined risks in the 5–20% atherosclerotic cardiovascular disease risk group.¹³

index or carotid intimal thickness. There is strong evidence that CAC = 0 can downwardly classify risk when 10 years ASCVD risk is between 5 and 15% and a moderate evidence to reclassify risk in people between 15 and 20% ASCVD to a level where no statin is required. Those who have undergone CAC screening in the ASCVD 5–20% intermediate risk group statin therapy is initiated or not initiated as per the Society of Cardiovascular Computed Tomography recommendations (Fig. 2). In a few patients where a progression of CAC score is anticipated and would support intensifying the preventive management, repeat scanning at an interval of 5 years for 0 CAC and 3–5 years interval for patients with CAC more than 0.¹²

At first, you should think that an innovative medical technology can see a dormant disease lying with your body without so much as scratching the skin would be perfect. However, the monetary aspects with low circumstantial evidence deter most insurers to pay for them in a preventive context. And there are some drawbacks. Quite frequently these scans show false positives. They detect suspicious lesions that turn out to be harmless, raising needless worry, and frequently prompting invasive tests. Conversely they also can be falsely negative, that can create a false sense of security that leads the patient to ignore early warning signs. Even if a recent scan of an employee's coronary arteries indicates a low risk of heart disease, he/she should tell her doctor about angina and the mild nausea he/she has started to feel after a short time on the treadmill. Not doing so could prove fatal. As imaging technology continues to get better and safer, the day may come when the risk/benefit ratio justifies scans as screening tests for healthy people in a preventive care setup. Today, though, the feasibility in most situations would not see a return on their investment when they are included as part of the executive physical with the occasional exceptions.

Presumably, the employers believe that the extensive workup will help reveal hidden health issues while they are most treatable, through a process, i.e., both thorough and efficient. If there is nothing detected, at least the executive will feel cared for. However, more does not necessarily mean better.

However, today many executive cardiac checkups are conducted at distant corporate hospitals which have tie-ups with majority of the multinational companies. Ideally, the doctor talking to the executive and noting down his medical history, performing the general examination, and ordering investigations should not be someone the patient will never see again. He or she should be that person's primary doctor. Unfortunately in today's day and age time-pressured primary care, it is practically impossible to have sufficient time and opportunity during periodic executive health checkup exam for any type of detailed and personalized conversation necessary to create that meaningful doctor-patient relationship and to sustain it. The executive health check frequently becomes a rushed, impersonal, and largely bureaucratic activity which ends up being nothing more than a brief interview focused reviewing of health habits, medications, and allergies, with additional supplemented by a physical examination and ordering of recommended screening tests and procedures—in essence, checking all the requisite boxes for reimbursement. No wonder some observers question the value of the annual physical as it is currently implemented. Physician-ethicist-commentator Ezekiel Emanuel, for one, views it as an antiquated habit of little worth (and even of potential harm) that consumes scarce physician time; he has called for the public to skip it while acknowledging that the opportunity to "reaffirm the physician-patient relationship" is an important draw for patients.¹³

The talk of scrapping the executive health checkup should take into account factors that stall its implementation and limit its contributions to care, especially in terms of relationship building. Time and continuity are clearly in short supply in primary care, yet both are critical to establishing and maintaining a trusting doctor-patient relationship. Discussing a person's values and health care preferences are important addendums to that inquiry and help build a sense of caring, respect, mutuality, and trust. Trust is built by the relationships continuity and the availability, reliability, and safety of the care provided over time. When performed in a thorough, gentle, and considerate manner, the physical examination can communicate caring and help build trust. From this point of view, the executive health checkup becomes as much an act of relationship building and continuity as it is a means of searching for clinically significant findings. In the age of imaging and advanced medical technology, physicians scarcely rely on physical examination and lose appreciation for its therapeutic effect, not to mention the skills required to perform it.

Rather than completely eliminating such executive checkups, it should be improved. This requires time and a dedicated team effort on part of both the employer and primary caregiving institutions, to free the physician of a routinized aspect of screening, data collection, and examination. Instead of predetermining the investigations and concluding a health check with the physician consultation, the order should be reversed, where the primary physician gets to decide the course of the executive health check. This will lead to a more thorough evaluation in terms of physician-optimized value-added elements. For active medical problems, a problem-based review could be included, complemented by a careful

evidence-based physical examination for relevant items. The visit could conclude with a summation of findings, recommendations for the coming year, and time for discussion. An hour-long visit could include about 30–40 minutes of physician time, making it practical and meaningful for both patient and physician. In this conceptualization, the executive health checkup would become the annual health review, just like an appraisal and managing your yearly health goals.

For low-risk patients (e.g., healthy young adults with health-conscious lifestyles), the interval between such visits might be longer than a year, but short enough to maintain the relationship and check on life events and stresses with health consequences. In places where primary care physicians are few and far between, this role, for patients without complex medical issues could very well be carried out by well-trained advanced-practice nurses or physician assistants with physician backup over communication.

CONCLUSION

To summarize, the mantra that "One size fits all" does not hold true for executive cardiac checkup as it does not have much value if too many tests are burdened on all asymptomatic individuals. However in my opinion, a basic cardiac checkup, comprising of routine blood investigations with lipid profile with high-risk lifestyles above the age of 30 years should be made a necessity in all corporate work places, not every year but once in 3 years. This can give the physician an idea about individual risk stratification and differentiate low-risk individuals from intermediate and high risk ones subjectively based on family history and physical examination. Those with a relatively higher risk can be subjected to further testing based on their subordinate features.

The health insurance, primary care providers and their affiliated organizations should create and maintain a well-oiled system for thorough and efficient preventive steps proven to be cost-effective and risk free. Executives get exactly what they want; they would get it from their own primary care physicians, which would save time and money for the employers. It seems reasonable for physicians to redouble their efforts to build meaningful relationships that can be trusted and sustained, particularly at a time when patients are experiencing problems at every step of healthcare delivery. Turning the executive health checkup into an annual health review will help create value for both patients and doctors, enabling the latter to serve as physicians rather than merely health care providers.

Cardiology and Ethics: Mission Impossible?

Raja Selvaraj, Jayaraman Balachander

INTRODUCTION

The practice of medicine is a unique blend of science and art and is exacting in its requirement of skills and qualities in its practitioners. Ethical issues have been interlinked with the practice of this discipline ever since the birth of modern medicine. Even today, taking the Hippocratic Oath continues as a rite of passage for medical trainees beginning practice and issues regarding ethics crop up each day while practicing.

An important reason why medical practice remains a minefield of ethical issues is that while providing medical care to a patient, the physician and patient enter into a contract which is inherently unbalanced. In this contract between unequal parties, the patient is always much more vulnerable than the physician, having less knowledge and understanding of the situation, usually less authority about deciding the course of action and always with more to lose. Being in a position of more power, the physician has to tread carefully and it is very easy to act in a manner that brings up questions of ethics. While this is common to all forms of medical practice, is there something unique about the field of cardiology, and especially about this time in history that makes it a challenge to practice ethical medicine in cardiology today?

CHALLENGES SPECIFIC TO CARDIOLOGY

At first glance, the odds appear to be stacked in favor of cardiologists. The heart is a vital organ and diseases of the heart remain one of the most common causes of death in the general population. Cardiologists who treat these diseases therefore have a large number of patients whom they can help and the potential change in the lives of these patients by good medical care is enormous. The most common heart disease, coronary artery disease, has an extensive evidence base for various treatment modalities with multiple large studies regarding the best treatment to offer. Guidelines are also provided and regularly updated by various national and

international scientific bodies for various cardiac disorders. All these should help the cardiologist decide the correct course of action easily and advise the patient accordingly. Despite these, not many would argue with the fact that the practice of cardiology today is particularly enmeshed with ethical issues. There are a few specific reasons for this.

Cost-Benefit Ratio

The cost of many interventional treatments for heart diseases is high because of the specialized hardware required and the evolving treatment approaches with introduction of new technology which tends to be expensive. This makes the financial implications of choosing an interventional therapy over a noninterventional treatment huge. Therefore, avoiding bias while choosing therapies is challenging for the cardiologist. It is an even greater challenge to avoid the perception of bias from this financial gain in the mind of the patient when advising an interventional therapy.

This is not helped by the fact that the benefit of many interventions remains arguable, often small or limited to specific subsets of patients. As an example, the benefits of percutaneous coronary interventions in stable coronary artery disease are small and questionable and have to be balanced against the risks and disadvantages when compared with medical management¹ or coronary artery bypass surgery.² Use of an implantable cardioverter defibrillator for primary prevention is associated with a number needed to treat to save a life³ which some consider acceptable, while others consider too large to justify for the cost. Communicating this uncertainty to the patient and taking a decision with their understanding is not an easy task.

Bias toward Interventions

Apart from financial gains, the technical aspects of a procedure may also prove very attractive for the cardiologist. This may be because of technical challenges presented by the procedure and the attendant satisfaction from completing it (e.g., percutaneous intervention for chronic

total occlusion of coronaries) or being an initial adopter of a new procedure leading to adulation from industry and peers (e.g., transcatheter aortic valve replacement). These can consciously or unconsciously introduce a bias in the mind of the cardiologist when taking a decision of doing a procedure.

The Uncertain Boundaries of Expertise

Cardiology continues to expand into a broad field of knowledge and skills where expertise in a specific area often is required to provide optimal treatment. Trained cardiologists are now available with specific expertise in fields like pediatric cardiology, interventional cardiology, or cardiac electrophysiology. At the same time, many specialized procedures continue to be performed by cardiologists who may not have special training in it. Especially in the absence of a strict certification system in our country, it becomes an ethical challenge for the practicing cardiologist to decide if he should do a certain procedure or refer it to a colleague who may have undergone specific training in that field.

Changing Doctor–Patient Relationship

The doctor–patient relationship is undergoing a sea change in our country which has led to a climate of distrust from both sides. From the traditional relationship of paternal beneficence wherein the physician was treated with reverence, equated with God and given a free hand to take all the important decisions, we are moving to a relationship of shared decision-making where the physician is seen as a caregiver with duties and responsibilities. In today's scenario, the physician is expected to act as mediator between the patient on one hand and medical science and technology on the other, providing the patient with adequate information in order to be able to participate in the decision-making process. In the field of cardiology especially, patient expectations run high because of the fear and awareness of heart disease and the implications of its treatment.

All these factors combine to make ethical issues a challenge in the practice of cardiology today. But is this a challenge that can be overcome with diligence or is it a mission impossible? We believe that it is the former, and that the challenge can be tackled with a concerted effort from the cardiologists and regulatory bodies of medicine and cardiology.

WHAT CAN THE CARDIOLOGIST DO?

The first step is for practicing cardiologists to recognize and understand that practice of cardiology is a challenge today and needs diligence from the practitioner to stick to an ethical path and avoid various biases. An acknowledgement of the challenge prepares him or her to consciously avoid these biases and practice ethical cardiology.

Evidence-based Medicine

It is important to zealously study the scientific literature, critically weighing the various studies and guidelines to decide on the scientifically correct treatment for various

conditions. The vast body of literature and the often conflicting results in different studies takes a lot of effort from cardiologists to sift through the available information and separate the wheat from the chaff. But, it is important to follow the evidence and give it precedence over gut feeling and anecdotal evidence. A scientific approach forms the underlying basis for an ethical practice.

Avoiding Discrimination

Multiple studies have shown the existence of differences in diagnosis and treatment of heart disease based on gender, race, and financial status. While this is not a consciously practiced discrimination most of the time, it is an ethical responsibility of the cardiologist to be aware of the existence of this and consciously take steps to avoid it.

Shared Decision-Making

The decision-making practice for many conditions is complex. Often there is a choice to be made between various available therapies and sometimes, an option of no treatment. Each treatment choice is associated with its attendant risks and benefits and sometimes the difference between these might be small and may vary depending on individual perception. The cardiologist should consider the subtle individual differences in the assessment of such risks and benefits that may exist between patients. In the absence of a clear choice of treatment, an approach of shared decision-making should be followed. The role of the cardiologist should not be to make the decision for the patient, but to provide adequate information for the patient to make the decision himself or herself.

Shared decision-making involves not just the provision of the requisite information to the patient, but also time and space to take decisions. For example, *ad hoc* angioplasty has been criticized on this ground because it is difficult, if not impossible for a patient to take a decision when lying on the table after a coronary angiogram. Therefore, this approach should be restricted to specific situations, with preference for a deliberate, joint decision-making process at other times.

Team Approach

The assistance of colleagues is often required for an ideal, ethical practice and the cardiologist should not shy away from obtaining it. An opportunity to obtain a second opinion should be freely provided to patients when necessary. Such a second opinion should also be obtained by the cardiologist when a choice needs to be made among different treatment options to reduce the chance of individual bias. For example, in a situation where there is a choice between a surgical or medical therapy, a surgical colleague may be consulted on the patient. While a colleague from a different field may have a very different view of the situation and this may be initially be uncomfortable to confront, such a different look will ultimately be of benefit to the patient. Joint meetings between the cardiologist and cardiothoracic surgeon were common and played an important role in decision-making in patients with coronary artery disease. As percutaneous

interventions have taken over a greater role in management of these patients, such meetings have become uncommon.

Performance Review

Periodic review of his or her own performance is important to do for every cardiologist. Clearly defined and objective key performance indicators may be used and provide an assessment of performance on an ongoing basis. Apart from this kind of self-audit, a periodic peer review process is also useful. In institutes and hospitals, this may take the form of group discussions where management of a patient is reviewed by multiple cardiologists.

Do No Financial Harm⁴

“Primum non nocere”, do no harm, is the cardinal rule in medicine. Today, healthcare cost is considered one of the most important forms of financial harm to a person and family. Cardiologists have an important role and an ethical responsibility to mitigate this harm. This involves being aware of the financial status of the patient and tailoring treatment strategies according to this information.

WHAT SHOULD REGULATORY BODIES DO?

The regulatory bodies have an important role as a watchdog to ensure ethical practice of medicine. The American College of Cardiology has published a code of ethics⁵ and similarly, code of ethics is published by the Medical Council of India.⁶ Such a code of ethics specific to Cardiology can be published by the Cardiology Society of India (CSI).

The American Heart Association (AHA) runs advocacy campaigns among cardiologists and the general public to raise awareness of health disparities and create health equity. Health equity is the term that has been coined to indicate that every patient should have the same opportunity for accessing healthcare. This is achieved by eliminating bias by age, gender, ethnicity, or other differences. The AHA also runs a program called “Get With The Guidelines” to ensure that hospitals follow evidence-based management of heart disease. Such initiatives should also be undertaken by the CSI to improve cardiac care in our country.

Certification by the regulatory bodies as is in vogue in the west will guide cardiologists on the procedures they are allowed to do and the competency required to do them and to maintain proficiency to continue doing them.

Medical Council of India and CSI should also lobby for and guide the inclusion of medical ethics in the curriculum for undergraduates and postgraduates in medicine. Apart from medical ethics, a case has also been made to include medical humanities in teaching including the history of medicine, medicine in literature, patients' perception of illness, life as a doctor and the art of doctoring, subjects which are covered poorly or not at all at present.

CONCLUSION

Cardiology has seen major technological advances in the last few decades, expanding the horizon of what can be done. In contrast, less emphasis seems to be placed on what should be done. Ethical challenges are mostly centered on this conflict between can and should. Cardiology, especially in today's times, presents various challenges to ethical practice. However, with a conscientious and diligent approach from cardiologists and regulatory bodies, this is a challenge that can be overcome and should be overcome.

SECTION **24**

Miscellaneous

Development of Cardiology and Interventions in India—An Insider's Glimpse

M Khalilullah

INTRODUCTION

Cardiology was part of medicine until late 1950s when cardiology lectures, bedside clinics, and even cardiac patients were treated by faculty of medicine and physicians at large.

In early 1960s, clinical cardiology was pioneered by Prof JN Berry from Nagpur and Chandigarh, Dr KK Datey and Dr Rustom Jal Vakil from Mumbai, Dr CRR Pillai and Dr Rajagopalan from Chennai, Dr DP Basu and Dr JC Banerjee from Kolkata, but it was Prof Sujoy B Roy at the All India Institute of Medical Sciences (AIIMS), New Delhi and Dr Kamla Vytilingam of CMC Vellore who introduced invasive cardiology and established first catheterization laboratory and pioneered hemodynamic studies. Dr S Padmavati started a catheterization laboratory in Lady Hardinge Medical College at the same time. The superspecialized departments of Cardiology ushered in an era of structured and focused training of cardiology by starting DM cardiology program. This involved in-depth training of clinical cardiology, electrocardiography, hemodynamic studies, and cardiology research programs.

First batch of DM cardiology students passed from AIIMS in early 1960s and then from CMC Vellore in mid-1960s. These two institutions trained true and dedicated cardiologists, who in turn became eminent teachers and trained hundreds of students who fanned out all over the country. Department of Cardiology started getting separated from departments of Medicine with qualified faculties and DM Cardiology program started spreading all over the country.

Prof Rajendra Tandon at AIIMS and Prof IP Sukumar at CMC Vellore pioneered the training in pediatric cardiology. First pacemaker implantation was carried out at AIIMS in April 1966, and first indigenous pacemaker (Khalil Mendes pacemaker) was developed in the same department. Cardiac pacing spread to other parts of the country, especially in Kolkata, and became the large turnover center. Some of the pioneering research of acute mountain sickness, high-altitude pulmonary edema, and high-altitude pulmonary hypertension were carried out by Prof SB Roy. Dr Padmavati,

who started her initial career at Lady Hardinge Medical College, became the Director Principal of Maulana Azad Medical College and GB Pant Hospital and soon started DM Cardiology program in 1970. Her pioneering work in rheumatic fever, school surveys of rheumatic heart disease, and prevention of rheumatic fever with establishment of All India Heart Foundation are huge contributions to the medical field. Her farsightedness and resourcefulness soon made GB Pant Hospital as the center of excellence with about the best training facilities in the country. Students who have qualified from this institution have spread all over the country and abroad, and are the epitome of excellence. Soon the DM training program started in Bengaluru, Hyderabad, Chennai, Mumbai, Jaipur, Lucknow, Kanpur, Kolkata, Thiruvananthapuram, Chandigarh, and many more centers all over the country. Clinical cardiac electrophysiology was started on March 5, 1975, at GB Pant Hospital and became the only center for training in electrophysiology. Soon electrophysiology developed in other parts of country such as Hyderabad, Bangalore, Mumbai, Thiruvananthapuram, Kolkata, Chennai, Ahmedabad both in government and private sectors and became the area of deep interest for large number of young cardiologists.

First catheter ablation was carried out in June 1984 using direct current (DC) shock and improvised DC energy delivery system in GB Pant Hospital and ushered in an era of therapeutic and interventional electrophysiology. At the same time, arrhythmia surgery was established for the first time in GB Pant Hospital where more than 50 patients with Wolff-Parkinson-White syndrome were treated by epicardial mapping and surgical/cryoablation. Many cardiologists got trained abroad and infused new talent in the field of electrophysiology and ablation.

First international conference on Interventional Cardiology was organized on April 1-4, 1985, preceded by a workshop in Interventional Cardiology with assistance of Dr James E Locke and Prof John Keane from Boston Children's Hospital and the first balloon procedure was performed in

India on March 23, 1985, in a patient with severe valvular pulmonary stenosis with suprasystemic Right ventricular (RV) pressure. This deeply blue child became pink instantly after pulmonary valvuloplasty and RV systolic pressure dropped from 180 to 65. Between March 27 and 30, five patients with rheumatic mitral stenosis were subjected to transseptal mitral valvuloplasty - three with single balloon and two with double-balloon technique. Thus the practice of balloon mitral valvuloplasty (BMV) was born. This has changed the entire management of rheumatic mitral stenosis, not only in the Indian subcontinent but the world over, although now the Inoue balloon is used all over the world.

The first case of balloon aortoplasty of coarctation of aorta was performed at GB Pant Hospital in June 1985 and this opened up a new chapter in the management of coarctation of aorta. Soon balloon dilatation technique was attempted in aortic stenosis in operation theater and the balloon was introduced in the stenosed aortic valve and inflated. The aortic cusps got beautifully separated. This was followed by percutaneous balloon aortoplasty of valvular, membranous subaortic stenosis, and supravalvular aortic stenosis; renal artery stenosis was treated with balloon angioplasty along with iliofemoral arterial stenosis.

In December 1985, balloon dilatation of aortoarteritis was established and this pioneering work was published in Circulation in 1986. We had the largest experience of adult coarctation and aortoarteritis probably in the world. Patients with tricuspid stenosis were subjected to double-balloon valvuloplasty, at GB Pant Hospital again the first time in the history.

In 1987, a team from Texas Heart Institute, Houston arrived in GB Pant Hospital comprising Dr Mike Duncan, Cardiac Surgeon, Dr VS Mathur, Cardiologist, Dr Sabavala, Cardiac Anesthetist, and a senior OT nurse for a 2-week workshop on coronary angioplasty and coronary artery bypass grafting (CABG).

During this 2-week workshop, 15 cases of Percutaneous transluminal coronary angioplasty (PTCA) and ten patients were operated for CABG and thus began the era of coronary interventions in India. About the same time Dr Samuel Mathews did his first case of PTCA in Mumbai. Soon a group of cardiologists and cardiac surgeons got trained in PTCA and CABG and the country began to offer PTCA and CABG at many centers in Delhi, Mumbai, Hyderabad, Bangalore, Kolkata, Chennai, and others. In 1988, rotablation started and Dr Gary Ruben brought the rotablator technique to be started in GB Pant Hospital. Dr DS Gambhir was first to be trained in rotablation.

Having achieved a great success in balloon dilatation of valvular stenosis and peripheral arteries, the first neodymium-doped yttrium aluminum garnet (Nd:YAG) laser equipment arrived in GB Pant Hospital and Nd:YAG laser-assisted peripheral angioplasty in 1988, especially chronic total occlusion (CTO) of iliofemoral arteries, was successfully performed along with total occlusion of aorta in eight patients.

Prof John Keane of Boston's Children's Hospital arrived in GB Pant Hospital to start the program of percutaneous closure of patent ductus arteriosus (PDA) using Rashkind's umbrella device. Several cases were performed in GB Pant Hospital and I had the opportunity to demonstrate this technique in Sri Lanka, Peshawar, and in Jayadeva Institute of Cardiology in Bengaluru. I had overheard that a Greek doctor named Dr EA Sideris has developed a kite-shaped device for closure of atrial septal defect (ASD) secundum. He was invited to GB Pant Hospital in 1991 and 15 cases of ASD secundum were successfully closed in 5 days using this occluder and counter-occluder on a button device, and thus percutaneous closure of ASD started in India.

Sideris device of small size was also used to close large PDAs and even acquired ventricular septal defect (VSD) following anterior myocardial infarction. This is the first-ever device historically used to close ASDs. Subsequently, Amplatzer device for PDA and ASD closure was introduced which was easy to handle and retrievable and has been widely used all over the world. This also enabled submembranous VSD to be closed percutaneously. Devices are being used for closure of rupture of sinus of Valsalva, pulmonary arteriovenous (AV) fistula, and vascular plugs have been used to block AV malformations in liver, kidney, and large subcutaneous malformations.

Coronary stents emerged in the later part of 1990s and again Gary Ruben from Atlanta brought two stents to be implanted in GB Pant Hospital. Samuel Mathews was the first to popularize this technique and soon stenting became an addition to PTCA. Peripheral stents became available for peripheral angioplasty including renal artery stenosis, iliofemoral stenosis, coarctation of aorta, aortoarteritis of aorta, and peripheral arteries. Soon carotid artery stenting started in carotid stenosis.

Doctor Tejas Patel from Ahmedabad was the first to start radial artery approach to coronary angiography and angioplasty and complex CTO interventions with the help of Japanese cardiologists. Today the radial approach has become the route of choice for coronary angiography and interventions all over the country; credit of this revolution should entirely go to Dr Patel.

IMPLANTABLE VALVES

After Dr Alain Cribier implanted an aortic valve percutaneously in aortic stenosis, this technique has slowly grown in India. Although expensive, but in patients with serious comorbidities and inoperable patients, this has been a great relief in patients with aortic stenosis. Dr Ashok Seth from Escorts Heart Institute and Dr Praveen Chandra from Medanta Heart Institute have been pioneers in this area and this technique is now being performed in Kerala, Bangalore, and Tamil Nadu. First-ever pulmonary valve implantation has been carried out by Dr Radhakrishnan at the Pediatric Cardiology Department of Escorts Heart Institute this year.

LEFT ATRIAL APPENDAGE CLOSURE

Stroke prevention in atrial fibrillation (AF) in nonvalvular AF has been a cause of concern because of high morbidity and mortality. To prevent the cerebral embolization of thrombus from left atrial (LA) appendage, LA appendage closure has been started by Dr Balbir Singh at Medanta Heart Institute using Watchman's device and this is now being done in several centers in the country.

INTERVENTIONAL ELECTROPHYSIOLOGY

Even since the first DC ablation of paroxysmal supraventricular tachycardia was performed at GB Pant Hospital in 1984, interventional electrophysiology has grown extensively with the availability of variety of hardware, in-depth understanding of genesis and perpetuation of arrhythmias, and advances

of imaging techniques with 3-D cardiac mapping, it is now possible to treat all types of SVT, atrial flutter, and AF. Pulmonary vein ablation has improved success rate of ablation of AF.

Ventricular ectopy and ventricular tachycardia can also be cured by ablation techniques. There are centers all over the country where enormous work has been done, which are also proving to be the advanced training centers for a young electrophysiologist.

The automatic implantable cardioverter-defibrillator (AICD) implantation started in 1980s and has been established all over the country. Lately, noninvasive ICD and implantable and leadless pacemakers have been added as newer therapeutic tools.

Interventional cardiology has been established in the country as an alternative to cardiac surgery in a large variety of cardiovascular diseases.

Evidence-based Medicine: Are Randomized Controlled Trials the Gold Standard?

Vitull K Gupta, Meghna Gupta, Varun Gupta

HISTORY OF EVIDENCE-BASED MEDICINE

Medical progress and teachings through the centuries, since the time of Hippocrates, have been based on experiences and authority of eminent physicians, without any solid scientific basis, struggling to balance the uncontrolled experience of healers with scientifically trustworthy empirical evidence. So entrenched was evidence-based medicine that it took more than a millennia for Vesalius (1514–1564) to contradict successfully the teachings of Galen.¹ Since 11th century, testing medical interventions for efficacy has existed, but in 19th century, the systematic application of evidence to medical situations first occurred in the field of epidemiology. The idea of science in medicine was promoted by Rudolf Virchow, Claude Bernard, and Louis Pasteur in Europe and in early 20th century the Flexner report consolidated the concept of scientific inquiry in American medicine. Until recently, solid scientific evidence for many treatments did not exist and the principles governing such evidence did not even emerge until 1948 when the first randomized controlled trial (RCT) was performed. In 1962, US Food and Drug Administration Kefauver-Harris Act was passed in the USA, legally necessitating rigorous clinical trials in human beings to establish claims regarding drug efficacy.² David Sackett, David Eddy, and Archie Cochrane in 1970s and 1980s stressed on the need for strengthening the empirical practice of medicine and proposed initial evidentiary rules for guiding clinical decisions.^{3–5} David Eddy first used the term “evidence-based” in 1990⁶ and in 1992, the term “evidence-based medicine (EBM)” first appeared in the medical literature in a paper by Guyatt et al.⁷ Evidence-based medicine focused on educating clinicians in assessing the credibility of medical research, understanding the results of clinical studies and determining how best to apply the results to their everyday practice.⁸ Evidence-based medicine rapidly transformed into an energetic intellectual community committed for more scientific and empirically based clinical practice with

an aim to achieve safer, consistent, and cost-effective care.⁹ Evidence-based medicine caused shift in medical paradigms suggesting that clinical decision-making should be based on scientific evidence and not on intuition, clinical experience or unscientific pathophysiologic rationale. More and more, clinicians are moving away from using time honored but unproven practices in clinical decision-making to using the most valid and reliable scientific information available. The key words are validity and reliability.¹⁰

WHAT IS EVIDENCE-BASED MEDICINE?

Centre for Evidence-based Medicine defines EBM as, “Evidence-based medicine is the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients”.¹¹

Best research evidence means clinically relevant research which is patient centric; it includes clinical examination, diagnostic tests, prognostic markers, the efficacy and safety of therapeutic, and rehabilitative and preventive regimens. New evidence generated by clinical research both invalidates and replaces old but accepted concepts in diagnostics and therapeutics with more accurate, safe, and powerful new ones.

Clinical expertise means the ability to utilize experience and clinical skills to identify patient's health status, diagnosis of the diseases, their individual risks and benefits of treatment according to their personal values and expectations.

Patient values mean consideration of patients concerns, preferences, and expectations integrated into clinical decisions.

With integration of these factors, a diagnostic and therapeutic alliance is formed between the clinicians and patients helping optimize clinical outcomes and quality of life (QoL).¹² Practice of EBM requires expertise in clinical sciences, expertise in collecting, retrieving, interpreting the data, and applying the results of scientific research in clinical practice and in communicating the patients about the risks and benefits of different courses of action.

"Half of what you are taught as medical students will in 10 years have been shown to be wrong. And the trouble is none of your teachers know which half."

Dr Sydney Burwell (1956),
Dean, Harvard Medical School

CLASSIFICATION OF EVIDENCE-BASED MEDICINE

Two types of EBM have been proposed:¹³

1. *Evidence-based guidelines:* At organizational or institutional level, EBM is practiced through evidence-based guidelines (EBG) or clinical practice guidelines (CPG) including the production, policy, and regulations of guidelines also known as evidence-based healthcare. In 1990, advisory committee of the Institute of Medicine issued a report which defined practice guidelines as: "Systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances"¹⁴
2. *Evidence-based individual decision-making:* When individual healthcare provider practices EBM, it is known as evidence-based individual decision (EBID) making and currently EBM focuses excessively on EBID.

QUALIFICATION OF EVIDENCE

A cornerstone of EBM is the hierarchical system of classifying evidence. This hierarchy is known as the levels of evidence (LoE) which is an important component of EBM. Different types of clinical evidence are categorized and ranked according to the strength of their freedom from the various biases that beset medical research. A system was developed by the US Preventive Services Task Force to classify the evidence based on quality and evidence was ranking according to the effectiveness of treatments or screening:

- *Level I:* Evidence generated by minimum of one properly designed RCT
- *Level II-1:* Evidence generated by nonrandomized well-designed controlled trials
- *Level II-2:* Evidence generated by preferably more than one research groups of centers which are case-control analytic studies or well-designed cohort studies
- *Level II-3:* Evidence generated from studies with or without intervention including multiple time series and uncontrolled trials expressing dramatic results
- *Level III:* Observations of learned authorities, based on expert committee reports, experience, or descriptive studies.

Similarly categories A, B, C, and D were developed by the UK National Health Service. Levels of evidence related to the design of the study and critical analysis of diagnosis, therapy, prevention, prognosis, and harm studies was developed by Oxford Centre for Evidence-based Medicine.¹⁵ The levels are:

- *A Level:* Relates to cohort studies, clinical RCTs, all or none and validated clinical decision guidelines or rules in different populations

- *B Level:* Relates to evidence extrapolated from level A study or exploratory or retrospective cohort, outcome research studies, ecological study or case-control study
- *C Level:* Relates to evidence extrapolated from level B study or case series study
- *D Level:* Relates to first principles, expert opinion without explicit critical appraisal, or based on bench research or physiology.

Several other methods, categories or classifications for LoE are adopted by various organizations and journals. Research questions are divided into the categories: treatment, prognosis, diagnosis, and economic or decision analysis. Detailed discussion on LoE is not in the preview of this chapter.

STATISTICAL MEASURES IN EVIDENCE-BASED MEDICINE

Mathematical methods and tools used by practitioners of EBM to express various interventions, clinical benefits of tests, and treatments are:

- *Likelihood ratios:* Post-test probability is determined by likelihood ratio multiplied by the pretest probability of a specific diagnosis, which is reflecting the Bayes' theorem. Usefulness and priority of a clinical test in a clinical scenario is determined by the differences in likelihood ratio of those clinical tests
- Relationship between specificity and sensitivity of a test is determined by the area under the receiver operator characteristic curve (AUC-ROC) and it approaches one for high-quality tests and publications. Cutoff values for both negative and positive tests do not affect AUC-ROC, but can influence sensitivity and specificity.

Safety and affectivity of an intervention in a clinically meaningful way is expressed by number needed to harm or number needed to treat (NNT). Generally, NNT is used to analyze data in relation to study two treatments A and B, one of which is a drug and other is a placebo. A defined endpoint has to be specified. If the probabilities pA and pB of this endpoint under treatments A and B, respectively, are known, then the NNT is computed as $1/(pB-pA)$.

HOW DO WE ACTUALLY PRACTICE EVIDENCE-BASED MEDICINE?¹⁶

Five steps or Principles are important for practice of EBM:

- *Step 1:* Construct a well-built clinical question and classify it into one category (therapy, diagnosis, etiology or prognosis)
- *Step 2:* Find the evidence in healthcare literature
- *Step 3:* Critically appraise or formally evaluate for validity and usefulness.
- *Step 4:* Integrate the evidence with patient factors to carry out the decision.
- *Step 5:* Evaluate the whole process.

TYPES OF RESEARCH STUDY DESIGNS¹⁷

There are various types of study designs and some are superior to others in context of nature of the study and answering specific questions.

- *Randomized controlled trials*: (Quires related to prevention and treatment is answered by RCTs). Bias in selection is avoided by randomization
- *Cohort study*: (Quires related to etiology, prognosis, and prevention is answered by cohort studies). Cohorts are the research design to the subgroup characteristics in populations as a whole and over a specific period of time, two groups are compared and results analyzed
- *Case-control study*: (Quires related to etiology, prognosis, and prevention is answered by case-control studies) Research related to case-control studies are studies compare the patients with problem and controls without that problem and analyze the results
- *Case series and case reports*: (Quires related to etiology, prognosis, and prevention is answered by case series or reports). Research related to case series including several patients and case reports of a single patient.

Randomized Controlled Trial

It was initially introduced into clinical medicine for the evaluation of the efficacy of streptomycin for tuberculosis in 1948.¹⁷ Further progress in understanding the strength of various study designs has resulted in RCT being the method of choice to assess the efficacy of interventions. Professor Archie Cochrane, a Scottish epidemiologist, through his book Effectiveness and Efficiency: Random Reflections on Health Services (1972) and subsequent advocacy caused increasing acceptance of the concepts behind evidence-based practice. The explicit methodologies used to determine "best evidence" were largely established by the McMaster University research group led by David Sackett and Gordon Guyatt.

LIMITATIONS OF EVIDENCE-BASED MEDICINE

Practice of EBM by clinicians has led to both negative as well as positive reactions. Universal limitations to science and medicine are: shortage of coherent, consistent scientific evidence, difficulties in applying any evidence to the care of individual patients, and barriers to any practice of high-quality medicine.

Practice of EBM specifically encounters unique limitations⁶ like difficulty in developing new skills in searching and critical appraisal of scientific evidence, availability of little time for busy clinicians to master and apply these new skills and instant access to scientific evidence and information is often inadequate in clinical settings. The generation of data and scientific evidence on which EBM depends is a slow process. Biggest challenge faced by physicians today is related to application of EBM in solving multimorbidity problems faced by aging populations, which the current generalized EBM guidelines are unable to solve effectively.¹⁸ Moreover generalized guidelines may not be

good for patients with multiple morbidities because many conflicting therapies may be needed which may not fit the actual requirements of the patient. It is simply not possible or feasible to develop trials which may include all potential disease combinations.^{19,20}

APPLICATION OF EVIDENCE-BASED MEDICINE IN DEVELOPING COUNTRIES LIKE INDIA

Foundation of EBM is based on systematically reviewed information generated from RCTs and meta-analysis and should be applied cautiously in the context of developing countries. Randomized controlled trials conducted in other countries like Europe or North America ignores well-documented issue of racial differences in therapeutic responses and survival rates and morbidity statistics are not directly applicable across races especially when geographical and cultural differences between continents are considered.

Based on their perceptions of health and illness, researchers of Europe or North America have developed QoL measures, which are used in some studies and their use in scientific research across continents and countries is questionable because these life measures are value-based and culturally sensitive.

CAN EVIDENCE-BASED MEDICINE BE INFLUENCED?

Many health professionals have expressed doubts about infiltration of medical research institutions and influence on peer-review process to promote drugs marketed by pharmaceutical companies undermining the validity and veracity of peer-reviewed research and so subverting the foundation of EBM.²¹ Medical scientists believe that industry-influenced studies camouflage or eliminate unfavorable results, remodeling the data to present favorable results to create "hyped" medications.²² It is believed by internists like John Abramson²³ that every aspect of health care, medical education, and basic research has been influenced by the pharmaceutical industry so much so that prominent and influential researchers are endorsing questionable studies and also influencing the mechanisms of evaluation of effective treatment for widely accepted illnesses.²⁴ Evidence-based medicine, a product of objective research, if conducted by disinterested medical researchers or under the influence of pharmaceutical industry or sponsored clinical trials, can have a corrosive impact both on physicians and the evidence itself. Results of all clinical trials are not published, particularly the pharma sponsored trials which do not show benefit of an agent.²⁵ In January 2006, an article was published in JAMA by imminent personalities sighting concerns about EBM being influenced and suggested a number of measures for protection of researchers and scientists from adverse influence of pharmaceutical industry on medical research.²⁶ Such a communication expressed increasing concerns of prominent medical researchers and faculty regarding growing risk of influence of pharmaceutical industry on EBM.

PHARMA INDUSTRY, RESEARCH, AND EVIDENCE-BASED MEDICINE

Funding of medical research by pharmaceuticals has been shown to have propharmaceutical results in several systematic reviews. Several causes like bias in trial protocols, results and publications have been documented expressing close relationship and influence of pharmaceuticals on medical research.²⁷ Statistically significant relationship was found between the study results and funding authority, like industry-selected drugs were likely to be proved more efficacious, in spite of the flawed study results, because scientists feared stoppage of funds in case of unfavorable results expressed by the study.²⁸ Influence of funding source on decision-making by the researcher has been documented in a number of research papers. Data analysis related to faculty of internal medicine at seven Midwest US teaching hospitals has shown that pharmaceutical support was an independent risk factor for making requests for formulary additions.²⁹

ARE RANDOMIZED CONTROLLED TRIALS THE GOLD STANDARD?

What is “Gold Standard”?

The original gold standard was a monetary system where currency was based on a fixed quantity of gold. The gold standard allusion derives from international finance, in which the rates of exchange among national currencies were fixed to the value of gold. Actual gold standard is the technique of international finance that links the value of a nation's currency to a set amount of gold, facilitating exchange between different currencies. The gold standard system collapsed in 1971 following the United States' suspension of convertibility from dollars to gold and in 1976 US revised its definition of the dollar to remove all references to gold.

Randomized Controlled Trials as the “Gold Standard”

In 1747, James Lind conducted the first reported clinical trial in the history to identify treatment for scurvy.³⁰ In 1865, Claude Bernard published the general guidelines of modern experimental medicine³¹ and in 1948 the paper entitled “Streptomycin Treatment of Pulmonary Tuberculosis” became the first published RCT in medicine.¹⁸ After that, RCTs were increasingly being recognized as the standard method³² providing the most rigorous test for preventive, diagnostic, and therapeutic interventions and generally referred to as the “gold standard” for clinical trials. Post World War II the importance of RCTs became critical especially in 1962 when the US Food and Drug Administration made well-controlled studies or RCTs mandatory before new drug approval as a proof of efficacy which lead to explosive increase in importance of RCTs throughout the world so much so that by 1990s most of the RCTs were funded by the pharma industry as compared to the government and academic bodies.³³ Over the past 70 years, RCTs have influenced medical research,

knowledge, and clinical practice and since then researchers have introduced many different clinical trial methods and innovative statistical methods to eliminate bias.³⁴ Over time, international standards for clinical research were established in collaboration with the national bodies systematizing RCTs and RCTs were increasingly being promoted as the best means to achieve EBM with case reports at the bottom of methodological hierarchies and RCTs at the top.³⁵

By early 1980s, government authorities and scientific associations responsible for methodological quality review and ranking of research studies gave RCTs the status of gold standard for therapeutics, medical research, and knowledge.³⁶ For the past two to three decades, medical and government organizations consider RCTs as a method for generating scientifically valid and reliable evidence about the usefulness of almost any type of therapy or for specific comparisons between treatments. Randomized controlled trials have achieved the status of gold standard of scientific evidence because RCTs employ randomization across study arms, eliminate patient-treatment selection bias, resulting in reliable causal inference. Randomized controlled trials challenged the popular beliefs of treatment like in Cardiac Arrhythmia Suppression Trial (CAST) conducted in 1989 in which the effect of antiarrhythmic drugs was tested versus a placebo in myocardial infarction patients. It was a known fact that ventricular arrhythmias were a poor prognostic factor in myocardial infarction and it was believed that suppressing ventricular arrhythmias will decrease the mortality rate. But the results of the trial showed about 3-fold increase in total mortality in patients on antiarrhythmic drugs. So, the use of antiarrhythmic drugs for treatment of ventricular arrhythmias in myocardial infarction became contraindicated.³²

Limitations of Randomized Controlled Trials as Gold Standard

With increasing popularity of EBM, there was emergence of methodological hierarchies with RCTs at the top and case reports at the bottom. Despite being at the top of methodological hierarchies, RCTs have substantial limitations which challenge their “Gold Standard” status and RCTs have never been able to monopolize medical knowledge production especially now with the emergence of registries, electronic data bases, randomized registry trials, and other modes of production of knowledge and research in medicine. Major limitations of RCTs relate to scientific limitations, cost, and practicality. Scientific limitations relate to RCT patient population which may not represent the patient population in practical world. Tightly controlled environment, limited patient population, clearly defined inclusions and exclusions like age limits, the presence or absence of comorbidities, the concomitant use of drugs, a range of clinical and biochemical criteria, treatment of patients according to detailed protocols, making it impossible to follow the tight RCT criteria in clinical practice. The results of a single RCT may not be generalized to different populations and establishes only one data point. Moreover the outcome results of RCTs may be of interest to researchers and may not be of interest to actual patients in real practice.

It may not be feasible to conduct an RCT in rare diseases as it may not be possible to recruit a sufficient number of patients to randomize across multiple treatment possibilities. Different approaches for clinical research have been experimented for the past several years and more flexible and acceptable new study designs have been developed to extract useful data from patient registries and electronic medical records which has erode the status of RCTs as a gold standard. Practice of personalized medicine focusing on several individual factors for determining the diagnostic and therapeutic strategies may not be influenced by the results of RCTs which analyze typical patients in a controlled environment.³⁷ Status of observational studies or nonrandomized trials in evaluating treatments is being debated and studies found greater effects of the same treatment comparisons in observational studies than in RCTs.^{37,38} No difference was found in two studies comparing the treatment effects between RCTs and nonrandomized trials, but these findings were not confirmed by the two studies comparing individual RCTs with observational studies in 19 therapeutic areas³⁹ and meta-analyses of RCTs with meta-analyses of cohort and case-control studies in five therapeutic areas.⁴⁰

No major differences were found between the estimates of treatment effects in the observational studies and RCTs. Previous systematic review estimating the effects of treatment in 22 areas, found no consistent difference between RCTs and observational studies. Evidence-based medicine popularly projecting that observational studies produce inferior results than that of RCTs may be misleading.⁴¹ Greater effects in five of the nonrandomised trials were found in a systematic review, which compared same intervention in eight RCTs with nonrandomised trials.⁴²

Comparison of different types of research modalities like RCTs, cross-sectional studies, cohort studies, and case-control studies shows that potential for external validity was more in cross-sectional studies, cohort studies, and case-control studies than RCTs, that is, the data can be extrapolated to a higher degree in general population. All the three study designs have the limitation of a lower internal validity, because the bias and confounding variables are difficult to eliminate and/or control.⁴³ Internal validity is more in a single well-done RCT as it is done for a specific intervention, for a specific sample, at a specific time and place producing valid results about that intervention only in that specific setting. For this reason most of the single RCTs lack external validity.⁴⁴ But other researchers suggest that strength of the instructional design and learning theory incorporated in the intervention can help guide which RCTs are carried out to establish external validity.⁴⁵ Registry studies are an important modality with several advantages for population-based case-control studies but are not free from bias.⁴⁶ The advantages of registry studies are large sample sizes, systematic data collection, faster studies, low costs, studies of rare effects and rare diseases is possible, informed consent is not required, and the analysis of long-term effects can be done easily. So, it is argued that relative importance of different research methodology is an unnecessary distraction and diverse

approaches should be accepted for providing evidence basis for modern therapeutics replacing hierarchies of evidence.⁴⁷

Randomized controlled trials were described by Feinstein and Horwitz as an elusive ideal research method in many circumstances and not as a gold standard, but supported other clinical epidemiological research designs and remarked, "epidemiological research has become increasingly important because it offers a substitute for the unattainable scientific gold standard of a randomized experimental trial". New methodology of observational research producing large comparative data from extensive databases of patients on different treatment outcomes in routine healthcare settings continued to emerge.⁴⁸ Intuitive logic of the techniques and angiography provided visual evidence to promote coronary angioplasty and stents and not the RCTs.⁴⁹

Randomized controlled trials became standard modality in pharmaceutical research, but medical scientists struggled to apply them in other fields of medicine. Though numerous RCTs were conducted but were thought to be inappropriate and sometimes impossible to study highly individualized and long-term effects of psychotherapy and methodological concerns undermined major psychotherapy trials.⁵⁰ Disproportionately more robust data on psychotropic drugs than psychotherapy was generated because of easy to conduct RCTs on psychotropic drugs as compared to psychotherapy which benefited pharmaceuticals and lead to suboptimal use of comprehensive psychiatric care.⁵¹ Similar limitations were faced by RCTs in surgery because pathological findings were different in different patients, surgical skills vary from surgeon-to-surgeon and numerous different choices existed for premedication, anesthesia, instrumentation, surgical approach, and postoperative care. All these different factors prevented standardization required for clinical trials.⁵² Sham controls could not be used for major operations, which limited blinding of trials.

Large studies with benefits of RCTs in low-cost are possible with the data from patient registries and electronic health records like a study explored outcomes of treatment for type 2 diabetes showing that thiazolidinediones were much more effective in reducing hospitalization and death than sulfonylureas using the data from the Veterans Health Administration and Medicare. When RCTs are given undue importance, ignoring other rigorously generated evidences, misconceptions like whether tobacco has adverse health effects or soft drinks do not cause obesity crop up. Progressively, RCTs became costly requiring massive bureaucratic and corporate support for infrastructure, record keeping research design, ethical review, and statistical analysis. Presently, the cost estimate for a single phase three RCT could be 30 million dollars or more⁵³ which resulted in high cost of prescription drug without any price controls. Because of high-cost involved in conducting RCTs, a clinical trial industry came into being and contract research organizations (CROs) become a \$25 billion industry.⁵⁴ Consequently the research was shifted from teaching and academic hospitals involving physicians and scientists to private sector employing nonacademic physicians on

a contract basis.⁵⁵ With high cost involvement, much of the clinical research is focused on drugs with substantial marketing potential rather than drugs with limited impact on public health like tuberculosis and malaria. In present scenario, the global knowledge production is dependent on the industry which has raised public health and ethical questions regarding the role of RCTs in benefit of public health. Evidence suggests that the RCTs which are funded by the private industry are likely to produce favorable results as compared to public-funded trials⁵⁶ and industry has substantial interests in publishing positive results than negative conclusions which is extremely damaging to medical research and knowledge.

Randomized controlled trials sometime have practical difficulties as they can take many years to complete or not long enough to study long-term beneficial or adverse effects of an intervention such as vaccine immunity. Results of RCTs may be valid only for a specific population like trial results in high-risk population may not be applicable or relevant in low-risk population. Practical difficulties arise if RCTs are planned for population-wide interventions or urgent health issues such as infectious disease outbreaks, for which urgent public health decisions are required.

Patient's environment may influence many complex treatments making even cluster randomized trials impossible. No study design is perfect because different research requires different methodology and patients respond differently to different therapy in practice compared to therapy during trials and responses are influenced by age of the patient and presence of multiple diseases.⁵⁷ So, we suggest new and revolutionary innovation in EBM, like system dynamics and narrative, complementary research paradigms of complexity science, combination of research methodologies, and qualitative approaches to deliver meaningful evidence to help clinicians in daily practice.

CONCLUSION

Evidence-based medicine has been considered as the gold standard parameter in taking decisions and standard healthcare practice. Randomized controlled trials are generally considered as the basic research tool related to EBM. Randomized controlled trials are specifically useful in the diseases caused by single factor or acute diseases treated by single modality, but are not so useful in studies related to chronic and multimorbidity diseases especially in epidemiological context. Evidence-based medicine generally do not give importance to local conditions, social factors influencing health, and effect of various factors related to healthcare services. There is no single or best approach to obtain better information about health interventions. Evidence grading systems, policy makers, and researchers must embrace other study types in addition to RCTs. Review of literature suggests and supports a flexible approach in which RCTs, observational studies, and other type of research methodology have complementary roles. Glorifying RCTs above other approaches, even when these other approaches may either be superior or the only practical

way to get an answer may force us to accept the evidence that is not based on best available evidence. An approach that uses all appropriate evidence types and builds on the existing evidence base using proven best practices is the one most likely to result in clinical and public health action that will save lives.

"Evidence-based practice", should be the valid ideal aimed to implement best proven clinical care and public policy interventions, but it is also important to develop "practice-based evidence", exploring and implementing programs in practice to generate data and document whether it is beneficial or not for the patients. Such interventions will help save lives and expand the data base.

Erectile Dysfunction in a Cardiac Patient

Ranjit K Nath, Neil Bardoloi

INTRODUCTION

Erectile dysfunction (ED) is not very uncommon among cardiac patients and is linked with a lack of complete physical well-being. Its incidence is expected to increase significantly along with the increase in various lifestyle diseases. Indian men are known to be at a much higher risk of coronary artery disease than men in most other countries; a biological risk factor has been postulated. The increase in risk is found from fourth decade of life onwards, when most men are still sexually active. As coronary heart disease (CHD) and ED may share a common etiology of atherosclerosis, ED attributed to atherosclerosis may be commoner in India than elsewhere in the world.

Male sexual function is a complex phenomenon that includes libido, erection, and orgasm and impairment of any of these components may lead to impaired sexual health, which can be temporary or permanent, leading to impotence. ED is defined as a lack of ability to sustain or maintain penile erection for sufficient amount of time, which leads to unsatisfactory sexual intercourse. It affects almost 26 cases per 1,000 men-years, and annual incidence rate increases with each decade of age. Also the incidence increases gradually with increasing age, lower level of education, diabetes, heart disease, and hypertension.¹ India has been dubbed as the impotence capital of the world due to the high incidence of the lifestyle diseases and probably the largest population of males affected by impotence in the world. Lack of awareness about the problem and very low therapy utilization rates along with poor compliance make it difficult to treat.

Cardiovascular disease (CVD) remains a source of considerable morbidity and mortality despite advances in prevention, diagnosis, and treatment. ED and CVD are the result of common risk factors like increasing age, high blood pressure, diabetes, hypercholesterolemia, use of tobacco, obesity, metabolic syndrome, lack of physical activity, and depression.² CVD and ED are said to be the result of a same pathophysiological mechanism of causation and

progression. Many studies have shown that ED is common in men who are already suffering from atherosclerotic CVD and so, it can be considered as an independent risk marker for CVD in future.²

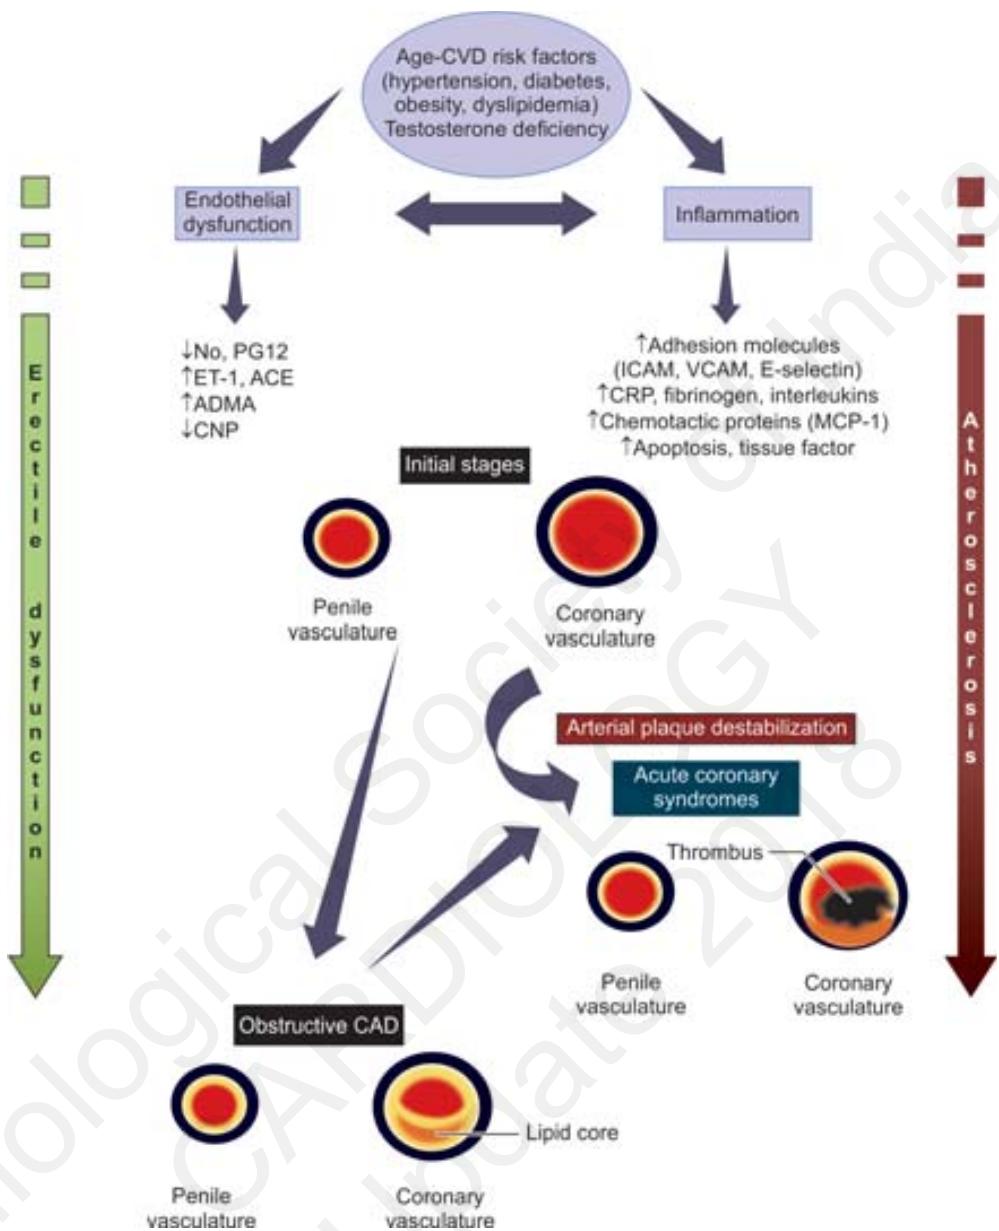

ETIOLOGY

Erectile dysfunction can be the result of a broad spectrum of disorders, which interplays significantly among them and there are lot of overlaps. The causes can be simple, related to the sex organs or complex, related to the physiology of erection, where psychological factors play an important role and can be divided as:³

- Organic causes:
 - Vascular (endothelial dysfunction, atherosclerosis)
 - Hormonal (hypogonadism, hyperprolactinemia)
 - Neurogenic (Parkinson's disease, multiple sclerosis, spinal cord disorders, etc.)
 - Drug-induced
 - Local causes (carcinoma of prostate, disorders of the penis).
- Psychological causes:
 - Performance anxiety
 - Depression
 - Partner-related problems
 - Psychosocial stress.
- Mixed.

PATHOPHYSIOLOGIC BASIS OF ERECTILE DYSFUNCTION AND CARDIOVASCULAR DISEASE

The association between ED and CVD is said to be because of their similarity in pathophysiological and clinical features (Fig. 1). Vascular cause of ED is said to be the result of impaired endothelial-dependent smooth muscle relaxation (functional ED of vascular cause), or due to narrowing or

CVD, cardiovascular disease; CAD, coronary artery disease; NO, nitric oxide; PGI₂, prostaglandin I₂; ET, endothelin; ACE, angiotensin-converting enzyme; ADMA, asymmetrical dimethylarginine; CNP, C-type natriuretic peptide; CRP: C-reactive protein; MCP, monocyte chemoattractant protein; ICAM, intercellular adhesion molecule; VCAM, vascular cell adhesion molecule.

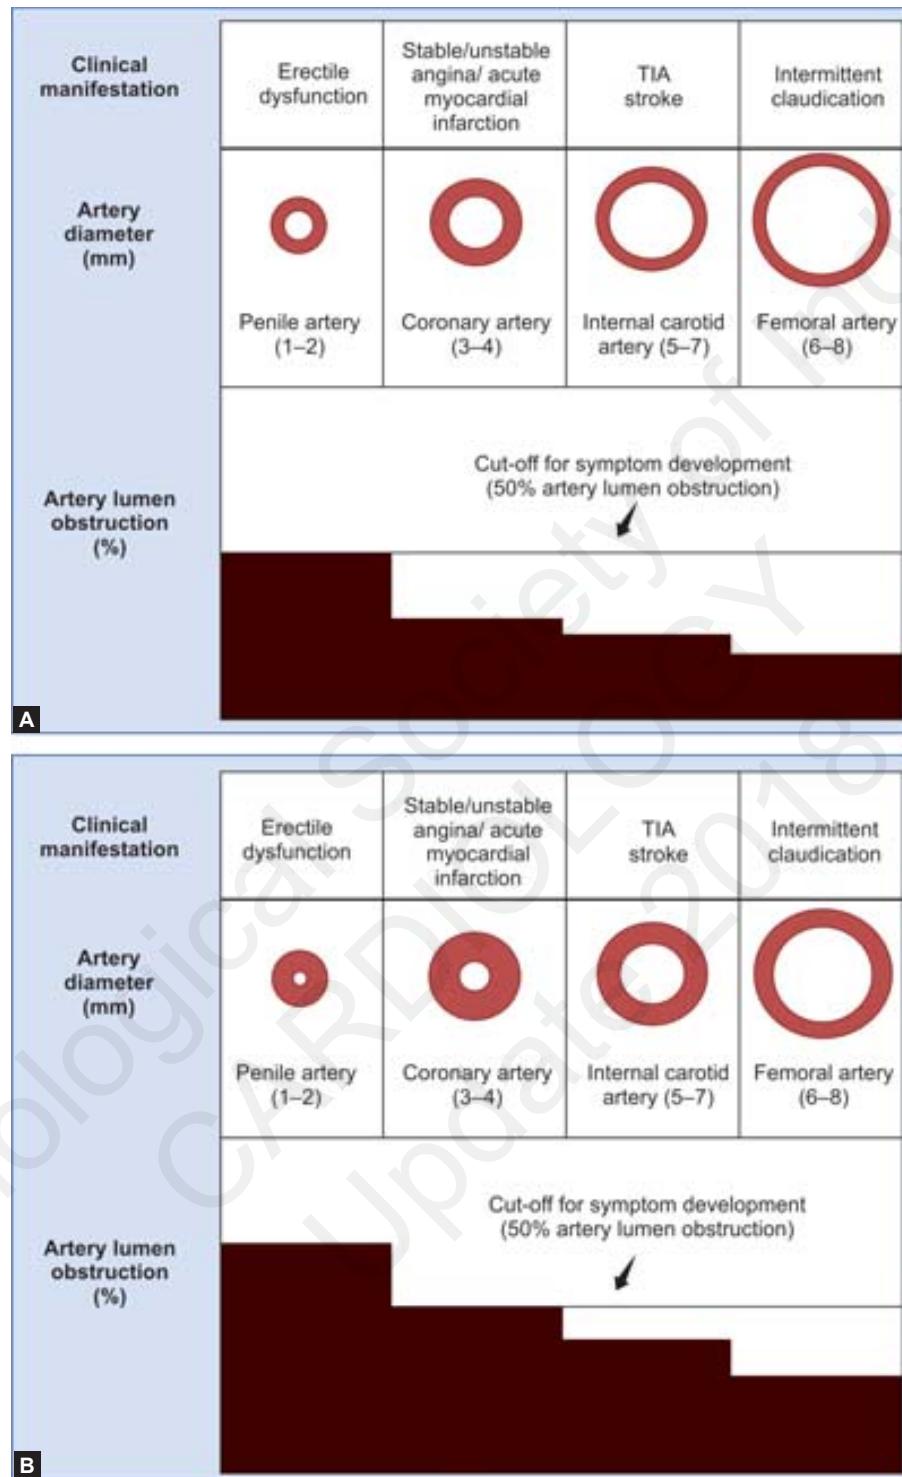

FIG. 1: Association and interplay between different risk factors, inflammatory markers, and pathophysiology of erectile dysfunction and coronary artery disease.

occlusion of arteries of penis by the atherosclerotic process (structural ED of vascular cause) or a combined mechanism of both these causes. Patients with ED show increased inflammatory and endothelial-prothrombotic activation, which is thought to be responsible for altered activity of smooth muscle cells and endothelial lining of target organ arteries. This leads to endothelial dysfunction, which is observed in men with or without CAD.⁴ Hence, endothelial

dysfunction acts as the common pathophysiological similarity between ED and CVD. Endothelial dysfunction is said to be the initial stage of atherosclerosis and affects all arterial vascular tree including penile, coronary, and other vascular structures including peripheral vascular bed.

Montorsi et al.⁵ postulated the artery size hypothesis, related to the involvement of the particular arteries of target organs, explaining that equal amount of atherosclerotic

TIA, transient ischemic attack.

FIG. 2: The “artery size” hypothesis. Equal amount of atherosclerotic plaque burden may produce clinical features earlier; **A**, in small caliber cavernosal arteries than; **B**, in large lumen coronary arteries.

burden may cause critical narrowing or occlusion of a small lumen artery like penile artery, whereas, it may not be sufficient to occlude or critically narrow a large lumen artery like the coronaries or other peripheral arteries (Fig. 2). So,

when there is 50% narrowing of the lumen of an artery, large vessels may not develop symptoms due to large luminal size, but there will be significant reduction in lumen size in small caliber arteries like cavernosal arteries leading to symptoms.

ERECTILE DYSFUNCTION WITH ESTABLISHED CARDIOVASCULAR DISEASE

Erectile dysfunction is commonly detected in patients in whom other risk factors of endothelial dysfunction or atherosclerosis are prevalent, such as high blood pressure, diabetes, hypercholesterolemia, symptomatic CAD and chronic kidney disease (CKD).

Kloner et al.⁶ administered a Sexual Health Inventory for Men Questionnaire for cardiac patients in the outpatient department to ascertain how often physicians treat ED in these patients with chronic CAD. The questionnaire took about 5 minutes to complete in the busy outpatient department. They found the prevalence of ED in 70% of CAD patients, suggesting an association between ED with stable CAD. Roumeguere et al.⁷ compared 215 patients with ED and 100 patients without ED. CHD risk at 10 years were 56.6% in the ED group as compared to 32.6% in the group without ED ($p < 0.05$).

An epidemiological study from Japan⁸ collected data from 6,112 male CAD patients from 447 clinics in 2003. The prevalence of ED was 81% in the cohort. ED was strongly associated with CVD [odds ratio (OR): 2.82; 95% confidence interval (CI): 1.95–4.23, $p < 0.0001$] and diabetes (OR: 2.88; 95% CI: 2.26–3.70, $p < 0.0001$). Diabetes mellitus, CAD and high blood pressure showed significant associations with ED with ORs of 2.88, 2.82, and 1.79, respectively.

ERECTILE DYSFUNCTION AND FUTURE CARDIOVASCULAR EVENTS

Erectile dysfunction is regarded as a vascular marker for future CVD, as ED indicated initiation of endothelial dysfunction and atherosclerosis involving the vascular tree and can be used for screening and initiation of treatment for CVD risk reduction.

Uslu et al.⁹ showed that flow-mediated dilatation (FMD) of the arteries decreases significantly in the group of patients having ED as compared to group without ED ($4.1\% \pm 3.1\%$ vs. $9.7\% \pm 3.5\%$; $p < 0.001$) and the relationship of suffering from ED and reduction of FMD was significant ($r = -0.66$, $p < 0.001$), concluding that aortic and brachial artery endothelial functions are impaired in men with ED without CVD.

Baumhakel et al.¹⁰ tried to evaluate association of endothelial dysfunction and left ventricular ejection fraction (LVEF), and postulated that endothelial dysfunction is common in patients with reduced LVEF, and hence will have higher prevalence of ED in them. LVEF was measured by magnetic resonance imaging (MRI), contrast angiography and with the help of 2D echocardiography. Prevalence of ED was 80.6% among patients with moderate-to-severe reduction of LVEF ($p = 0.001$), and symptoms of ED were detected 3.04 ± 7.2 years before development of a cardiovascular event ($p = 0.005$). They concluded that reduced LVEF is a risk factor for ED in high CVD risk patients, probably caused by endothelial dysfunction.

Solomon et al.¹¹ showed that coronary plaque burden was well correlated to the International Index of Erectile Function (IIEF) score. The erectile function score of the 132 patients with angiography proven CAD correlated with the CVD risk factors ($r = 0.54$, $p < 0.001$) and with the severity of disease burden ($r = 0.44$, $p < 0.001$) as evaluated with the help of Gensini score.

All these studies point to the fact that endothelial dysfunction and atherosclerosis is the key for initiation of ED and CAD, and ED can be used as a clinical marker for prevention of future CVD or treatment of underlying CAD.

ERECTILE DYSFUNCTION WITH OCCULT CARDIOVASCULAR DISEASE

There are some patients of isolated ED not having any clinical symptoms of CAD, but may be suffering from asymptomatic or occult CAD. Earlier studies have reported prevalence with the help of exercise stress testing (EST) at 22%. More importantly, obstructive coronary artery disease was detected by invasive coronary angiography in 90% of the cases. In another prospective study of ED patients evaluated with angiography, 19% of them were suffering from silent CAD with definite obstruction.¹²

WORKUP FOR PATIENTS WITH ERECTILE DYSFUNCTION AND CARDIOVASCULAR DISEASE

Patients should be assessed for presence of risk factors through a proper history, family history of premature atherosclerosis, clinical examination to look especially for body mass index (BMI), peripheral pulsations, blood pressure, and cardiovascular and neurological examination. Investigations like blood sugar levels, lipid profile, renal function tests, electrocardiogram (ECG), and echocardiography should be carried out to identify risk factors and underlying cardiac disease.

Assessment of whether a cardiac patient is suffering from ED, its severity and duration is important aspects and can be obtained by meticulous history of sexual health and related questionnaires. The commonly used IIEF, a 15-item, self-evaluation module, having questionnaire as a validated method for evaluating and assessing male sexual functions including libido, erectile function, and satisfactory orgasm.¹³ A shortened version questionnaire of the original 15-item IIEF is the 5-item module, called the Sexual Health Inventory for Men (SHIM) or IIEF-5 is given in table 1. The sum of the score of the responses to the questions can range from the worse (scoring 1) to the best (scoring 25); progressive decrease in score indicates gradual worsening of the erectile function, and a value of less than or equal to 21 is diagnostic of ED.

Exercise stress testing along with imaging or without imaging can be used to identify patients who are having underlying obstructive asymptomatic CAD, to identify patients with reversible ischemia, especially in detecting silent CAD in diabetic patients. Pharmacological stress evaluation methods

TABLE 1: The International Index of Erectile Function-5 (IIEF-5) scoring system used for screening and assessing severity of erectile dysfunction (ED). The total score is the sum of points scored to the five queries and overall score ranges from 1 to 25. ED is absent (score 22–25), mild (score 17–21), mild-to-moderate (score 12–16), moderate (score 8–11), and severe (score 1–7)

Questions	Score 0	Score 1	Score 2	Score 3	Score 4	Score 5
1. How do you rate your confidence over the past 6 months that you could get and keep an erection?	–	Very low	Low	Moderate	High	Very high
2. When you had erections with sexual stimulation over the past 6 months, how often were your erections hard enough for penetration (entering your partner)?	No sexual activity	Almost never or never	A few times (much less than half the time)	Sometimes (about half the time)	Most times (much more than half the time)	Almost always or always
3. During sexual intercourse in past 6 months, how often were you able to maintain your erection after you had penetrated (entered) your partner?	Did not attempt intercourse	Almost never or never	A few times (much less than half the time)	Sometimes (about half the time)	Most times (much more than half the time)	Almost always or always
4. During sexual intercourse in last 6 months, how difficult was it to maintain your erection to completion of intercourse?	Did not attempt intercourse	Extremely difficult	Very difficult	Difficult	Slightly difficult	Not difficult
5. When you attempted sexual intercourse during last 6 months, how often was it satisfactory for you?	Did not attempt intercourse	Almost never or never	A few times (much less than half the time)	Sometimes (about half the time)	Most times (much more than half the time)	Almost always or always

are more appropriate for those who are unable to perform EST due to physical limitations or with baseline significant ECG abnormalities. Patients with known CAD or diabetes are always considered to be at increased risk. So, patients with adequate exercise capacity or negative EST can restart or continue normal sexual activity along with proper treatment and lifestyle measures for ED. In patients with positive stress test results or in high-risk of repeat events, normal sexual activity is deferred until the condition of the patient is stabilized with adequate treatment. They need to be followed regularly with timely stress evaluation after treatment or interventions, before normal sexual activity can be advised.²

Measurement of serum testosterone level is strongly recommended in those with diagnosed organic ED especially if condition is not treated adequately with phosphodiesterase type 5 (PDE5) inhibitor agents. Low testosterone level can cause dyslipidemia by increasing total cholesterol and low-density lipoprotein cholesterol, and also to increased production of proinflammatory markers and mediators.¹⁴ Endothelial dysfunction, progressive arterial wall thickening, gradual increase in arterial stiffness, and calcification also ensue in those with lower testosterone level. Hence, it is hypothesized that CVD risk is amplified by chronically reduced levels of testosterone.

MANAGEMENT OF ERECTILE DYSFUNCTION AND CARDIOVASCULAR DISEASE

As the basic mechanism and pathophysiology of CVD and ED are same, treatment of ED is mostly treatment of risk factors like treating high blood pressure, proper control of diabetes, treatment of dyslipidemia, cessation of all forms

of tobacco use, maintaining a healthy body weight or loss of body weight in case of obesity, balanced diet, and regular physical exercise. Treatment of CAD may confer benefit in improving ED and conversely, treatment of ED may benefit patients with established CVD.

Lifestyle Measures

Lifestyle modifications is an important and integral part of treating patients of both CVD and ED. Regular physical exercise helps reducing CVD burden as well as control of the risk factors like hypertension, diabetes, hyperlipidemia, and obesity. Cessation of smoking or use of tobacco products, emphasis on proper diet with reduced salt intake, and weight control are necessary for treatment of ED.¹⁵ Management of stress is another aspect of lifestyle measures necessary for treatment of ED.

Phosphodiesterase Type 5 Inhibitors for Erectile Dysfunction

Phosphodiesterase type 5 inhibitors are the main therapy for ED of nonfunctional etiology and they can be used safely if there is no contraindication for their use.¹⁶ Mechanism of action include pulmonary artery and systemic arterial vasodilation, improvement in myocardial contractility, reduction in the stiffness of large arterial beds, improvement in the deteriorated endothelial function, and reduction in apoptosis, fibrosis and hypertrophy. Drug-to-drug interactions with other cardiac drugs are very minimal except nitrates and other nitric oxide (NO) donors (like nifedipine). Coadministration of these drugs may cause severe vasodilation, leading to hypotension. American Urological Association recent guidelines advise that cardiac patients who carry sublingual nitroglycerin for

angina should be advised not to take nitrate within 24 hours of taking sildenafil and 48 hours of taking tadalafil. Transient systemic vasodilatation caused by these agents may be aggravated by coadministration of alpha-blocking agents. It is recommended that vardenafil and tadalafil, any dose, and sildenafil at 50 mg and 100 mg doses should be administered with caution in patients who are on alpha-blocker agents.¹⁷

All four agents of this group (sildenafil, tadalafil, vardenafil, and avanafil) have not shown to increase the risk of silent or overt myocardial ischemia, stroke, or cardiac death. These drugs also do not worsen ischemia or reduce exercise tolerance or exercise duration in patients with established CAD who are having good exercise capacity and are engaged in normal sexual activities.

Selection of Proper Cardiovascular Drugs in Erectile Dysfunction

Different cardiovascular drugs have been implicated by different investigators as to be having causal association with ED. Though all of them may not have been proven to have strong correlation other than thiazide diuretics that clearly lead to ED, they need to be remembered while treating a cardiac patient having ED. The drugs implicated are:

- *Sympathetic depressants*: Reserpine, alpha-methyldopa, and clonidine
- *Antihypertensive drugs*: Thiazide diuretic, some beta-blockers
- *Statin*: High-dose
- *Spirostanolactone (antiandrogen side effect)*
- *Cardiac glycosides*: Digoxin.

Some older beta-blockers are said to be responsible for causing ED, but this side effect was reported to be as low as 3% when the patients were blinded for the drug they were given. In fact, the newer vasodilator beta-blocker nebivolol is said to improve ED.¹⁸ Botros SM et al.¹⁹ studied hypertensive patients treated with beta-blockers atenolol, bisoprolol, carvedilol, and nebivolol. Pretreatment penile artery peak systolic and diastolic velocities were compared with 8–12 weeks post-treatment velocities. They found that blood flow was significantly reduced by atenolol, bisoprolol, and carvedilol but not by nebivolol.

Erectile dysfunction is frequently encountered in hypertensive population as a whole and sexual dysfunction is commonly encountered in treated than in untreated patients. Evidence suggests that older groups of drugs like diuretics, beta-blockers cause more ED as compared to the newer groups like nebivolol, angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), which are said to possess neutral or rather beneficial effect on erectile function in some studies.²⁰ However, they have not been studied extensively in large clinical trials from this angle.

Statins are helpful in improving endothelial dysfunction and preventing progression of atherosclerosis. So they should be helpful in ED prevention or treatment. Statins have mostly shown beneficial effect. However, higher statin doses may have a negative effect. In a clinical trial with patients of atherosclerosis on statin therapy, the baseline median IIEF

score of 21 worsened to 6.5 after 6 months of statin therapy and baseline prevalence of ED of 57% increased to 79%. Difference in statin dose and type of the drugs prescribed showed no definite relation with the change in IIEF score.²¹ Larger clinical trials with statin therapy need to be conducted to come to a conclusion in this regard as statin is the most essential drug in the treatment of atherosclerotic CVD.

Role of Testosterone and Prostaglandin Therapy

Testosterone replacement therapy (TRT) can be considered in patients who are symptomatic due to testosterone deficiency or who have laboratory documentation of low serum testosterone (TT <8 nmol/L or 2.3 ng/mL). Men with ED and/or with visceral obesity and metabolic diseases should be evaluated for testosterone deficiency.²² TRT can be delivered by different routes like oral, injectable, gel, or transdermal. Bioavailability after oral administration is minimal, and hence, this route is not very effective. Gel applied regularly over skin or transdermal patches are effective alternatives of injectable therapy. Another option is prostaglandin E1 (PGE1), alprostadil that can be delivered by injection or by transurethral pellets.

While a PDE5 inhibitor is considered as first-line therapy, addition of TRT or PGE1 should be considered when the condition is not improved with PDE5 inhibitor alone. Improvement on TRT is dependent on the baseline testosterone levels and better results are expected at lower levels of testosterone.

CONCLUSION

Erectile dysfunction and coronary artery disease share the common platform of endothelial dysfunction and atherosclerosis, and associated with same risk factors like high blood pressure, diabetes, smoking, dyslipidemia, visceral obesity, and sedentary lifestyle, in its causation. Hence, ED can be an important risk marker of silent CVD. Assessment of sexual health should be a part of complete assessment of cardiovascular risk in men. A comprehensive approach of reducing cardiovascular risk with the help of both lifestyle measures and necessary pharmacological treatment improves overall vascular disease risk, including sexual function in persons suffering from this condition.

Noncardiac Surgery: How to “Clear” a Patient?

PC Manoria, Pankaj Manoria, Sharad Kumar Parashar

INTRODUCTION

Worldwide, it is estimated that around 20 million people undergo noncardiac surgery annually.¹ One-third of surgeries are performed in geriatric population. The overall mortality is 1–5%, in individual less than 65 years the average mortality is 1% whereas in individuals above 65 years the morality is higher about 5%. Cardiovascular (CV) complications are the most common cause of death.^{2,3} All deaths in the first 48 hours are due to cardiac causes like heart failure (HF), acute coronary syndrome (ACS). The deaths from 48 hours to 6 weeks are usually due to a noncardiac cause like pneumonia, sepsis, pulmonary embolism, renal failure, etc.

Preoperative evaluation is of paramount importance as appropriate preventive and therapeutic strategies may decrease CV morbidity and mortality and shorten the hospital stay.

The main purpose of perioperative evolution is to get familiar with the following basic questions:

- What are the underlying risk factors which the patient is having prior to noncardiac surgery?
- What is the anticipated patient-related risk?
- What is the proper preoperative treatment to reduce the anticipated risk during surgery and steps to be taken in the postoperative period to reduce morbidity and mortality?

The cardiac complications after noncardiac surgery depend on three things:

- Procedure-related risk
- Patient-related risk
- Functional capacity (FC).

Procedure-related risk: The surgical risk for cardiac events depends on the type of procedure carried out. High-risk procedures have a mortality of 5%, intermediate-risk 1–5%, and low-risk less than 1% (Table 1).

Patient-related risk: The patient-related risk depends on the underlying disease as shown in table 2.

Functional capacity: It is an important test in preoperative cardiac risk assessment and is measured in metabolic

TABLE 1: Procedure-related risk

High (5%)	Intermediate (1–5%)	Low (<1%)
Emergent major operations (elderly)	Carotid endarterectomy	Endoscopic procedures
Aortic and other major vascular surgery	Head and neck surgery	Superficial procedure
Peripheral vascular surgery	Intraperitoneal, Intrathoracic surgery	Cataract surgery
Anticipated prolonged surgical procedures	<ul style="list-style-type: none"> • Orthopedic surgery • Prostate surgery • Pulmonary, renal/liver transplant 	<ul style="list-style-type: none"> • Breast surgery • Dental • Gynecology, urologic-minor

TABLE 2: Patient-related risk

Major	Intermediate	Minor
ACS	Prior Myocardial infarction	Advanced age
Decompensated HF	Mild angina	Abnormal ECG
Significant arrhythmias	Compensated HF	Rhythm other than sinus
Severe VHD* stenotic lesions like AS, MS	Diabetes Mellitus	Past stroke
Poor FC	Renal insufficiency	Uncontrolled hypertension

ACS, acute coronary syndrome; AS, aortic stenosis; ECG, electrocardiogram; FC, functional capacity; HF, heart failure; MS, mitral stenosis; *VHD, valvular heart disease.

equivalents (METs). Exercise testing provides an objective assessment of FC but without this it can be estimated from the ability to perform activities in daily life (Table 3).

Poor FC is associated with an increased incidence of postoperative cardiac events. When FC is good, the prognosis is excellent even in presence of stable ischemic heart disease (IHD) or risk factors.

TABLE 3: Assessment of functional capacity

Severity	Assessment
Poor	Unable to climb a flight of stairs (<4 METs)
Moderate	Climbing flight of stairs (4–7 METs)
Good	Participation in moderate recreational activities (>7 METs)
Very good	Participation in strenuous sports swimming (>10 METs)

METs, metabolic equivalents.

TABLE 4: Revised cardiac risk index variables

Variables	Pts
Hx of IHD	1
Hx of CHF	1
Hx of CVD	1
Insulin for diabetes	1
Serum creatinine >2.0 mg/dL	1
High-risk surgery	1

CHF, congestive heart failure; CVD, cardiovascular disease; Hx, history; IHD, ischemic heart disease.

TABLE 5: Assessment of cardiac events in preoperative period based on RCRI points

Total RCRI points	Risk of MI, cardiac arrest, or death 30 days after surgery
0	0.4% (95% CI: 0.1–0.8)
1	1.0% (95% CI: 0.5–1.4)
2	2.4% (95% CI: 1.3–3.5)
≥3	5.4% (95% CI: 2.8–7.9)

CI, confidence interval; MI, myocardial infarction; RCRI, revised cardiac risk index.

Perioperative cardiac morbidity risk evaluation: This is commonly assessed by revised cardiac risk index.

Revised cardiac risk index: The revised cardiac risk index^{4,5} is a simple tool that has been validated to assess the perioperative risk of major cardiac events. The variables of this score are shown in table 4 and single point is assigned to every risk factor present. The risk of cardiac arrest or death 30 days after surgery is shown in table 5. Patients having zero or only one risk factor have a low-risk of major adverse cardiac events (MACE), whereas those with two or more risk factors have elevated risk.

ANCILLARY PREOPERATIVE CARDIAC TESTING: RECOMMENDATIONS

Electrocardiogram

A 12-lead electrocardiogram (ECG) preoperatively is useful in patients with atherosclerotic cardiovascular disease

(ASCVD), structural heart diseases or arrhythmias. Low-risk patients going for surgery do not require ECG preoperatively.

Left Ventricular Function

Patients with HF or with documented left ventricular (LV) dysfunction in past or unexplained dyspnea should be subjected to echocardiography for assessment of LV function. Evaluation of all patients going for surgery is not required.⁶ Decrease LV systolic function with ejection fraction less than 35% may be associated with adverse outcome. Further, in patients with LV systolic dysfunction, a restrictive pattern of mitral inflow on echocardiography is associated with increased morbidity and mortality because advanced diastolic dysfunction implies marked elevation of left ventricular enddiastolic pressure and this predisposes to precipitation of HF. In such patients surgery should be postponed and treatment optimized. Only when their LV function improves they should be submitted for surgery.

Stress Testing and Cardiopulmonary Testing

All patients undergoing noncardiac surgery do not require stress testing.⁷ Only in patients with poor FC (4 METS), stress test is required. Patients with good FC can be directly submitted for surgery. In cardiopulmonary testing, a low anaerobic threshold of 9–11 mL/O₂/kg/min is a bad prognostic sign and condition of such patients should be improved prior to submission for surgery.

Pharmacological Testing

The use of pharmacological testing with stress dobutamine or myocardial perfusion imaging is restricted to patients who have poor FC and ECG changes like LV hypertrophy (LVH), left bundle branch block (LBBB), etc. which interferes with ECG evaluation of myocardial ischemia. All patients should not be submitted for these tests prior to surgery.⁸ Presence of large areas of myocardial ischemia is associated with adverse CV outcome.

Coronary Angiography

Routine angiography is not indicated preoperatively except for patients who are candidates for organ transplantation like liver, kidney, etc. Calcium scoring on computed tomography is also not recommended.⁹

Therapeutic Strategies

Percutaneous Coronary Intervention or Coronary Artery Bypass Graft

Percutaneous coronary intervention or coronary artery bypass graft (PCI or CABG) is not recommended prior to noncardiac surgery as no benefit has been demonstrated.¹⁰

If patient develops ACS prior to surgery, then treatment is offered as per guidelines.

ELECTIVE NONCARDIAC SURGERY IN PATIENTS WITH PRIOR PERCUTANEOUS CORONARY INTERVENTION: TIMING AND RECOMMENDATIONS

Patient with bare-metal stent (BMS) or drug-eluting stent (DES) implantation, if they require noncardiac surgery in the early postimplantation period, i.e., less than 4 weeks for BMS and 6–12 months for DES^{11,12} one should carefully assess the risk of stent thrombosis after withdrawal of antiplatelet drugs versus the bleeding risk during surgery due to continuation of dual antiplatelet therapy (DAPT) and then take decision.

The period during which noncardiac surgery should be avoided after balloon angioplasty/BMS/DES implantation is outlined in table 6.

If surgery is to be performed in BMS implantation before 30 days or DES implantation before 6–12 months, then the strategy for using antiplatelet drugs depends on the bleeding risk of the patient as outlined in table 7.

In such subset of patients, the surgeon should be encouraged to operate on aspirin at least in patients with low or intermediate bleeding risk.

ANTICOAGULANT THERAPY

Vitamin K Antagonists

The decision to continue anticoagulants or bridging with low molecular weight heparin (LMWH) or unfractionated heparin (UFH) depends on the thromboembolism risk of the patient and the bleeding risk of surgery. If the surgery is a low-bleeding risk like cataract surgery bridging is not required and surgery can be done without stopping anticoagulant.¹³

Prosthetic Valves

Patients of prosthetic valves on warfarin even in absence of risk factors for thromboembolism like atrial fibrillation (AF), past history of embolic episodes, LV dysfunction will require cessation of anticoagulant therapy and bridging with UFH/LMWH in the perioperative period.¹³

Atrial Fibrillation on Vitamin K Antagonists

Patients of AF with high thromboembolism risk, i.e., CHA₂DS₂-VASC score of 2 in males and 3 in females or more will require bridging with UFH/LMWH in perioperative period for surgery. If the thromboembolism risk is low with CHA₂DS₂-VASC score of 1 in males and 2 in females, anticoagulants can be stopped and when international normalized ratio (INR) is less than 2, surgery can be performed. Vitamin K antagonists (VKAs) can be restarted after homeostatic is achieved.^{14,15}

Direct Oral Anticoagulants

The half-life of novel oral anticoagulants (NOACs) is about 12 hours. If the bleeding risk is mild-to-moderate, NOACs are discontinued for a period of 2–3 half-life but if the bleeding risk is high, they are discontinued for five times the half-life.

The renal function must always be assessed by estimated glomerular filtration rate (eGFR). This is particularly important for dabigatran because 80% is excreted through kidneys.¹⁶ Apixaban, only 25% is excreted through kidneys and may be preferable in patients with chronic kidney disease. For reinitiating NOACs, the bleeding and embolic risk must be taken into consideration. For low-bleeding risk and high-embolic risk, NOACs can be resumed as early as 12–24 hours. If bleeding risk is high and embolic risk is low, one may wait

TABLE 6: Decision policy for noncardiac surgery in patients who have undergone prior coronary interventions

Recommendations	COR	LOE
Elective noncardiac surgery should not be performed within 14 days of balloon angioplasty in patients in whom aspirin will need to be discontinued perioperatively	III Harm	C
Elective noncardiac surgery should not be performed within 30 days after BMS implantation or within 6–12 months after DES implantation in patients in whom DAPT will need to be discontinued perioperatively	III Harm	B
Elective noncardiac surgery after DES implantation may be considered after 180 days if the risk of further delay is greater than the expected risks of ischemia and stent thrombosis	IIb	B

BMS, bare-metal stent; COR, class of recommendation; DAPT, dual antiplatelet therapy; DES, drug-eluting stent; LOE, level of evidence.

TABLE 7: Use of antiplatelet drugs in patients requiring early surgery after coronary intervention

Bleeding risk		
Low	Intermediate	High
Cataract, oral dental surgery	GI surgeries, cholecystectomy, appendectomy, etc.	Intracranial, prostate, aortic, ENT, posterior segment surgery
Continue aspirin and clopidogrel	Stop clopidogrel continue aspirin	Stop aspirin and clopidogrel and bridge with cangrelor: 0.75 µg/kg/min or tirofiban: 0.1 µg/kg/min. If renal dysfunction, decrease dose to 0.05 µg/kg and start 24–48 hours. After last dose and continue till 4–8 hours before surgery (ESC DAPT update 2017)

DAPT, dual antiplatelet therapy; ENT, ear, nose, and throat; ESC, European Society of Cardiology; GI, gastrointestinal.

for up to 72 hours. It must be ensured that homeostasis has been achieved before initiating NOACs. Periprocedural bridging with LMWH is not required because of short half-life of NOACs.

Reversal of Vitamin K Antagonist

Vitamin K is not preferred for reversal of VKAs because even after intravenous administration it takes 8–12 hours to act. Fresh frozen plasma or prothrombin complex concentrates are utilized for this purpose as their onset of action is immediate.¹³

Beta-blocker Therapy

The use of β-blocker in perioperative period¹⁷ is outlined in table 8.

Statin Therapy

If patient is already on statins, this should be continued. Statins should be started in patients undergoing vascular surgery or they are indicated otherwise.¹⁸

Alpha-2 Agonist

Alpha-2 agonists are not useful in prevention of cardiac events in perioperative period.

Calcium-channel Blockers

Verapamil or diltiazem can precipitate HF in patients with reduced ejection fraction and they should be avoided in this subset of patients.

Angiotensin-converting Enzyme Inhibitors or Angiotensin Receptor Blockers

If the patient is already on angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARBs) perioperatively they should be continued. If the patient is not on these drugs, it is desirable to restart as soon as possible postoperatively.¹⁹

TABLE 8: Perioperative beta-blocker therapy

Recommendations	COR	LOE
Beta-blocker should be continued in patients undergoing surgery who have been on it chronically	I	B ^{SR}
It is reasonable for the management of β-blocker after surgery to be guided by clinical circumstances, independent of when the agent was started	IIa	B ^{SR}
In patients with intermediate or high-risk myocardial ischemia noted in preoperative risk stratification tests, it may be reasonable to begin perioperative β-blocker	IIb	C ^{SR}
In patients with three or more RCRI risk factors (e.g., diabetes mellitus, HF, CAD, renal insufficiency, cerebrovascular accident), it may be reasonable to begin β-blocker before surgery	IIb	B ^{SR}
In patients with a compelling long-term indication for β-blocker therapy but no other RCRI risk factors, initiating β-blockers in the perioperative setting as an approach to reduce perioperative risk is of uncertain benefit	IIb	B ^{SR}
In patients in whom β-blocker therapy is initiated, it may be reasonable to begin perioperative β-blockers long enough in advance to assess safety and tolerability, preferably more than 1-day before surgery	IIb	B ^{SR}
Beta-blocker therapy should not be started on the day of surgery	III	B ^{SR}

CAD, coronary artery disease; COR, class of recommendation; HF, heart failure; LOE, level of evidence; RCRI, revised cardiac risk index.

PREOPERATIVE EVALUATION IN SPECIFIC PATIENTS POPULATION: GENERAL CONSIDERATIONS

Age

Noncardiac surgery in elderly patients is associated with increased morbidity and mortality because of associated diabetes, kidney disease, stroke, and other medical conditions.

Coronary Artery Disease

Coronary artery disease (CAD) is an important determinant of postoperative CV outcomes. Noncardiac surgery should not be performed for at least 3 months after acute myocardial infarction (AMI).²⁰ Perioperative AMI is associated with very-high morbidity and mortality and should be prevented as far as possible by appropriate pre-op check-up and treatment. Even mere elevation of serum markers without AMI is also associated with adverse outcomes.

Heart Failure

Patients with HF or even history of HF in past are associated with increased morbidity and mortality after noncardiac surgery. Systolic dysfunction with an ejection fraction less than 35% even if it is asymptomatic is associated with increased morbidity and mortality.²¹ In patients with LV systolic dysfunction, if there is associated diastolic dysfunction with a restrictive pattern, surgery should be postponed and treatment optimized to improve LV function before submitting for surgery. Data suggest that mortality in HF is higher (9.3% ischemic and 9.2% nonischemic) compared to CAD mortality of 2.9%.²¹

PERIOPERATIVE ARRHYTHMIAS

The development of arrhythmias in perioperative period is multifactorial like ischemia, disturbed internal milieu, drug toxicity, underlying cardiopulmonary disease, etc.

Very few studies are available in this context. Patients with supraventricular or ventricular ectopics or nonsustained ventricular tachycardia are not of serious concern.^{22,23} Patients with AF with CHA₂DS₂-VASc score of more than 2 in males and 3 in females should receive anticoagulation to prevent stroke. Routine use of antiarrhythmic drug prophylaxis is not recommended for postoperative AF as this would subject all patients to their potential side effects, while only a minority of the patients actually develops this problem postoperatively. Withdrawal of β-blockers in the postoperative period has been implicated as one of the major causes of postoperative atrial fibrillation (POAF). β-blockers and amiodarone are mainstays of pharmacological and treatment of POAF.

CONCLUSION

Clearing a cardiac patient for noncardiac surgery is a common issue in our day-to-day practice. CV complications like HF and ACS are the most common cause of death in first 48 hours while mortality from 48 hours to 6 weeks is usually due to a noncardiac complication like pneumonia, sepsis, pulmonary embolism, renal failure, etc. A careful evaluation of the patient taking into consideration the procedure-related risk, the patient-related risk, and FC coupled with use of appropriate drugs and necessary precautions paves the way for minimizing CV morbidity and mortality in the perioperative period and also shorten the hospital stay.

How to Defend a Complaint in Cardiology

KK Aggarwal

Facing a lawsuit can be a traumatic and stressful experience for any person, more so for a doctor, who is dedicated to taking care of this patients. Lawsuits are not only expensive, they are also time-consuming as it may take a few years before the case goes to trial and a judgment is delivered. Recently, there has been an unprecedented increase in the number of malpractice claims being filed against doctors. Doctors are, more often than not, ignorant of the various nuances of the law as it relates to the practice of medicine because law as a subject is not a part of our medical curriculum.

There have been several landmark judgments of the Supreme Court of India on medical negligence in India. Defenses are available in these Supreme Court judgments, including those of the National Consumer Disputes Redressal Commission (NCDRC). It is very important that doctors are knowledgeable about these judgments and identify those defenses, which can be applied to their lawsuit, should such a situation arise. However, prevention is still the best defense. Follow all required guidelines and self-regulate to maintain professional standards and avoid litigation.

DEFENSE ARGUMENT NO. 1

"I have done nothing that any reasonable prudent doctor would not have done (act of commission) nor I have refrained from doing anything, which a reasonable prudent doctor would do (act of omission)."

"While a doctor cannot be forced to treat any person, he/she has certain responsibilities for those whom he/she accepts as patients. Some of these responsibilities may be recapitulated, in brief:

(c) to exhibit reasonable skill: The degree of skill a doctor undertakes is the average degree of skill possessed by his professional brethren of the same standing as himself. The best form of treatment may differ when different choices are available. There is an implied contract between the doctor and patient where the patient is told, in effect, "Medicine is not an exact science. I shall use my experience and best judgment and

you take the risk that I may be wrong. I guarantee nothing" (**PB Desai versus State of Maharashtra, AIR 2014 SC 795**).

DEFENSE ARGUMENT NO. 2

"I acted as per my thinking and at the most it can be a case of difference of opinion and or error of diagnosis and the same is not negligence. An error of diagnosis can never be labeled as deficiency in services."

"In the realm of diagnosis and treatment there is scope for genuine difference of opinion and one professional doctor is clearly not negligent merely because his conclusion differs from that of other professional doctor (v)" (**Kusum Sharma and Others versus Batra Hospital and Medical Research Centre, 2010 (3) SCC 480**).

DEFENSE ARGUMENT NO. 3

"I have taken all the care that was expected from any reasonable prudent medical practitioner and therefore there cannot be any element of negligence or rashness in the services rendered by me."

"...Failure to act in accordance with the standard, reasonable, competent medical means at the time would not constitute a negligence. However, a medical practitioner must exercise the reasonable degree of care and skill and knowledge which he possesses. Failure to use due skill in diagnosis with the result that wrong treatment is given would be negligence (iv)" (**Malay Kumar Ganguly versus Sukumar Mukherjee & Ors. AIR 2010 SC 1162**).

DEFENSE ARGUMENT NO. 4

"I am a qualified doctor (....degrees), have received many honors (.....), have over years of experience and have been updating my knowledge regularly (.....state CME hours)."

"76. The basic principle relating to the law of medical negligence is the Bolam Rule which has been quoted above.

The test in fixing negligence is the standard of the ordinary skilled doctor exercising and professing to have that special skill, but a doctor need not possess the highest expert skill" [Martin F. D'Souza versus Mohd. Ishfaq, 2009 (3) SCC 1].

DEFENSE ARGUMENT NO. 5

"When I treated the patient, the line of treatment adopted by me was the best option thought by me."

"In case, the doctor brings in his task of providing medicine, a reasonable degree of skill and knowledge and exercise the same to a reasonable degree, then, the medical practitioner cannot be held guilty for the medical negligence only because someone else of better skill and knowledge had prescribed different treatment or operated in a different way. Petitioner failed to produce any evidence to show that the line of treatment adopted by the respondent was not in line with the reasonable body of medical practitioners. Mere difference of opinion in adopting different line of treatment than the one adopted by the medical practitioner does not prove that the medical practitioner was guilty of medical negligence. Respondent-doctor had taken due care and caution. The doctor cannot be held negligent simply because something went wrong. He also cannot be held liable for making one choice out of two or for favoring one school rather than another. He can be held guilty only where his conduct fell below that of the standards of a reasonably competent practitioner in his field, so much so, that his conduct might be deserving of censure or inexcusable" [Prabha Shankar Ojha versus Neelmani Rai, 2009 (4) CPR 307].

DEFENSE ARGUMENT NO. 6

"There are number of diagnosis or treatment of medical problem and I have adopted this diagnosis or treatment for the same."

"Para 11: The duties which a doctor owes to his patient are clear. A person who holds himself out ready to give medical advice and treatment impliedly undertakes that he is possessed of skill and knowledge for the purpose. Such a person when consulted by a patient owes him certain duties, viz., a duty of care in deciding whether to undertake the case, a duty of care in deciding what treatment to give or a duty of care in the administration of that treatment. A breach of any of those duties gives a right of action for negligence to the patient. The practitioner must bring to his task a reasonable degree of skill and knowledge and must exercise a reasonable degree of care. Neither the very highest nor a very low degree of care and competence judged in the light of the particular circumstances of each case is what the law requires. The doctor no doubt has a discretion in choosing treatment which he proposes to give to the patient and such discretion is relatively ampler in cases of emergency" [Laxman Balkrishna Joshi v. Trimbak Bapu Godbole and Anr AIR 1969 SC 128].

DEFENSE ARGUMENT NO. 7

"Though the procedure/diagnosis/treatment adopted by me involves higher risk, it has greater chances of success

in comparison to the other procedure, which involves less risk but has greater chances of failure."

"The medical professional is often called upon to adopt a procedure which involves higher element of risk, but which he honestly believes as providing greater chances of success for the patient rather than a procedure involving lesser risk but higher chances of failure. Just because a professional looking to the gravity of illness has taken higher element of risk to redeem the patient out of his/her suffering which did not yield the desired result may not amount to negligence (vi)" [Kusum Sharma & Others versus Batra Hospital & Medical Research Centre, 2010 (3) SCC 480].

DEFENSE ARGUMENT NO. 8

"I have treated the patient as per general and approved practice. Expert opinions have been taken by me/us from other eminent doctors of the city and they too have agreed with the line of management adopted and found no negligence or deficiency in services."

"Negligence cannot be attributed to a doctor, so long as he performs his duties with reasonable skill and competence. Merely because the doctor chooses one course of action in preference to another available, he would not be liable if the course of action chosen by him was acceptable to the medical profession (vii)" [Kusum Sharma & Others versus Batra Hospital & Medical Research Centre, 2010 (3) SCC 480].

DEFENSE ARGUMENT NO. 9

"I have added the opinion of experts, who have agreed with my line of treatment. Even if the experts about by the Council differ with the opinion of my experts, I must get the benefit of doubt."

"Thus in large majority of cases, it has been demonstrated that a doctor will be liable for negligence in respect of diagnosis and treatment in spite of a body of professional opinion approving his conduct where it has not been established to the courts satisfaction that such opinion relied on is reasonable or responsible. If it can be demonstrated that the professional opinion is not capable of withstanding the logical analysis, the court would be entitled to hold that the body of opinion is not reasonable or responsible" [Vinitha Ashok versus Lakshmi Hospital, AIR 2001 SC 3914].

DEFENSE ARGUMENT NO. 10

"The complication, which occurred in this case has been well-described in literature (quote a reference) and cannot amount to negligence. Whatever happened during treatment in this case was a pure accident. Accidents are not actionable."

"Para 27: A mere deviation from normal professional practice is not necessarily evidence of negligence. Let it also be noted that a mere accident is not evidence of negligence. So also an error of judgment on the part of a professional is not negligence per se. Higher the acuteness in emergency and higher the complication, more are the chances of error of judgment. At times, the professional is confronted with

making a choice between the devil and the deep sea and he has to choose the lesser evil. The medical professional is often called upon to adopt a procedure which involves higher element of risk, but which he honestly believes as providing greater chances of success for the patient rather than a procedure involving lesser risk but higher chances of failure. Which course is more appropriate to follow, would depend on the facts and circumstances of a given case. The usual practice prevalent nowadays is to obtain the consent of the patient or of the person in-charge of the patient if the patient is not in a position to give consent before adopting a given procedure. So long as it can be found that the procedure which was in fact adopted was one which was acceptable to medical science as on that date, the medical practitioner cannot be held negligent merely because he chose to follow one procedure and not another and the result was a failure" [Jacob Mathew v. State of Punjab & Anr. 2005 (3) CPR 70].

DEFENSE ARGUMENT NO. 11

"I treated the patient in emergent situations and am likely to make errors. The standard expected from any medical practitioner in an emergency are always lower than the standards expected from him in an ideal setting is the law."

"The higher the acuteness in an emergency and the higher the complication, the more are the chances of error of judgment. At times, the professional is confronted with making a choice between the devil and the deep sea and has to choose the lesser evil. The doctor is often called upon to adopt a procedure which involves higher element of risk, but which he honestly believes as providing greater chances of success for the patient rather than a procedure involving lesser risk but higher chances of failure. Which course is more appropriate to follow, would depend on the facts and circumstances of a given case but a doctor cannot be penalized if he adopts the former procedure, even if it results in a failure. The usual practice prevalent nowadays is to obtain the consent of the patient or of the person in-charge of the patient if the patient is not in a position to give consent before adopting a given procedure (45)" [Martin F. D'Souza versus Mohd. Ishfaq, 2009 (3) SCC 1].

DEFENSE ARGUMENT NO. 12

"The death did not occur due to negligence but was due to the consequence of ailments suffered. Because the patient died, it does not necessarily mean negligence."

"It must be remembered that sometimes despite their best efforts the treatment of a doctor fails. For instance, sometimes despite the best effort of a surgeon, the patient dies. That does not mean that the doctor or the surgeon must be held to be guilty of medical negligence, unless there is some strong evidence to suggest that he is (para 124)" [Martin F. D'Souza versus Mohd. Ishfaq, 2009(3) SCC 1].

DEFENSE ARGUMENT NO. 13

"The respondent has come to the Council or Commission with unclean hands: (i) Deliberate nondisclosure of relevant information (suppressio veri) and (ii) Deliberately resorting to falsehood to obtain a favorable order (suggestio falsi)."

"Dismissal of frivolous or vexatious complaints – Where a complaint instituted before the District Forum, the State Commission or, as the case may be, the National Commission is found to be frivolous or vexatious, it shall, for reasons to be recorded in writing, dismiss the complaint and make an order that the complainant shall pay to the opposite party such cost, not exceeding ten thousand rupees, as may be specified in the order" (Section 26 of the Consumer Protection Act was amended by the Amendment Act of 1993 w.e.f. 18-6-1993).

"A litigant, who approaches the court, is bound to produce all the documents executed by him which are relevant to the litigation if he withholds a vital document in order to gain advantage on the other side than he would be guilty of playing fraud on the court as well as on the opposite party (para 8)" [SP Chengalvaraya Naidu (dead) by LR Appellants versus Jagannath (dead) by LR and Ors. AIR, 1994 SC 853].

DEFENSE ARGUMENT NO. 14

"The law does not require professionals to give guarantee and warranty with respect to the end results of their services. I never gave any assurance or a guarantee to the patient/family about the treatment outcome."

"Negligence by professionals: In the law of negligence, professionals such as lawyers, doctors, architects and others are included in the category of persons professing some special skill or skilled persons generally. Any task which is required to be performed with a special skill would generally be admitted or undertaken to be performed only if the person possesses the requisite skill for performing that task. Any reasonable man entering into a profession which requires a particular level of learning to be called a professional of that branch, impliedly assures the person dealing with him that the skill which he professes to possess shall be exercised and exercised with reasonable degree of care and caution. He does not assure his client of the result. A lawyer does not tell his client that the client shall win the case in all circumstances. A physician would not assure the patient of full recovery in every case. A surgeon cannot and does not guarantee that the result of surgery would invariably be beneficial, much less to the extent of 100% for the person operated on. The only assurance which such a professional can give or can be understood to have given by implication is that he is possessed of the requisite skill in that branch of profession which he is practicing and while undertaking the performance of the task entrusted to him he would be exercising his skill with reasonable competence. This is all what the person approaching the professional can expect (para 20)" [Jacob Mathew versus State of Punjab & Anr, 2005 (3) CPR 70].

DEFENSE ARGUMENT NO. 15

"No medical treatment or surgical operation is risk free."

"Some relevant decisions on the issue of medical negligence: It is to be accepted that every surgical operation involves risk. When a person who is ill and is going to be treated in a hospital no matter what care is taken, there always exists some risk. Simply because a mishap had occurred, neither the hospital nor the doctors cannot be made liable. A doctor is not guilty of negligence if he has acted in accordance with the practice accepted as proper by a responsible body of medical men skilled in that particular art. A doctor or a hospital is expected to take reasonable care in administration of the treatment. They cannot be condemned in case of misadventure.

It is also to be remembered that medical negligence is a complicated subject and the liability of doctor always depends upon the circumstances of a particular case.

Hence, in view of the aforesaid discussion and the law on the subject as the doctors have performed their duties to the best of their ability and with due care and caution, it cannot be held that there is deficiency in service. Admittedly, the deceased was a high-risk case and such accidental eventuality cannot be controlled or avoided. Further, as stated above, every surgical operation is attended by risk. And, therefore, simply because something goes wrong, conclusion of deficiency cannot be drawn" [Mrs Shantaben Muljibhai Patel and Ors. versus Breach Candy Hospital and Research Centre and Ors, I (2005) CPJ 10].

DEFENSE ARGUMENT NO. 16

"Standard of care is the care, which the law expects from a doctor. Law does not expect the highest standard nor does it expect low standards. The standard of care expected is the standard of any reasonable medical practitioner. Circumstances in which a medical practitioner is placed always determines the standard expected from him. I have treated the patient with the best of my skill and knowledge."

"The medical professional is expected to bring a reasonable degree of skill and knowledge and must exercise a reasonable degree of care. Neither the very highest nor a very low degree of care and competence judged in the light of the particular circumstances of each case is what the law requires (iii).

A medical practitioner would be liable only where his conduct fell below that of the standards of a reasonably competent practitioner in his field (iv)" [Kusum Sharma & Others versus Batra Hospital & Medical Research Centre, 2010 (3) SCC 480].

DEFENSE ARGUMENT NO. 17

"Whatever treatment I gave was the right thing to do; done by the right technique; done by the right person; done in the right place; done with all care and caution and an informed consent was taken which also included all the possible complications. Such an accident and/or complication is

well-described in literature and can occur in spite of best of care."

Section 80 of the Indian Penal Code (IPC) has defined the word "accident". It states as follows: "Nothing is an offence which is done by accident or misfortune and without any criminal intention or knowledge in the doing of a lawful act in a lawful manner by lawful means and with proper care and caution".

"...At times, the professional is confronted with making a choice between the devil and the deep sea and he has to choose the lesser evil. The medical professional is often called upon to adopt a procedure which involves higher element of risk, but which he honestly believes as providing greater chances of success for the patient rather than a procedure involving lesser risk but higher chances of failure. Which course is more appropriate to follow, would depend on the facts and circumstances of a given case. The usual practice prevalent now-a-days is to obtain the consent of the patient or of the person in-charge of the patient if the patient is not be in a position to give consent before adopting a given procedure. So long as it can be found that the procedure which was in fact adopted was one which was acceptable to medical science as on that date, the medical practitioner cannot be held negligent merely because he chose to follow one procedure and not another and the result was a failure (para 27)."

No sensible professional would intentionally commit an act or omission which would result in loss or injury to the patient as the professional reputation of the person is at stake. A single failure may cost him dear in his career. Simply, because a patient has not favorably responded to a treatment given by a physician or a surgery has failed, the doctor cannot be held liable per se by applying the doctrine of *res ipsa loquitur* (para 28)" [Jacob Mathew versus State of Punjab & Anr., 2005 (3) CPR 70].

DEFENSE ARGUMENT NO. 18

"I acted as per standard practice."

"While a doctor cannot be forced to treat any person, he or she has certain responsibilities for those whom he/she accepts as patients. Some of these responsibilities may be recapitulated, in brief:

- To continue to treat, except under certain circumstances when doctor can abandon his patient
- To take reasonable care of his patient
- To exhibit reasonable skill: The degree of skill a doctor undertakes is the average degree of skill possessed by his professional brethren of the same standing as himself. The best form of treatment may differ when different choices are available" (PB Desai versus State of Maharashtra, AIR 2014 SC 795).

DEFENSE ARGUMENT NO. 19

"Just because things have gone wrong, it does not mean medical negligence."

"49. When a patient dies or suffers some mishap, there is a tendency to blame the doctor for this. Things have gone wrong and, therefore, somebody must be punished for it. However, it is well known that even the best professionals, what to say of the average professional, sometimes have failures. A lawyer cannot win every case in his professional career but surely he cannot be penalized for losing a case provided he appeared in it and made his submissions.

76. The basic principle relating to the law of medical negligence is the Bolam Rule which has been quoted above. The test in fixing negligence is the standard of the ordinary skilled doctor exercising and professing to have that special skill, but a doctor need not possess the highest expert skill" [Martin F. D'Souza versus Mohd. Ishfaq, 2009 (3) SCC 1].

DEFENSE ARGUMENT NO. 20

"It was a complicated case and in such a situation, the doctor must get the benefit of doubt."

"The skill of medical practitioners differs from doctor to doctor. The very nature of the profession is such that there may be more than one course of treatment which may be advisable for treating a patient. Courts would indeed be slow in attributing negligence on the part of a doctor if he has performed his duties to the best of his ability and with due care and caution. Medical opinion may differ with regard to the course of action to be taken by a doctor treating a patient, but as long as a doctor acts in a manner which is acceptable to the medical profession, and the court finds that he has attended on the patient with due care skill and diligence and if the patient still does not survive or suffers a permanent ailment, it would be difficult to hold the doctor to be guilty of negligence" [Achutrao Haribhau Khodwa versus State of Maharashtra, 1996 SCC (2) 634].

DEFENSE ARGUMENT NO. 21

"I observed all the precautions and adhered to all guidelines, which had also been verified by an expert I had consulted with as mentioned in the judgment of the Supreme Court in Martin D'Souza versus Mohd Ishfaq case."

The Supreme Court of India has laid down guidelines regarding precautions taken by doctors and hospitals in Martin F. D'Souza versus Mohd. Ishfaq, 2009 (3) SCC 1 as follows:

- Current practices, infrastructure, paramedical, and other staff, hygiene and sterility should be observed strictly
- No prescription should ordinarily be given without actual examination. The tendency to give prescription over the telephone, except in an acute emergency, should be avoided
- A doctor should not merely go by the version of the patient regarding his symptoms, but should also make his own analysis including tests and investigations where necessary
- A doctor should not experiment unless necessary and even then he should ordinarily get a written consent from the patient
- An expert should be consulted in case of any doubt.

DEFENSE ARGUMENT NO. 22

"I cannot be liable for a service, which was not available in the hospital."

"We must bear in mind that negligence is attributed when existing facilities are not availed of. Medical negligence cannot be attributed for not rendering a facility which was not available. In our opinion, if hospitals knowingly fail to provide some amenities that are fundamental for the patients, it would certainly amount to medical malpractice. As it has been held in Smt Savita Garg (supra), that a hospital not having basic facilities like oxygen cylinders would not be excusable. Therein, this court has opined that even the so-called humanitarian approach of the hospital authorities in no way can be considered to be a factor in denying the compensation for mental agony suffered by the parents. The aforementioned principle applies to this case also in so far as it answers the contentions raised before us that the three senior doctors did not charge any professional fees" [Malay Kumar Ganguly versus Sukumar Mukherjee & Ors. AIR, 2010 SC 1162].

DEFENSE ARGUMENT NO. 23

"I did not waive off the fee as the same was my right to charge."

"Where services are provided against charges including the charges for consumables, charges for ward, service charges, etc. by the government hospitals/health centers/ dispensaries, these services fall within the ambit of service for the purpose of section 2(1)(o) of the Act and the patient availing such service falls within the definition of consumer as defined by section 2(1)(d) of the Act. It is immaterial whether these charges are not charged from poor sections. If such charges are charged from any other patient, poor patients can avail the benefit as a consumer (iii) (26)" [ESI Hospital versus Amresh Kumar dated 15-03-2007].

DEFENSE ARGUMENT NO. 24

"I did nothing that overruled the manufacturer's instructions. The dose prescribed by me was as recommended by the manufacturer."

A doctor may be liable for medical negligence if he/she fails to properly adhere to the instructions of the manufacturer given on the package of the medicine (or any medical equipment) including dosage and administration.

"The necessity of following the instructions given in the packet insert cannot be underestimated. Admittedly, the instructions in the said packet insert had not been followed in the instant case. EFFECT OF EXCESS DOSAGE There is, thus, a near unanimity that the doses of glucocorticosteroid and in particular Depomedrol were excessive. From the prescription of Dr Mukherjee, it is evident that he not only prescribed Depomedrol injection twice daily, but had also prescribed Wysolone which is also a steroid having the composition of Methyl Prednisolone.

We enumerate heretobelow the duty of care which ought to have been taken and the deficiency whereof is

being complained of in the criminal case and the civil case, respectively, so far as respondent Nos. 1 to 3 are concerned.

When Dr Mukherjee examined Anuradha, she had rashes all over her body and this being the case of dermatology, he should have referred her to a dermatologist. Instead, he prescribed "Depomedrol" for the next 3 days on his assumption that it was a case of "vasculitis". The dosage of 120 mg Depomedrol per day is certainly a higher dose in case of a TEN Patient or for that matter any patient suffering from any other bypass of skin disease and the maximum recommended usage by the drug manufacturer has also been exceeded by Dr Mukherjee. On 11th May, 1998, the further prescription of Depomedrol without diagnosing the nature of the disease is a wrongful act on his part." [Malay Kumar Ganguly versus Sukumar Mukherjee & Ors. AIR, 2010 SC 1162].

DEFENSE ARGUMENT NO. 25

"It is not a case of gross mistake."

"Adoption of one of the modes of treatment, if there are many, and treating the patient with due care and caution would not constitute any negligence (iii).

Failure to act in accordance with the standard, reasonable, and competent medical means at the time would not constitute a negligence. However, a medical practitioner must exercise the reasonable degree of care and skill and knowledge which he possesses. Failure to use due skill in diagnosis with the result that wrong treatment is given would be negligence (iv).

In a complicated case, the court would be slow in contributing negligence on the part of the doctor, if he is performing his duties to be best of his ability (v).

Bearing in mind the aforementioned principles, the individual liability of the doctors and hospital must be judged.

[Malay Kumar Ganguly versus Sukumar Mukherjee & Ors. AIR, 2010 SC 1162].

DEFENSE ARGUMENT NO. 26

"My junior was also competent."

"Gross medical mistake will always result in a finding of negligence. Use of wrong drug or wrong gas during the course of anesthetic will frequently lead to the imposition of liability and in some situations even the principle of *res ipsa loquitur* can be applied. Even delegation of responsibility to another may amount to negligence in certain circumstances. A consultant could be negligent where he delegates the responsibility to his junior with the knowledge that the junior was incapable of performing of his duties properly" [Spring Meadows Hospital versus Harjol Ahluwalia, (1998) 4 SCC 39].

CONCLUSION

Facing a malpractice complaint is a serious matter for a physician because of the implications on their professional reputation as competent doctors. In medical colleges, doctors are taught clinical skills and not legal skills. Going through the process of defending a complaint therefore can be unnerving for them as they are ill-prepared and ill-equipped to handle such a situation. Being ignorant of the law can now be no more an excuse. While the best way to defend oneself in such situations is maintaining meticulous case records, knowledge about Court decisions supported by high-quality published evidence will also help shape the defense strategy. This can challenge even an expert opinion. Hence, all doctors should be vigilant about protecting themselves and read the judgements delivered by Courts in medical malpractice claims. It's time they become well-versed with the nuances of law as it applies to clinical practice.

Sports and Heart Diseases

Kewal C Goswami, Vikash Kumar, Nagendra Boopathy Senguttuvan

INTRODUCTION

Athletes are the epitome of health, owing to their unique lifestyle and physical achievements. Numerous physiological changes occur in the heart, autonomic system, musculoskeleton, etc., when individuals perform repetitive activity and this enhances endurance and fitness. However, in a small proportion of individuals sports has been associated with sudden cardiac death (SCD) due to unmasking of silent cardiovascular (CV) abnormalities. In others it may lead to brady and tachyarrhythmias as well as structural changes that may be constituted as abnormal. In adult athletes, even recreational sports has been associated with sudden death due to coronary artery disease.

For this reason it is important for cardiologists to have a thorough knowledge of exercise physiology, benefits and risks of exercise, and adaptation of heart to exercise training as they are often confronted by athletes for advice on exercise, decide whether abnormal symptoms or findings in athletes represent disease or a physiologic response to exercise training.

DEFINITION OF TERMS

Athlete

While there are many definitions for an athlete, an athlete, in layman's terms is an individual proficient in a particular exercise, game, or sport that enhances strength, stamina, or endurance as well as participates in competitive sports. In order to have a uniform definition for medical professionals, an athlete is defined as a person who trains in sports to enhance his/her performance, participates in competitive events, is formally enrolled in a program (local/national), and spends most of his/her time in sports often making it a way of life.¹ All of these criteria must be met to define an athlete. The limitation of this definition is that it would necessarily exclude the recreational athlete who may achieve nearly the same level of fitness, stamina, and endurance, but

would not be included as he would not meet the remaining criteria. However, for clinical purposes his CV physiology would mimic that of a well-trained athlete. A young athlete is generally considered to be below 35 years of age while an adult athlete is anyone older.

Physical Activity

Physical activity refers literally to any body movement producing substantial increase in oxygen consumption. Physical activity designed to improve health or obtain performance benefits is called exercise.

TYPES OF EXERCISE

Exercise requiring increase in oxygen transport is called endurance or aerobic exercise, whereas exercise primarily stressing skeletal muscle is called strength or resistance exercise. Endurance or aerobic exercise helps improve overall stamina and the ability of the heart to pump oxygenated blood in those with and without prior CV disease. Strength or resistance exercise increases the muscle strength.

CARDIOVASCULAR RESPONSE TO EXERCISE

Aerobic or endurance exercise imposes a volume overload state on the CV system that affects all the four chambers of the heart. In response to aerobic exercise, the body reacts by increased oxygen uptake (VO_2), heart rate (HR), and cardiac output (Q). There will also be an initial peak and then plateau in stroke volume (SV). Each 1 liter increase in oxygen consumption causes increase in cardiac output by 5–6 liters.² Systolic blood pressure (SBP) progressively increases along with a drop in peripheral vascular resistance resulting in decreased diastolic blood pressure and the result is widened pulse pressure and a mild increase in mean pressure. Active exercising muscle selectively gets more blood, bypassing the less active ones. Arteriovenous oxygen difference (A-VO_2)

widens as the duration of exercise increases due to more and more oxygen being extracted by the exercising muscle.

If the exercise performed statically or isometrically, the contraction of muscles occurs in a fixed or stationary position (i.e., without movement). There are several daily activities which incorporate a static component, as do many sports (e.g., rowing, cycling, weightlifting, and wrestling). Most important difference in the CV response to static compared with dynamic exercise resides in its effect on the active muscle blood flow.

During an isometric contraction, there is a decrease in muscle blood flow in response to the stiffening of active muscle fibers, which increases intramuscular pressure causing a mechanical constriction of the vessels. Though a similar constriction occurs during dynamic exercise, there is rhythmic alternation between contraction and relaxation, such as in running which encourages blood flow through the muscle pump.

Intense and prolonged endurance exercise training produces wide spectrum of CV adaptations, resulting in a condition referred to as "athlete's heart".³ Such changes include an increase in resting SV and a decrease in resting HR. Reduced HR in athletes is likely due to increased vagal tone and decreased sympathetic tone. Bradyarrhythmias that might be observed in athletes include significant sinus arrhythmia, first-degree heart block, second-degree atrioventricular (AV) block (type-1), or very rarely third-degree AV block during sleep. Such reduced AV conduction may unmask conduction through accessory pathways. One of the frequently observed patterns in athletes is early repolarization variant, which is also likely attributed to increased vagal tone.⁴

BENEFITS OF EXERCISE

Multiple cross-sectional studies examining the frequency of CV events in healthy individuals demonstrate that the more active participants have lower CV risk than their more sedentary counterparts.⁵ The reduction in risk in the most active versus the least active individuals is approximately 40%.⁵ It has recently shown that exercise causes mortality reduction in patients. The quantity of benefit is higher in high-risk patients. Beneficial effects of exercise attain a plateau at 9.1 hours of exercise per week.⁵ After this level of exertion, there appears to be little additional benefit and, possibly diminution, of the beneficial effects.⁵ Habitual

physical activity has multiple, potentially beneficial affects on atherosclerotic risk factors. Specifically, habitual physical activity reduces SBP, body weight, blood glucose, and triglycerides and increases high-density lipoprotein cholesterol.⁶

RISKS OF EXERCISE

Evidence has shown that vigorous physical activity, generally defined as greater than six metabolic equivalents (METS) transiently increases the risk for SCD and acute myocardial infarction (AMI).^{7,8} The pathologic substrate associated with these acute cardiac events varies by age, primarily because the prevalence of the pathologic cardiac conditions responsible for SCD also varies by age (Box 1).

Most of the exercise related SCD in young individuals has been attributed to congenital and inherited conditions, including hypertrophic cardiomyopathy (HCM) and anomalous coronary artery (ACA), although acquired conditions such as pericarditis, myocarditis, and cardiomyopathy can also cause exercise-related SCD in young individuals.⁹

However, recent studies have noted that up to 40% of SCDs in young athletes remain unexplained even after an autopsy suggesting that other conditions, such as inherited channelopathies, may be the cause.¹⁰ HCM was responsible only for 6% of the deaths.¹⁰

Atherosclerotic cardiovascular disease (ASCVD) causes most exercise-related AMI and SCD in adults.⁷ AMI occurring in a previously asymptomatic adult during exercise is usually associated with acute coronary arterial plaque disruption.¹¹ Higher flexing and more bending of coronary arteries might be associated with plaque rupture leading to AMI after exercise.⁷ Approximately 33% of SCDs in adults caused by ASCVD are associated with clinical and pathologic findings of an acute coronary syndrome (ACS), whereas the remainder show evidence of nonacute ASCVD.¹²

CLINICAL PROBLEMS IN SPORTS CARDIOLOGY

Decreased Exercise Capacity

Exercise capacity is defined as the maximum amount of physical exertion that an athlete can sustain. Athletes who have decreased exercise capacity are frequently referred to cardiologists for evaluation. Unlike cardiac output which

BOX 1 Common cardiovascular conditions associated with sudden death in athletes

- HCM
- Congenital coronary anomalies
- Genetic channelopathies
(Brugada, early repolarization syndrome, LQTS, SQTS, CPVT)
- Blunt trauma
- Commotio cordis
- Coronary artery disease
- ARVC
- Myocarditis
- Bicuspid aortic valve with stenosis or dilated aortic root
- WPW syndrome
- Heat stroke

ARVC, arrhythmogenic right ventricular cardiomyopathy; CPVT, catecholaminergic polymorphic ventricular tachyarrhythmias; HCM, hypertrophic cardiomyopathy; LQTS, long QT syndrome; SQTS, short QT syndrome; WPW, Wolff-Parkinson-White.

is critically dependent on SV, maximum oxygen uptake ($\text{VO}_{2\text{max}}$) requires HR and A- VO_2 difference other than SV. It is also dependent on signals from the central nervous system, skeletal muscle, and lungs. Decrement in any of these components can compromise exercise performance. Conditions resulting in inappropriately fast HR at low levels of exertion such as hyperthyroidism can decrease exercise performance, as can exercise-induced asthma, diseases of skeletal muscle, and reduced O_2 -carrying capacity from anemia. Atrial fibrillation or frequent premature contractions during exercise can reduce exercise capacity.

These same issues can reduce exercise performance in older athletes, but occult coronary disease with atypical symptoms always requires consideration first in older patients. Psychological factors and overtraining also can cause decreased exercise capacity in athletes.

Unlike regular patients, athletes are very sensitive to their performance-related symptoms. A careful history-taking will reveal history of decreased underperformance in athletes. As compared to general public, the attributable risk of health-related problems in athletes for a given problem is high as they do high METs requiring exercise. Exercise echocardiography and oxygen pulse curve obtained from cardiopulmonary exercise testing are very useful measures in assessing their symptoms.

Arrhythmic issues in athletes can be addressed by long-term implantable loop recorders. Once all possible workup are done and have been found to be normal, psychological or emotional issues or overtraining in athletes need to be considered.

Cardiac Complaints in Athletes

It is common to see athletes underplaying and overplaying their symptoms. As they are very sensitive to their performance, most of the diseases could be diagnosed early in them, but sometimes their presentation might be fatal.

Chest pain is a common complaint seen in young and old athletes and should not be dismissed callously. Exertional chest pain may be the first sign of important cardiac diseases, including HCM, aortic stenosis, ACA, or coronary artery atherosclerosis. Very momentary chest pain might be due to ectopic atrial or ventricular beats. Few athletes who have died with ACA had normal exercise stress test results,¹³ indicating the importance of pursuing workups that include coronary imaging in athletes if the symptoms are worrisome, even when exercise testing yields normal results.

Due to resting bradycardia and large venous capacity which permits sequestration of large quantity of blood, well-trained athletes often have vasovagal syncope, also known as "neurally-mediated syncope" when the athlete is upright and motionless.¹⁴

Athletes also often have positive tilt table tests as a result of the same physiologic changes. Neurally-mediated syncope most often occurs in athletes immediately following exercise, particularly with abrupt termination of exercise. This common entity called as "postexertional syncope", is benign and can frequently be managed by teaching the

athlete avoidance techniques. The most important avoidance technique advised to the athlete is to keep moving after effort and to gradually slow down so that the muscle pump in the calf continues to return blood to the systemic circulation.

The key issue that needs to be evaluated for syncope in athletes is to determine whether the syncope occurred during exertion. Syncope at rest or immediately after exercise under conditions consistent with vasovagal syncope or postural syncope is usually benign. In contrast, syncope during exercise should prompt a careful search for more serious problems, including HCM, aortic stenosis, cardiac arrhythmia, or ACA.

Atrial fibrillation is now being described in long distance runners, cross country cyclists, and skiers.¹⁵ Why such athletes are prone to atrial fibrillation as well as atrial flutter is still unclear, but an association is increasingly being recognized. Autonomic changes, cardiac remodeling, atrial ectopy, gastroesophageal reflux, food supplements, anabolic steroids, and other mechanisms are variously believed to be responsible for these arrhythmias.

SCREENING ABNORMALITIES

Both the American Heart Association (AHA) and the American College of Cardiology (ACC),¹⁶ as well as the European Society of Cardiology (ESC),¹⁷ recommend preparticipation screening (PPS) for athletes. The ESC also recommends a resting electrocardiogram (ECG) as a part of PPS, which is not recommended by AHA.

Regardless of the benefit, most of the athletes undergo screening with an ECG, and abnormalities are seen. Screening athletes with or without an ECG can detect a multitude of CV "problems."

Athletes can also have ECG evidence of biventricular hypertrophy, left ventricular hypertrophy (LVH),¹⁸ incomplete or complete right bundle branch block (RBBB), ST-T wave abnormalities, and conduction abnormalities (Tables 1 and 2, Box 2). Most of these abnormalities occur in endurance athletes undergoing intense training. Such changes in strength-trained athletes or in endurance athletes with low training volumes should raise suspicion of a cardiac problem.

Most of the CV abnormalities found on screening may be normal, and can be dismissed by a simple clinical examination and review of the ECG or with cardiac imaging procedures to remove any doubt. Even then some athletes and families may have on going concern once a screening abnormality is identified. So it is advisable to make them return in 3–6 months even when no abnormalities are found, to provide them with additional reassurance.

Common problem that will be found in athletes with a screening abnormality is diagnostic creep which can be defined as the finding of a minor abnormality on screening such as early repolarization, sinus bradycardia or incomplete RBBB which may prompt for a second diagnostic test such as echocardiography, which reveals another borderline finding such as mild LVH, which may prompt for another diagnostic test like cardiac magnetic resonance imaging (MRI).

Sometimes, because of the extensive CV adaptations that may occur due to exercise training, each diagnostic study

TABLE 1: Classification of abnormalities of the athlete's electrocardiogram¹⁷

Group 1: Common and training-related ECG changes	Group 2: Uncommon and training-unrelated ECG changes
<ul style="list-style-type: none"> • Sinus bradycardia • First-degree AV block • Incomplete RBBB • Early repolarization • Isolated QRS voltage criteria for left ventricular hypertrophy 	<ul style="list-style-type: none"> • T wave inversion • ST segment depression • Pathological Q waves • Left atrial enlargement • Left axis deviation/left anterior hemiblock • Right axis deviation/left posterior hemiblock • Right ventricular hypertrophy • Ventricular pre-excitation • Complete LBBB or RBBB • Long or short QT interval • Brugada-like early repolarization

AV, atrioventricular; LBBB, left bundle branch block; RBBB, right bundle branch block.

TABLE 2: Seattle criteria: Abnormal findings in athletes¹⁹

Abnormal ECG	Definition
T-wave inversion	>1 mm in depth in two or more leads V2–V6, II and aVF, or I and aVL (excludes III, aVR, and V1)
ST segment depression	≥0.5 mm in depth in two or more leads
Pathological Q waves	>3 mm in depth or >40 ms in duration in two or more leads (except for III and aVR)
Complete left bundle branch block	QRS ≥120 ms, predominantly negative QRS complex in lead V1 (QS or rS), and upright monophasic R wave in leads I and V6
Intraventricular conduction delay	Any QRS duration ≥140 ms
Left axis deviation	−30–90°
Left atrial enlargement	Prolonged P wave duration of >120 ms in leads I or II with negative portion of the P wave ≥1 mm in depth and ≥40 ms in duration in lead V1
Right ventricular hypertrophy pattern	R–V1+S–V5 >10.5 mm and right axis deviation >120°
Ventricular pre-excitation	PR interval <120 ms with a delta wave (slurred upstroke in the QRS complex) and wide QRS (>120 ms)
Long QT interval	QTc ≥470 ms (male) QTc ≥480 ms (female) QTc ≥500 ms (marked QT prolongation)
Short QT interval	QTc ≤320 ms
Brugada-like ECG pattern	High take-off and downsloping ST segment elevation followed by a negative T wave in ≥2 leads in V1–V3
Profound sinus bradycardia	<30 beats per minute or sinus pauses ≥3 s
Atrial tachyarrhythmias	Supraventricular tachycardia, atrial fibrillation, atrial flutter
Premature ventricular contractions (PVCs)	≥2 PVCs per 10 s tracing
Ventricular arrhythmias	Couplets, triplets and non-sustained ventricular tachycardia

BOX 2 Seattle criteria: Normal ECG variants in athletes¹⁹

- Sinus bradycardia (≥30 beats/min)
- Sinus arrhythmia
- Ectopic atrial rhythm
- Junctional escape rhythm
- 1° AV block (PR interval >200 ms)
- Mobitz type 1 (Wenckebach) 2° AV block
- Incomplete RBBB
- Isolated QRS voltage for LVH

Except: QRS voltage criteria for LVH occurring with any nonvoltage criteria for LVH such as left atrial enlargement, left axis deviation, ST segment depression, T-wave inversion, or pathological Q waves

- Early repolarization (ST elevation, J-point elevation, J-waves, or terminal QRS slurring)
- Convex ("domed") ST segment elevation combined with T-wave inversion in leads V1–V4 in Black/African athletes.

AV, atrioventricular; ECG, electrocardiogram; LVH, left ventricular hypertrophy; RBBB, right bundle branch block.

reveals an additional borderline abnormality, which will make it difficult for a clinician to declare the athlete fit.

Hence, it is advisable to judge the screening abnormalities with less concern, especially if they are borderline abnormal than definite abnormalities that are seen in symptomatic athletes, because those screening abnormalities will mostly represent normal variants.

It must be recognized that some athletes are more likely to express extreme hypertrophy when they engage in intensive training programs. In these athletes left ventricular wall thickness may reach 16 mm in males. To distinguish this from HCM ECG, echo and tissue Doppler criteria have been evolved along with use of MRI.

Preparticipation Screening for Eligibility

In light of beneficial effects of screening first documented from Italy,²⁰ the ESC made it mandatory to undergo national PPS strategy with routine ECGs.¹³ The International Olympic Committee (IOC) also recommends PPS with routine ECGs.

American Heart Association is conservative regarding usage of ECGs as a routine part of screening mainly due to cost-effectiveness and beneficial effects. It recommends thorough personal, family, and physical examination comprising of 14 elements as a part of PPS (Box 3).

The AHA and ACC had also developed eligibility and disqualification recommendations for cardiac conditions according with the advice of 15 task forces who created the

BOX 3

The 14 elements American Heart Association (AHA) recommendations for preparticipation cardiovascular screening of competitive athletes

Medical history

- Personal history
 - Chest pain/discomfort/tightness/pressure related to exertion
 - Unexplained syncope/near-syncope
 - Excessive and unexplained dyspnea/fatigue or palpitations, associated with exercise
 - Prior recognition of a heart murmur
 - Elevated systemic blood pressure
 - Prior restriction from participation in sports
 - Prior testing for the heart, ordered by a physician
- Family history
 - Premature death (sudden and unexpected, or otherwise) before 50 years of age attributable to heart disease in ≥1 relative
 - Disability from heart disease in close relative <50 years of age
 - Hypertrophic or dilated cardiomyopathy, long QT syndrome, or other ion channelopathies, Marfan syndrome, or clinically significant arrhythmias; specific knowledge of genetic cardiac conditions in family members
- Physical examination
 - Heart murmur
 - Femoral pulses to exclude aortic coarctation
 - Physical stigmata of Marfan syndrome
 - Brachial artery blood pressure (sitting positions)

guidelines based on the type of sports that the athlete is involved.¹⁵ These guidelines may appear restrictive, but at present these are the best available resource to guide the athlete regarding the risk involved with sports participation.

The conditions for which eligibility and disqualification are advised are HCM, myocarditis, pericarditis, arrhythmicogenic right ventricular cardiomyopathy, left ventricular noncompaction, congenital heart diseases, hypertension, valvular heart disease, ASCVD, arrhythmias, etc.

CONCLUSION

Even though sports cardiology is evolving as a subspecialty of cardiology, general cardiologists should have a working knowledge of exercise physiology, the cardiovascular adaptations to exercise training, and also the risks and benefits of exercise to advise and evaluate athletes appropriately.

Cardiological Society of India
CARDIOLOGY
Update 2018

Salient Features

- The latest edition of Cardiology Update is a comprehensive compilation of our current understanding of various disease processes and their management in Cardiology
- The book includes articles from the leading experts in the field of Cardiology from India and overseas
- These articles not only provide up-to-date information from available research, but also decode them allowing the reader to understand the implications in Indian scenario
- Divided into 24 sections having 154 chapters the book will enhance knowledge and has the potential to provide ideas for innovation and new research in the field
- The book covers a lot of chapters that reflect the theme of the Annual Conference of Cardiological Society of India, 2018 -'Translating Recent Advances into Regional Needs'
- A valuable resource for clinicians and postgraduates in every day clinical practice.

Kewal C Goswami MD DM
